The cost of establishing a Central Office forbad the recommendation, at present, of this scheme and it was agreed to advise the adoption of a provisional scheme by which the patent granted under existing conditions in the United Kingdom should be extended to any of the territories desired by the applicant on payment of a simple registration fee, but the grant in that territory to be subject to the local objections and to local opp[illegible]ition; nevertheless, the specification accepted in the United Kingdom should be held to be in conformity with local requirements as to sufficiency of description and claims. In the Colonies and Protectorates, where examination of applications is non-existent or perfunctory, registration of the United Kingdom patent should follow as a matter of course.

The Conference further recommended that whether or not any scheme for a British Empire Patent be found practicable, steps should be taken to render patent legislation uniform throughout the Empire.

Extracts from the Annual Report of the Ministry of Health for 1921-1922 and Abstract of Reports of Public Analysts for the Year 1921. Sale of Food and Drugs Acts. *Pp.* 16. *H.M. Stationery Office*, 1922. *Price* 1*s.* 6*d.*

The total number of samples purchased under the Acts in 1921 was 113,664; of these 7582 were reported against, showing a decrease from 7·1 per cent. in 1920 to 6·7 per cent. in 1921.

Of the above samples, 61,439 were samples of milk, of which 8·6 per cent. was adulterated or not up to standard. In London 678 samples of milk (5·1 per cent.) were reported against, 357 contained extraneous water, the remainder being chiefly samples deficient in fat; only 10 samples contained preservative (generally boric acid). Excluding London the proportion of adulterated samples was 9·6 per cent.

Out of 984 samples of ordinary cream, 315 contained preservative, and 86 out of 707 samples of preserved cream contained preservative (boric acid in all cases) in excess of the permitted amount, or otherwise failed to satisfy the Regulations. One informal sample of cream taken at Burnley contained 0·59 per cent. of boric acid and a later formal sample from the same source 0·36 per cent.

Over 10,000 samples of butter were examined and 245 were reported against; of these 129 contained foreign fats, generally in large proportions, and 96 contained an excess of water. In one case a fine of £40 was inflicted for the sale as butter of a mixture containing 25 per cent. of margarine; 31 out of 4296 samples of margarine were reported against, 21 of these containing water in excess of 16 per cent. Only 5 out of 3490 samples of lard were reported against, but 41 out of 692 samples of dripping or cooking fats were reported as adulterated; one sample of dripping contained 40 per cent. of cottonseed oil, and 15 per cent. of rice flour was present in a sample of chopped suet.

The adulteration of flour was again small; 507 samples of ordinary flour were examined, 16 contained persulphate "improver" and one was a self-raising flour; only 7 out of 806 samples of self-raising flour were reported against. Deficiency in available carbon dioxide was the chief defect in baking powders; 45 samples out of 1210 were condemned.

The presence of copper salts in preserved peas still persists; 73 out of 168 samples contained copper salts, and a fine of £20 was inflicted for spinach containing 6·8 grains per lb. of copper sulphate.

A sample of "raspberry syrup" examined consisted of sugar solution acidulated with phosphoric acid and coloured with coal-tar dye; a penalty of £[illegible] was inflicted.

In Surrey large fines—in one case £30—were inflicted for the sale of effervescing solutions of sugar acidulated with phosphoric acid as "lemon squash" or "lemonade." Of 5500 samples of drugs examined, [illegible]·7 per cent. was reported against.

OFFICIAL TRADE INTELLIGENCE

(From the Board of Trade Journal for August 24, 31, and September 7)

OPENINGS FOR BRITISH TRADE

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence), 35, Old Queen Street, London, S.W. 1, from firms, agents or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number.

Locality of Firm or Agent	Materials.	Reference Number
Australia	Crockery, glassware	204
"	Sodium acetate (tender for)	9320/E.D./C.P.
Bolivia	Glass, glassware, pottery ..	225/73/F.G./M.C.
Brazil	Paper	242
British East Africa	Oils, grease, soap, aluminium ware	205
British India ..	Antimony, brass, sheets of copper, lead and zinc ..	3701/8/T.G.
Bulgaria	Copper, brass (tender for) ..	8988/F.E./E.P.
Colombia	Dry colours	224
Denmark	Metals, crude rubber ..	220
"	Iron and steel, tinplate, black sheets	221
"	Tinplate, black plate ..	222
Dominican Republic	Drugs, perfumery	216
Finland	Tinplate, tinned sheet ..	210
France	Tinplate	16664/F.W./E.C.
Mexico	Glass, glassware, pottery ..	225/47/F.G./M.C.

TARIFF CUSTOMS EXCISE

Angola.—Particulars of the revised scale of export duties are given in the issue for September 7.

Barbados.—Amendments to the customs tariff affect potable, non-potable, and perfumed spirits.

Ceylon.—Cocaine or its derivatives may not be imported without a certificate that the drug is required solely for scientific or medicinal purposes and that the Government approves the importation of the quantity specified.

Dominica.—Kerosene oil of 110° fire test and under may not be imported.

Germany.—The importation, except under licence, is prohibited of cocoa and cocoa products. From September 3 the duties on goods exported under licence have been increased in general by 60 per cent., but in some cases by 30 per cent. only.

Iraq.—Schedules of import and export duties are given in the issue for August 24. Many of the duties on chemicals range from 11 to 20 per cent. *ad valorem.*

Italy.—The manufacturing tax on national sugar nd the surtax on imported sugar have been inreased from 245 to 300 lire per 100 kg. of sugar hich yields over 94 per cent. on refining, and from 40 to 288 lire per 100 kg. on other sugar. Inreased duties are to be levied on goods imported rom countries which differentiate against Italian oods.

New Zealand.—The prohibition of the import and xport of tungsten and its alloys, compounds, and res has been revoked.

Peru.—The export duty on petroleum and its erivatives has been fixed at 3·50 soles per metric on.

Poland.—Goods which may not be exported inlude sugar, bone manures, hides, mineral, sperm nd cylinder oil, potassium salts, ores, minerals, crap iron and steel, and cellulose.

South Africa.—Until June 30, 1923, the importaion of sugar is prohibited, save under permit issued y the customs authorities. A law has been passed roviding for the inspection and grading of coal roduced in the Union and intended for export or or bunkering steamers.

Tunis.—The prohibition of the export of coal, oke, hides and skins has been withdrawn.

Yugoslavia.—The export duties on certain animal ats and oleaginous seeds have been increased, and ew export duties have been applied to edible oils.

TRADE NOTES

FOREIGN

lsatian Potash

The Commercial Secretary at Paris has forwarded o the Department of Overseas Trade an extract rom the *Bulletin Quotidien de l'Agence Téléraphique Radio*, which states that a French deleation, headed by Monsieur Louis Mercier, vicepresident of the "Comité des Forges," is now ngaged at the Hague in an endeavour to re-establish the group formed by the producers of potash in Alsace and in Germany, which before the war possessed the world monopoly of this product.

Chemical Exports from the United States

The Chemical Division of the Bureau of Foreign and Domestic Commerce has issued an analysis of the exports of chemicals and allied products for the fiscal year ended June 30, 1922, based upon preliminary returns. The figures show a decline of over 50 per cent. in the value of the total export trade ($100,518,943 compared with $220,000,000 for 1920-21), but this does not signify a corresponding decline in quantity; there were important increases as well as marked decreases in exports of the more important chemicals. The following table gives approximate figures for the exports of certain chemical products in 1921-22, together with rough indications of the increases and decreases in quantity over the previous fiscal year:—

Material	Quantity 1,000's of Short Tons	Value $	Gain or Loss in Quantity
Acetate of lime	13·80	587,174	+50%
lycerin	1·81	508,807	+50%
austic soda	61·50	4,660,815	+20%
orax	5·05	545,601	+150%
odium silicate	13·02	279,041	(small gain)
opper sulphate	2·41	227,019	(small gain)
leaching powder	15·22	502,870	—30%
oda ash	16·50	757,684	—71%

The expanded classification of chemical exports, which was initiated in January last, indicates important trade in several articles which were not previously mentioned separately; thus in the six months to June 30, 1922, there were exported (short tons): dextrin 3862, potassium dichromate 1858·4, aluminium sulphate 5993·1, ammonia and ammonium compounds (excluding ammonium sulphate) 1286·8, and boric acid 417·3.

The value of the foreign trade in coal-tar dyes, colours and stains, except lake colours, decreased from $13,577,788 in the fiscal year 1921, to $3,805,917 in 1922; and the exports of pigments, paints and varnishes decreased by about 50 per cent. to $10,069,211, the decline being mainly due to the reduced exportation of white lead (8700 short tons in 1921, 4500t. in 1922). During the first 6 months of 1922 there were exported 954·5 short tons of lithopone, 507·2 t. of bone black, and 5093·5 t. of carbon and lamp black. Exportation of medicinal and pharmaceutical preparations decreased in value during 1921-22 by nearly two-thirds to $5,383,399. Among fertilisers, exports of ammonium sulphate rose by nearly 100 per cent. to 168,077 long tons, valued at $8,720,775, but those of phosphate rock declined. Shipments of prepared fertilisers in the period Jan.-June, 1922, amounted to only 9204 long tons valued at $469,366.

In 1921-22 exports of rosin from naval stores increased from 877,109 barrels to 1,403,921 barrels, but declined in value from more than $10,000,000 to $6,623,499; foreign shipments of turpentine increased slightly in quantity to 10,786,280 gallons (U.S.), but diminished in value by $3,000,000.—(*U.S. Com. Rep., Aug.* 14, 1922.)

BRITISH

British Guiana in 1921

The sugar crop amounted to 110,985 tons, which compares with 104,069 t., the average yield of the previous 10 years, and 108,270 t. of sugar was exported. Successful experiments on the production of motor fuel from waste molasses have been made, and a sugar company is preparing to manufacture power alcohol on an industrial scale; the Government is assisting the undertaking by exempting the industry temporarily from taxation. Cacao was grown on a smaller area (1176 acres), but the acreage under Para rubber remained unchanged; shortage of labour for tapping and the leaf disease are the main factors that prevent the area under Para rubber from extending. Coconuts are now grown on 26,321 acres and 15,648,646 nuts were used locally as food or for making oil and 2,760,000 nuts, 39 t. of copra and 15,934 gallons of coconut oil was exported. The cultivation of limes increased slightly and the Government factory continued to work. Exports of lime products included 439 cwt. of citrate of lime, 4175 galls. of lime-juice, and 544 galls. of essential oil of limes. The output of diamonds rose from 233,456 stones, weighing 39,362 carats, in 1920, to 507,200 stones, weighing 102,604 carats, in 1921.

Imports declined in value by £1,691,878 to £3,487,608, and exports by £2,718,508 to £3,424,490. Of the aggregate trade of the [illegible]ony, the United Kingdom took 52·82 per cent., Canada 24·22 per cent. and the United States 13·49 per cent. Prospects for British trade are promising.—(*Col. Rep.-Ann., No.* 1123, 1922.)

REVIEWS

Technical Records of Explosives Supply, 1915—1918. No. 5. Manufacture of Sulphuric Acid by the Contact Process. *Pp.* 128. *Ministry of Munitions and Department of Scientific and Industrial Research. London: H.M. Stationery Office,* 1921. *Price* 26*s.*

This volume, containing results of scientific and industrial value obtained in the national factories during the war, maintains the high standard of excellence established by the four previous publications. Indeed, it is no exaggeration to say that the volume will be regarded as a classic, to which works chemists and technicians will have frequent recourse, not only for operating details, but for information concerning chemical control, thermal values and efficiencies, methods of calculation, platinisation, recovery and purification of platinum from old contact mass, and other such valuable data. The Ministry and Mr. Macnab are to be congratulated on the signal success which has attended their efforts.

The book is divided into two sections. One deals with the Mannheim oleum plant, the distinctive feature of which is that conversion of the sulphur dioxide into trioxide is effected in two stages, viz., by using ferric oxide and platinum as the catalytic media; the other section is assigned to the Grillo oleum plant, where platinum alone serves as the catalyst. Three excellent appendices complete the book, the value of which is enhanced by the scale drawings, graphs, and other illustrations, several of which are unique.

The first section commences with a general outline and description of the Mannheim plant, and is followed by commendably clear descriptive details of the several parts constituting the integral unit. The whole gamut is traversed: nothing apparently is omitted. With equal lucidity and detail is indicated the operation of the various parts of this plant, and valuable notes are furnished (pp. 11—37) on the working and control of the plant and the experiments which have been conducted from time to time to determine the conditions calculated to promote greater uniformity and higher efficiencies at all stages of the operation. Section 2 follows much the same arrangement as the preceding section, although supplementary information is afforded in relation to the production of the magnesium-sulphate mass, chemical control, thermal values and efficiencies, etc. The completeness of the thermal data is significant, and adds materially to the outstanding merit and value of the book. Indeed, the methods used and the data afforded will doubtless serve as a guide for calculations of a cognate nature covering a wide range of chemical operations. An equally prominent feature of this section is to be found in the calculations involved in the design of the plant, etc. These are given in considerable detail and are invaluable from many points of view. They are typical of the meticulous care and attention to detail which characterised Quinan's design of chemical and explosives plants.

It is known that certain oleum installations, outside the Ministry's control, proved a woeful failure owing to imperfect design of the purification section, and to faulty preparation of the catalyst. These imperfections could hardly have arisen had this volume been in the hands of those responsible for the design of the plants in question.

Very little further comment is called for, or indeed is possible within the limits of this review. It is noted that the name and characteristics of the pyrites ore are not given in connexion with the experiments cited relative to the working of pyrites lump burners. Manifestly they have an important bearing. Some well-known pyrites ores are notorious for the ease with which they decrepitate, a disability which contributes to the formation of clinker and, incidentally, to an abnormal sulphur-content of the burnt ore.

Experience suggests that the Herreshoff mechanical burner is peculiarly responsive to the slightest irregularities of feed and air-admission, the temperature of the beds fluctuating appreciably, unless the most constant conditions are maintained. The Wedge burner, which has a greater throughput, has been found to be free from some of these disabilities. It is unfortunate that mechanical sulphur-burners were not installed at one or other of the factories of the Ministry of Munitions, as it would have been interesting to contrast the results of the operation of, say, the Tromblee and Paul continuous, mechanical sulphur-burner with the results known to be obtained with the hand-operated sulphur-burners described on page 49.

The book is printed in clear type, and its cost places it within the reach of all. It is an eminently practical contribution, and in the phraseology of Bacon needs "to be chewed and digested"; in other words, it is essentially a work to be studied.

P. Parrish.

Iron Ore (*Summary of Information as to the Present and Prospective Iron-ore Supplies of the World*). **Part 1, United Kingdom** (*pp.* 237, 6*s.*); **Pt. 2, British Africa** (*pp.* 76, 3*s.*); **Pt. 3, British America** (*pp.* 115, 3*s.* 6*d.*); **Pt. 4, British Asia** (*pp.* 65, 2*s.* 6*d.*); **Pt. 5, Australia and New Zealand** (*pp.* 106, 4*s.*). *Imperial Mineral Resources Bureau. London: H.M. Stationery Office,* 1922.

The above five parts deal with the statistics, production and iron-ore resources of the British Empire. As is well known, the Imperial Mineral Resources Bureau has been issuing an important series of publications on the mineral industry of the British Empire and foreign countries, with statistics of production, during the war period, 1913-1919, when most official statistics were in abeyance. With regard to iron ore, the National Federation of Iron and Steel Manufacturers felt that something more was required, and they offered their assistance, both personal and financial, in order to enable the Bureau to produce a work not merely dealing with production but summarising the known and prospective iron-ore resources of the world. This information is particularly valuable to British iron-masters, as the British iron industry relies more than that of any other country, with the exception perhaps of Belgium, upon imported iron ores.

The work before us gives evidence of much care and painstaking research into the vast mass of information that exists scattered in many places upon the subject of iron-ore resources. Part 1 is naturally little more than an abstract of the publication of the Geological Survey on British iron ores, but in addition it contains a number of important statistical tables showing production, imports, exports, domestic consumption, etc. of iron ore and of the chief products of iron and steel manufacture. The information upon which the other parts is based has been for the most part obtained from the geological survey departments of the respective countries, some of which, notably the Geological Survey of Canada, have long devoted much attention to economic questions. It is self-evident that anything like a review of the immense mass of detailed information collected in these five volumes is out of the question. It can only be said that they cover very fully the intended ground, and constitute as complete and accurate a survey of the iron-ore resources of the British Empire as it is possible to compile at the present day.

H. Louis.

First Report of the Adhesives Research Committee. *Department of Scientific and Industrial Research. Pp. 129. London: H. M. Stationery Office, 1922. Price 4s.*

The Adhesives Research Committee was appointed by the Advisory Committee of the Privy Council for Scientific and Industrial Research in December, 1919, to continue the work of the Adhesives Committee of the Conjoint Board of Scientific Societies. The present report includes the unpublished work of the latter committee, thus making a comprehensive summary of the work done from 1918 to the end of 1921. Two appendices are added, viz.: (1) a descriptive bibliography of gelatin prepared and revised by Dr. T. Slater Price, and (2) an account of the recent work of Prof. J. W. McBain on the nature of soap solutions and gels. The volume may be very highly recommended to all interested in glue, gelatin and other nitrogenous adhesives. The work done, however, appears to be almost entirely connected with nitrogenous adhesives, and the title "Adhesives Research Committee" is somewhat incorrect and misleading. Starch adhesives, which for many purposes have entirely replaced glue, are not even mentioned. A few experiments on casein cements are recorded, and the possibility of utilising the proteins of castor bean as a substitute for casein has also been demonstrated.

The necessity for the work arose during the war owing to a threatened shortage of the raw materials necessary for the manufacture of glues and casein cements. Hence, at first, conservation of materials and more economical methods of manufacture were more important than purely scientific investigations. The early work of the Committee was therefore chiefly empirical and confined to (*a*) the differentiation of good and bad glues by mechanical tests, (*b*) an attempt to discover the substances (and their properties) which give glue its adhesive power, (*c*) the prevention of waste of raw material during manufacture, and (*d*) the investigation of the adhesive power of substances obtained from material other than bone, hide, or casein. Later on, empirical inquiry gave place to systematic scientific investigation. In dealing with the mechanical tests of glues, reference is made to Major Robertson's work described in the "Report on the Materials of Construction used in Aircraft and Air Engines," published by H.M. Stationery Office at 21s. It is a pity that a detailed description of the test employed was not included in the present report.

It is unfortunate, but perhaps unavoidable, that a Research Committee should have to spend so much time rediscovering what is already known to many chemists who work upon glue or gelatin. Thus on page 16 five general conclusions of the investigations are stated. Four of these are already quite well understood, and could have been ascertained by inquiry, with the saving of much time and trouble. The fifth conclusion is that gelatin can be made from undecalcified ground bones of $\frac{1}{32}$ inch diameter at temperatures below 100° C. The reviewer studied this question more than ten years ago, and has an experimental plant with which he prepared a high-grade gelatin from undecalcified bones and brought the method to the notice of a large manufacturer. Of course, it may be desirable to restate the simple principles of manufacture, but it can hardly be necessary for a Research Committee to carry out experiments to rediscover such facts as the deterioration of glue solutions at high or even on prolonged heating at low temperatures.

Under "Classification of Glues" a useful summary of various known tests is given. To these is added an important new one, viz., the "diffusible-nitrogen test," which is fully described. It is shown that the tensile strength of a glue is roughly inversely proportional to its diffusible nitrogen content. Valuable work, though with negative results, has also been carried out in the determination of the "Hausmann numbers" of different types of glue. These numbers are the percentages of nitrogen existing as "amide," "humin," "diamino," and "other" nitrogen. Similarly, the percentages of free amino-acids and phosphorus have been studied, but, like the Hausmann numbers, they appear to have but little relation to the tensile strength of a glue. The opinion is expressed that, as a general rule, a gelatin or glue which forms a poor gel is not a good adhesive. In the experience of the reviewer, this is only true when dealing with any particular type of glue, and even then only serves as a measure of efficiency of the processes. One of the difficult things to explain is that certain glues, which will not gel, still have excellent adhesive properties, unless hydrolysis has proceeded far enough to reduce their viscosity seriously. For some purposes glues with a low jelly-strength are actually preferred, provided that they possess what the report terms the "optimum viscosity" which is necessary for the particular class of material to be glued.

In carrying out the study of the formation of gelatin, the rate of extraction of gelatin from both bones and skin has been studied, and in the case of ossein reduced to a mathematical formula. The effects of the presence of acids or alkalis in the extraction fluid and of prolonged heating are also here described.

The last 77 pages of the report, dealing with the descriptive bibliography of gelatin and the bearing of the results obtained in recent investigations of soap solutions upon the structure of gels, are a valuable addition. Altogether the report may be regarded as the first volume of a much-needed treatise upon a hitherto neglected subject.

S. R. Trotman.

Distillation Principles and Processes. *By* Dr. Sydney Young, and Collaborators. *Pp. xiii. + 509. London: Macmillan and Company*, 1922. *Price* 40*s. net.*

The general arrangement of the material in the first section of this book is satisfactorily consecutive, and, considered in conjunction with the literary style, it may be said that there are few technical books, published in this country, containing matter which may be read with such little effort.

Commencing with introductory notes, mainly dealing with general laboratory directions and descriptions of apparatus, the next chapter deals rather scantily with the boiling-points of pure liquids. Following this we have a discussion on the vapour pressure of mixed liquids, and the influence of chemical relationship, and molecular association, thereon. In this chapter (Chapter III), it is suggested that miscibility is a function of intermolecular attraction, so that the relationship suggested by D. Berthelot and by Galitzine holds good. If, however, we accept the supposition that the boiling-point of a pure substance is a function of the attraction between molecules, the above relationship imposes upon us the necessity of adopting the doctrine that the greater the difference in boiling-point between two liquids, the greater will be their tendency to yield a heterogeneous mixture. This point is brought to notice in view of the prominence accorded to the work of F. D. Brown, and to the use of this relationship as a basis for carrying out experimental investigations. Chapter IV deals with the boiling-points of homogeneous and heterogeneous liquid mixtures, the effect of pressure on the boiling-points, and the composition of azeotropic mixtures. A list of the boiling-points and composition of a very large number of azeotropic mixtures is also given.

The treatment of experimental determinations of the composition of liquid and corresponding vapour phases (Chapter V) is satisfactory. Concise descriptions are given of the apparatus and methods employed by F. D. Brown, Lehfeldt, Rosanoff, Zawidski, and others, together with notes on the errors likely to arise in work of this kind. It is questionable whether Linebarger's work should be dismissed without discussion. The subject is taken up from a "theoretical" standpoint in the following chapter, but the treatment appears to be inadequate.

In Chapter VII the author gives laboratory directions relating to fractional distillation.

After discussion of the composition of liquid and vapour phases (*cf. s.*), the theme passes on to the relations between the weight and composition, and between the boiling-points, of the residue and distillate (Chapters VIII and IX); whilst in the same connexion, an able and critical treatment of various types of still-heads comprises the following three chapters, followed by notes (Chapter XIII) on the continuous stills devised by Carveth and by Lord Rayleigh. Chapter XIV deals largely with results obtained with the Young and Thomas type of column.

A short general description of the plant necessary to effect distillation on the industrial scale, given in Chapter XV, forms an introduction to the specialised matter given in subsequent sections of the book.

On reading the four following chapters one feels that a subject has been reached to which all that has preceded forms merely an introduction. Professor Young has treated the subject of fractional distillation as a method of quantitative analysis in such a manner that one cannot but make the suggestion that this section should be published *per se.*

Section I concludes with a brief consideration of processes involving sublimation.

The subsequent sections of the book, devoted to industrial processes, include the manufacture of acetone and n-butyl alcohol, ethyl alcohol, the petroleum industry, distillation of coal tar, glycerin, and essential oils.

It is rather difficult to criticise without bias any technical matter written from a standpoint diametrically opposed to that which has formed the basis of one's training. However, in reviewing these sections of Prof. Young's treatise, we must bear in mind to what extent this work will benefit the technologist and chemical engineer who may specialise in such processes. This country has never become famous for the efficiency of its distillation plant; and, on reading through the sections devoted to the industrial aspect of the subject, one cannot but feel that we have not yet got away from the empirical and rule-of-thumb methods which have characterised such processes. A slight all-round improvement occurred during the war, with the advent of technical chemists from abroad; and, therefore, it is unfortunate that the latter sections of the book under review do not in any way illustrate the application of the theoretical side of the subject to the successful design of plant.

REVIEW

Vol. XLI] SEPTEMBER 30, 1922 [No. 18

SODIUM SILICATE AS AN ADHESIVE

REX FURNESS

THE First Report of the Adhesives Research Committee (*cf.* J., 1922, 379 R) has been criticised from many points of view in the technical Press; perhaps its most noteworthy omission is the consideration of commercial sodium silicate—" water glass " —as an adhesive, the advantages of which are becoming increasingly realised. In this country several firms are using upwards of a thousand tons of this adhesive yearly, whilst in the United States its use is even more favoured. Owing to shortage of animal and vegetable products during the war, silicate adhesives were used on a large scale in Germany, and their advantages have ensured continued use under post-war conditions.

Commercial sodium silicate possesses all the essential properties of an efficient adhesive, viz., (1) ease, suitability, flexibility, and general efficiency of application to the materials to be united; and (2) power of " setting " in a suitable manner and time, with the formation of a bond of desired strength.

(1) The physical characteristics of a sodium silicate solution can be predetermined by the manufacturer (*cf. i.*) so that it will penetrate into the surface pores or irregularities, whether these be of large or microscopic dimensions, of the materials to be united, without saturating or passing through such materials; in other words, its viscosity can be so adjusted that it is neither too thick nor too thin for a required purpose. The surface phenomena exhibited between silicate solutions and the various materials which may be united with its aid are not well understood, nor is the reason why a bond is formed at all (this applies to adhesives in general, since the precise physical or chemical property upon which adhesion depends is not definitely known); it must, therefore, suffice to state in this place that silicate solutions will " wet " the surfaces of such substances as paper and paper products, wood, and abrasive materials.

(2) The setting of a silicate adhesive may result from cooling, or from the evaporation or absorption of water, or from all these causes combined. A smaller abstraction of water is needed from concentrated silicate solutions than from many animal and vegetable glues, so that the speed of setting can be greatly increased, and with it the speed of the particular machine upon which the work is being effected. The bond is permanent and is not disturbed by warmth, as in the case of certain adhesives. The bond strength is perhaps not so high as that of animal glue, but it is superior to that of most other adhesives, and, what is far more important, the minimum bond is greater than the tearing strength of the materials with which it is used.

ADVANTAGES OF SILICATE ADHESIVES

Silicate adhesives may be prepared with any desired viscosity and setting time, and their composition can be varied to enable articles made with their aid to withstand any particular conditions of temperature and humidity. These adhesives do not putrefy or decay, they are immune from any form of bacterial activity, and they repel vermin. They are fireproof, and although not absolutely resistant to water the materials manufactured with their aid are damp-proof. The fact that they are odourless is of especial importance in the manufacture of built-up paper-board and corrugated containers for food products.

Again, silicate adhesives are cheap, both relatively as to the quantity required for uniting materials and absolutely. These facts, taken in conjunction with the important point that they are perhaps the easiest to use, as they do not require the application of heat, and may thus be kept ready for immediate use, must be regarded as constituting very substantial claims.

Let us compare briefly some of the above-mentioned properties of silicate adhesives with those of animal and vegetable products. Animal glue, for instance, is liable to deteriorate if not kept dry. Its solutions must contain disinfectants in order to prevent mould growth, and they are by no means odourless. Batches of glue solution must be freshly made at frequent intervals; and this adhesive is much more troublesome to apply than silicate adhesives, which are almost always applied cold and in the state in which they are received from the manufacturers. The organic constitution of glue and other popular adhesives renders them combustible, putrescible, and attractive to vermin.

Casein adhesives are troublesome in use as compared with the always available silicate solution, and in addition casein glues must be used very soon after the solution has been made. Even the patented and special types have a hardening period of a few hours only, and casein glues in general, like animal or gelatin glues, cannot be relied upon to afford constant and uniformly reproducible batches. Many influences have been traced which affect casein and render such irregularity inevitable. Silicate adhesives of a specified quality and composition can always be relied upon to give constant results, provided temperature, humidity of the workroom, and other variable factors are controlled. Starch and dextrin adhesives are relatively weak in bonding strength, and in spite of the numerous special and patented "modified" starch adhesives, they are troublesome to prepare for use.

SODIUM SILICATE SOLUTIONS

The large variety of silicate solutions has rendered possible their use in many manufactures. Thus, the built-up paper-board industry finds no better adhesive; the facing or lining of corrugated paper or board, the production of multi-ply veneer, the manufacture of "mandrel" paper articles for food containers, etc., the employment of silicate as a sealing agent for packages, cartons, etc., the binding of artificial or natural abrasives in the making of abrasive wheels, and so forth, may be cited as examples of the use of silicate adhesives.

It will be obvious that one definite adhesive solution cannot serve for more than a limited number of purposes. The great merit of silicate is that it can be made into a large number of solutions of varying viscosity, stickiness, etc., and the composition of the "silicate" itself (the word "silicate" covers a wide field in commerce) can be modified so as to confer almost any desired physical state upon its solutions. To gain an insight into the basis of this wide range of properties, some account must be given of the variations possible in the constitution of silicate glass itself, and of the inter-relations of its solutions.

SODIUM SILICATE AND ITS COLLOIDAL SOLUTIONS

Although the chemical compound Na_2SiO_3, Aq. can be isolated as a crystalline solid, it has little or no interest to the manufacturer or user of sodium silicate, since in solution it possesses none of those physical properties upon which most of the applications of "silicate" depend. The sodium silicate of commerce may be said, broadly, to consist of a colloidal solution of silica in Na_2O,SiO_2 or $Na_2O,2SiO_2$ (or both). Although not extensively applied in industry, the yellow and green silicate "glasses" are well-known to the chemist—the colours being due to iron compounds in the ferric and ferrous state respectively. The ordinary "water glass" of commerce is obtained from these "glasses" by dissolving them in water, allowing the aluminous and ferrous impurities to settle out, and evaporating the solution.

The ratio of sodium oxide to silica in commercial silicate solutions is usually calculated from percentage compositions, and is not expressed molecularly; it varies from about 1 : 1·5 to 1 : 4. Many changes occur as the proportion of alkali increases; the total possible solid content increases greatly, the solution becomes heavier, and the viscosity at a given specific gravity diminishes. To take the case of two silicate solutions in which the ratios are approximately 1 : 1·5 and 1 : 4, respectively. At a constant gravity, say about 70° Tw., the more alkaline silicate is a thin liquid, easily poured, whilst the product high in silica is jelly-like and stiff. Conversely, to obtain both silicate solutions in an approximately similar state of viscosity, the alkaline product must be concentrated to almost twice the above gravity.

At this commercial limiting concentration, there are differences in the physical properties of the two types of silicate solutions. The product high in silica is jelly-like, and can be moulded to some extent, but the highly alkaline silicate is a viscous and sticky liquid, which can be drawn into threads, and which easily absorbs water from the atmosphere, so that it "dries" badly in use.

Between these two chosen extremes of alkali-silica ratio lie the silicates of commerce, and it will be appreciated that all grades of viscosity, stickiness, setting time—dependent upon ease of "drying"—and total content of solids can be produced by altering the alkali-silica ratio, and working the gravity in correlation.

The facts may be summed up as follows: (1) When the specific gravity of the solution is kept constant, the viscosity and alkali content vary inversely; (2) if the viscosity be kept constant, the gravity and alkalinity vary directly.

Examples of solutions from large shipments may be quoted to illustrate this point:—

Gravity (°Tw.).	Ratio $Na_2O : SiO_2$.	Viscosity (at 20° C.).
(1) 85	1 : 3·26	21·9 C.G.S. units.
(2) 87·7	1 : 3·16	10·8 C.G.S. units.
(1) 71·6	1 : 3·53	3·1 C.G.S. units.
(2) 71·96	1 : 3·48	1·7 C.G.S. units.

Although the gravity is not quite constant in either of the two cases shown, it increases from (1) to (2) and should therefore, of itself, tend to *increase* the viscosity. Limits are, however, set to the indiscriminate extension of these variations. Thus, if the alkalinity of the solution be too high, a very slow-drying water absorbent silicate results; and there are other objections which will be discussed later.

Broadly speaking, the viscosity and stickiness of a silicate solution can be arranged by the producer so that it will fulfil all requirements from an adhesive standpoint and possess no disadvantageous qualities.

THE ALKALINITY OF SILICATE

Such an alkalinity as is represented by a 1 : 1·5 ratio would lead to discoloration of the paper or wood products with which silicate is chiefly used as an adhesive. Many paper-ard articles, *e.g.*, food containers, are vered with a facing paper or label printed in lours. Now many colours are affected by kali and labels printed in such dyes or inks come discoloured after long contact with a ckage of which the material has been built p with the aid of silicate adhesives of high kali content. Paper tubes, made from echanical woodpulp stock are " stuck " in the urse of making by means of silicate, and if is is too alkaline, a yellow colour develops the overlap. Further discussion of the fects of alkali in highly alkaline silicate lutions is unnecessary, as it has been stated at the chief use of silicate as an adhesive is r paper and wood products, which are readily sceptible to alkali attack. It should, howver, be pointed out that other factors influence taining, and that a thin " neutral " silicate ill stain a white board more than a thick ighly alkaline product, facility of surface bsorption and penetration having to be onsidered.

No one realises the significance of alkali ontent more than the manufacturer of silicate ; or this reason silicates are not made with a igh alkali content, and if the user will employ he adhesive as sparingly as possible—which s not difficult, as silicate spreads easily—no taining need be feared.

Labels printed in alkali-destructible colours ave been successfully pasted on to containers ith the aid of silicate of low alkali content, he labels being reasonably thick and not pread too thickly with the adhesive. In eneral, however, dyes affected by alkali should ot be used in labels or coloured outside rappings which are to be affixed by means of ilicate.

Excessive alkali in a silicate adhesive tends o make the material with which it is used omewhat hygroscopic, and to render it very ' slow " on the machine, *e.g.*, in paper-board nanufacture. An alkaline silicate can be made ticky enough to cause edges to adhere after short contact. Hence a balance must be truck between the various desirable qualities ; n this way only can an article be produced hich is sufficiently viscous and sticky, which as a convenient drying and setting rate, and hose alkali content is as low as is consistent ith the realisation of the other essentials.

Applications of Silicate Adhesives

Built-up paper-board, box-board, container-oard and the like are made by uniting several heets of paper-stock, not in themselves thick strong enough for use in making packages, od containers, etc. A four-ply board is a mmon article of manufacture, and is made uniting two " inners " of cheap mechanical oodpulp stock or chip stock, with two outers " of a suitably (resin) sized Manila or te stock. The " inners " are, say, 23 to 30 points " in thickness—a " point " represents a thousandth of an inch—whilst the " outers " range from 4 to 8 " points " in thickness. Silicate is applied by suitable spreading rollers to the " inners " only, the machine positions the " outers," and the potential board passes to pressure rollers, where the union is completed. A good adhesive has dried at this stage, so that the completed board can pass on immediately to the cutters and trimmers. The edges of the board do not become loose, and the loss by cutting and trimming is only a few per cent. even with the machine running at, say, 100 ft. per minute. A consumption of 35-40 lb. of silicate per 1000 sq. ft. of board made is a normal usage.

Several factors influence the efficiency of the machine, and of these temperature, humidity and quality of stock may be noted. In some factories the temperature is kept uniform by artificial means. It is obviously possible to use heated silicate adhesive, so that after application to the stock, the union takes place both by cooling—the silicate becoming more viscous—and by increased evaporation of the water. The stock should absorb the silicate as uniformly as possible, for if the " inners " are relatively more porous, it will be necessary to overload them in order to leave enough adhesive to make the bond with the uncoated " outers."

The production of wall-board, book-bindings, cloth-board, and in fact all kinds of built-up products made of wood or paper stock, requires no elaborate consideration, but it may be noted that mandrel-made articles—spiral or lap wound—are produced with silicate adhesives. The making of cylinders from plane sheets of strong board—the cylinders afterwards being cut into suitable sizes for food containers—presents difficulties which can be overcome. Thus, the " spring " of the board demands that a good " hold " at the overlap be quickly attained, otherwise the rate of manufacture is lowered. The alkali content of the adhesive must be watched, so that staining of the board shall not result, and, as above noted, the balance is struck between the various essentials.

Corrugated or crimped paper or board is often made into a three- or five-ply product. Thus, the latter consists of two corrugated sheets with a central, an outer and an inner liner or facing of suitable paper. This is affixed by smearing the tips of the ridges with silicate and pressing the liners upon them. The same qualities in the adhesive are again demanded, and the output of the machines is regulated by the speed of drying, the completion of the bond, etc. Silicates with 8·8 to 9·3 per cent. of sodium oxide and 28–29 per cent. of silica (76–81° Tw.), are found suitable but a compound with as much as 11 per cent. of sodium oxide has been tried; such silicates, however, are not as yet in general use.

The adhesives used in the production of built-up wood-board—veneers—are casein, alkaline starch, glue, etc., but silicate is finding increased application. A thinner silicate can be employed, since pressure is applied for some time after building up the composite product. A silicate of about 55° Tw., with a relatively low alkali content, is preferable. "Fillers" may be added.

As a final example, the bonding of natural or artificial abrasives for the manufacture of abrasive wheels may be indicated. A mixture of abrasive, clay, and silicate is moulded and subsequently baked. A strong bond is formed, possibly by interaction between the alkaline silicate and the aluminium hydrosilicate of the clay. Occasionally there is interaction between the alkaline silicate and a silicon carbide abrasive employed, but the addition of potassium permanganate, which reacts with the hydrogen otherwise evolved, has been claimed to prevent imperfections caused by liberated gas. Silicate adhesive is largely employed in abrasive-wheel manufacture, but dry silicate "glass" is perhaps more suitable than the solution, the "glass" being employed in the dry process of wheel construction.

FILLERS

Whiting, dry (but not baked) clay, etc. may be added to increase the viscosity of the adhesive. If a thicker and more quickly setting adhesive be required, the filler is added alone, up to an equal weight. If a thicker adhesive with no increased setting speed be demanded, dilution with water may be practised, whilst the addition of both filler and water in larger amount will provide a thicker adhesive with a diminished setting speed. The action and relations of silicate and various fillers require further study, and this field of research appears to offer great possibilities. Such problems as the increased difficulty of application, the less "handy" type of adhesive which is necessarily produced, the requirement of agitation devices for the adhesive trough at the machines, must be investigated before "filled" silicates can be employed to supplant plain silicate solutions. They are, however, finding increased application, for example, in uniting very porous materials or surfaces of unequal porosity.

CONCLUSIONS

Sodium silicate solutions can be prepared to meet all the requirements of a good adhesive; they are superior to animal and vegetable adhesives in that they are fire-resisting, do not become rancid, and are vermin-repellent. Silicate adhesives are quite odourless, and produce damp-proof articles, they have a relatively high bond strength, and their setting times can be varied over a wide range. They are ever-ready, requiring no heat before or during application, and they give consistent result[illegible] The apparatus required for their application to wood, paper, etc. is extremely simple.

TECHNICAL ASPECTS OF HYDROGENATION*

THE technical application of what would appear to be a comparatively simple catalytic reaction—if any catalytic reaction may be considered simple—has inspired the subject matter of some 300 patents. All of these have for their aim the production of substantially the same product by reaching the same chemical end-point.

Our sympathy must be given to any unfortunate investigator, who, desiring to take up the study of the subject at this stage, is faced with contradictory statements and complications out of all proportion in magnitude to the simple manipulation necessary to effect hydrogenation on a commercial scale. I would that I could lay before you some sound scheme for the reconstruction of Patent Law, as applied to chemical products, framed in such a way as to frustrate the registration of so many patents on the one subject, without in any way doing an injustice to the genuine research worker and without producing stagnation of enterprise. Let those who have a ready solution of this problem read the able words of Horatio Ballantyne† so that they may first learn where angels fear to tread.

Hydrogenation has two main effects—(1) To produce a hard solid fat from a liquid oil; (2) To remove certain impurities which are not removable by any other means, so rendering the oil of use for purposes for which it could not otherwise be adapted.

Passing over theoretical considerations, the process may be briefly described as the introduction of a comparatively small weight of hydrogen into the oil (only a few pounds per ton). This small weight of hydrogen, however, occupies as much as 1 cb. ft. per lb. of oil treated, and it is this comparatively great volume of hydrogen which raises the first difficulty on the commercial scale and brings before the manufacturer the necessity for making the first decision—namely, shall operations be conducted near a convenient supply of hydrogen or near the source of the oil?

The production of cheap hydrogen, free from carbon monoxide and oxygen and having as little nitrogen as possible, has grown with the hardening industry.

The most important methods of producing hydrogen are—(1) By electrolysis; or (2) By decomposition of water by alternate oxidation and reduction of iron with producer gas.

Of the electrolytic methods there are—(*a*) Direct electrolysis of water, in which operation oxygen is a valuable by-product or (*b*) electrolysis of salt, having for its main issue the production of caustic soda with chlorine as a by-product.

---

* A paper read by Mr. E. Richards Bolton to Section B (Chemistry) of the British Association, Hull, 1922.

† Lecture on "Chemists and the Patent Laws", published by the Institute of Chemistry, 1922 (*cf.* J., 1922, 121 B).

In both these cases hydrogen is directly obtained from water. Many other methods have been employed—such as the utilisation of the hydrogen of hydrocarbons and so forth. Of the possibilities of the future one must consider *hydrogen carriers,* where advantage is taken of the affinity of oil for hydrogen, in that oil, under the stimulus of the catalyst, can rob other compounds of their hydrogen; but whether a liquid, easily obtainable at a competitive price, can be found ready to give up its hydrogen to oil is one of the fascinating possibilities of the future, and one which might cause a readjustment of the whole hydrogen position.

In countries like Norway—providentially provided with water-power—production by electrolysis must, in the present state of our knowledge, hold the field; and it is only recent improvements that have allowed hydrogen, produced by other methods, to compete with the electrolytic product so as to permit the process of hardening to be carried out in a locality suitable to the oil supply.

I pass over the production of hydrogen thus ightly, not from want of realisation of its mportance, but rather to emphasise what has always received the least attention—namely, the *oil* itself. One reads of hydrogen poisons, of catalyst poisons, and of the extraordinary care taken in the preparation of products to free them from these poisons. One finds works where all this care is taken and yet a perfect catalyst together with the most ideally pure hydrogen is introduced into oil, which oil has received quite inadequate attention and is reeking with impurities many of which are easily removable.

I have always held the view that the economy and efficiency of the process lie in a careful attention to the purity of the oil, and I feel that workers have been led astray by the fact that hydrogenation purifies so effectively that very little treatment is necessary to begin with. For this reason they have let slip from their observation the fact that most impurities, easily removable before hydrogenation, if left in the oil are merely wasters of catalyst and spoilers of hydrogen, and that impurities, more economically removed by simple means, are being dealt with in a more costly manner at the expense of catalyst and hydrogen. If I may for a moment poach on the field of theory, I would aim at the mark arrived at from theoretical considerations—namely, that, given a chemically pure oil and chemically pure hydrogen and catalyst, then, under these hypothetical conditions, the catalyst should retain its activity for ever, and, while such a state of affairs is obviously impossible, it is surely sound policy to approach it as nearly as practicable.

Now, to pass on to the catalyst, the working of which has been so often explained and is still so little understood.

With a few exceptions nickel is the catalyst universally employed. Among the exceptions are platinum and palladium, which, whilst almost prohibitive in price and involving very refined methods of recovery, cannot hope to compete with nickel in spite of the small quantity which is necessary, unless it can be shown that their activity at low temperatures—in fact appreciable activity at room temperature—confers some benefit on the finished product, not otherwise obtainable, for example, the hardening of particular oils without the destruction of vitamins. Otherwise, unless these metals fall very considerably in price, nickel has the field to itself.

The catalyst problem consists of three parts—(1) The preparation of a suitable catalyst; (2) the maintenance of its catalytic activity for as long a period as possible; (3) the recovery and reactivation of spent catalyst.

For the preparation of the catalyst the methods are many, but those commonly employed are based on the preparation of nickel carbonate precipitated on a vehicle, such as kieselguhr, and, after drying, reduced in hydrogen either directly in powder form or actually in the oil. The oil-reduction method produces a very active catalyst of a colloidal nature, a nature which, as one might expect, renders it more susceptible to poisons, and, in common with colloids, liable to sudden coagulation. In fact cases have come to my notice in which a nickel catalyst has suddenly coagulated from oil, in quite large particles as big as lead shot, and sunk, leaving a clear oil. (Research in this direction might be recommended to the colloid chemist, for whom, incidentally, there is a large field in connexion with oils generally.)

Notwithstanding such occasional irregularities, I have visited works where the catalyst is prepared on this principle with the most excellent results.

The simplicity of the dry-reduction method doubtless explains its great popularity. When this method first came into use a diversity of results was obtained, which was due to lack of temperature control and uneven heating. The more consistent results now so generally obtained are due to a clear appreciation of the following facts—namely, that:—

Low temperature of reduction (250° C.) increases activity but renders the catalyst more susceptible to poisons; whereas high temperature of reduction (350° C.) lowers the activity of the catalyst but increases its life.

Catalysts may well be compared to horses: the low-temperature product is swift as a racehorse, and the high-temperature product is steady and slow as a cart horse. The first gets there more quickly, no doubt, but the canny manufacturer who has to drag a thousand tons a week through his factory will choose the Clydesdale every time.

Having chosen the method of preparing our catalyst the maintenance of its activity must receive very careful attention, for therein lies one of the great sources of profit or loss in the process.

I began by emphasising the great need of purifying the oil, and I would ask those who take so much laudable care in purifying hydrogen and catalyst to remember that as little impurity as 0·2 per cent. in the oil represents one-fifth of the weight of 1 per cent. of catalyst, and, should the impurity be one which forms a film on the catalyst, the result is obvious; whereas, if the impurity be moisture, hydrolysis will result and the fatty acid produced will tend to form a coating of metallic soap.

All workers know how often a failure to hydrogenate effectually is associated with a rise of acidity. Hydrogenation is essentially a problem for those experienced in the properties of oil rather than for metallurgists and gas chemists.

The greatest solicitude that science can pay to the catalyst does not prevent the havoc of age, and, sooner or later, the time comes when the question of recovery and re-activation arises. In the early days the process of hydrogenation was so profitable that residues consisting of approximately 1 part of nickel, 1 part of kieselguhr and 2 parts of oil were discarded. The proportion of oil was subsequently somewhat reduced, but ere long recovery of nickel became essential to economic working.

Attempts to extract the oil by solvents from press residues have met with partial success, though, owing to the extreme fineness of the nickel, this is attended with some difficulty. A simpler method is to roast the residues or boil them out with caustic soda and roast the settled sludge. In some cases it may be sufficient to pass air over the ignited mass in a roaster, and, after displacing the air by CO_2, reduce at 250°–300° C. by hydrogen. A catalyst recovered in this way does not regain its original activity, so that when working with fish and other low-grade oils the ignited nickel residue is dissolved in acid, preferably nitric acid, and re-precipitated. In the latter case it is important not to introduce impurities by the solution of other metals contained as impurities in the kieselguhr.

Processes have recently been suggested whereby both the oil and the nickel are recovered from residues in a condition suitable for immediate re-use, and these will, no doubt, come into general use in the future. The successful operation of such processes really means that the catalyst becomes a capital charge, in fact, a part of the plant, and such a revolutionary change is likely to lead to a complete alteration in the whole procedure of hydrogenation.

A most extraordinary amount of engineering skill has been directed to the designing of all kinds of mechanical devices aimed at violent agitation and intimate admixture. The advancement of the art, however, is in no way commensurate with the skill and energy expended. The engineers—to use an Americanism—have been "barking up the wrong tree" when they have aimed at such violent methods; whereas, to the simple-minded, who have not been led into mystic paths of theory, it seems obvious that once the catalyst has become impregnated with oil, hydrogen can only reach it by penetrating through the oil—and to get through the oil, it must be in solution in the oil.

Once this is clearly understood it is easy to explain why such excellent results are obtainable with a gentle circulation of hydrogen-saturated oil. All that is really necessary is to remove the hardened oil from the surface of the catalyst in order to make access to fresh material.

The main types of plant devised may be briefly summarised under three headings:—

(1) A vessel nearly full of oil containing catalyst in suspension, through which hydrogen is circulated by mechanical means; possibly also with circulation of oil to maintain suspension of catalyst;

(2) A vessel full of hydrogen into which an intimate mixture of oil and catalyst is sprayed;

(3) Vessels containing stationary catalyst, through which oil and hydrogen are circulated.

Each of these three methods has fallen in for its share of elaboration, and it is unfortunate that, sometimes, the aim seems more the securing of a patent at any price than any real improvement of the processes.

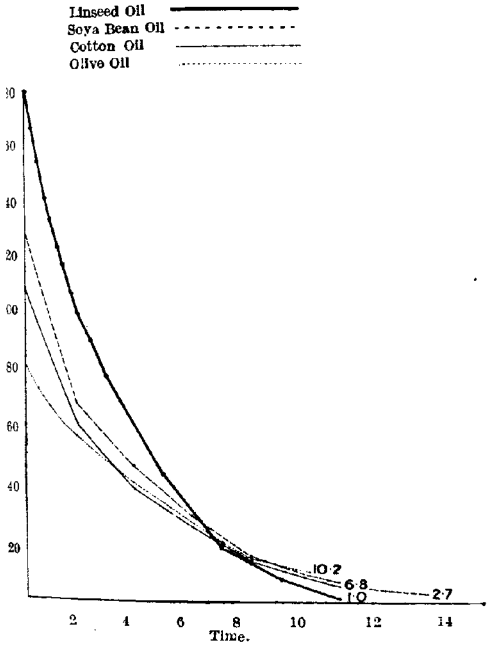
After considering all these complications and elaborate devices it seems absurd to find that the very simple method which I use in my laboratory for testing samples of oil as to their suitability for hydrogenation, should achieve the same result just as well.

Activated nickel wire is lightly pressed into a test-tube and covered with the oil to be treated. A slow stream of hydrogen is bubbled through the oil, the test-tube and its contents being maintained at 180° C. Hydrogenation then takes place evenly, and the operation may be continued in this simple apparatus until the iodine value of the oil is reduced to nothing. The oil is poured away from the catalyst and is clear without filtration.

Practical experiments have proved to me that this laboratory method can be extended in its simplicity to a works scale.

It has been suggested that poisoning of a catalyst by sulphur obtained from impure oils is proportional to the mass of catalyst, whilst hydrogenation is a function of surface only. This suggestion has received experimental support in the work of Dr. Maxted on the action of sulphuretted hydrogen on palladium.* This being so it would be expected that a catalyst with relatively large mass in proportion to its surface would hydrogenate oils containing small quantities of poisons almost independently of these poisons—that is, as shown by Dr. E. F. Armstrong, the velocity-time curve would be a straight line.

I have here some curves to show the results of hydrogenating oils by means of nickel wool which lend some support to this view. Though when we consider, for example in the case of linseed oil, the different chemical substances present — triglycerides of highly unsaturated fatty acids with three double linkages, hydrogenated down to olein and finally to pure tristearin—the fact that no break is shown in the curve may mean that the physical factors of contact, etc., are overwhelming the chemical side of the reaction altogether.



In conclusion, it is pleasant to think that the ideal at which we should aim—namely, a continuous process with a fixed catalyst capable of revivification *in situ* delivering oil without appreciable loss of catalyst—is really not out of sight. An added refinement is the possibility of setting an indicator to deliver automatically a continuous stream of oil of any desired degree of hydrogenation; that is to say, a self-operating mechanical control to alter the conditions necessary to compensate variations in the speed of the process.

POST-WAR PROGRESS IN THE FIXATION OF NITROGEN*

THE ARC PROCESS

THE arc process of fixing atmospheric nitrogen was put into commercial operation in Norway as long ago as 1904, and has now reached an enormous development. It was pointed out in the Report of the Nitrogen Products Committee (*cf.* J., 1920, 25 R) that although the power requirements of the process are very large, it nevertheless affords the cheapest known method for the manufacture of nitric acid.

It has not been sufficiently recognised that the arc process in its industrial form owes its initiation in a very great measure to scientific researches carried out mainly by British investigators. When, during the war, the writer was privileged to see the whole of the developments at Notodden, also the much larger and newer plants at Rjukan, officials of the Norsk Hydro Company told him that Prof. Birkeland used to recognise frankly that his inspiration to found an industrial process was derived from the famous British Association address of Sir William Crookes, and especially from the quantitative experimental work of the late Lord Rayleigh. At Notodden plant is now installed to utilise about 45,000 kilowatts, and in the two great works at Rjukan there are furnaces employing in all over 200,000 kw., or 270,000 continuous horse-power, this energy being generated at what is almost certainly the cheapest hydro-electric plant in the world. At Rjukan II. a 15,000 kilowatt steam-operated set has now been added to utilise waste steam raised in the boilers employed in the cooling of the process gases, which leave the furnaces at about 1000° C. During the later war period almost the whole output of these enormous works came to France and England for munition purposes.

Though the arc process has now reached the stage of a magnificent engineering achievement, it must be remembered that less than 2 per cent. of the electrical or heat energy expended in the average arc furnace is absorbed as chemical energy in the initial oxidation of the nitrogen. The concentration of nitric oxide in the gases leaving the furnace averages only about 1·2 per cent., and therefore it is not surprising that many suggestions have been made to improve the efficiency of the process, and all kinds of alternative forms of furnace plant have been proposed. Some of these have been tried during the war, and about fourteen arc plants of various types, mostly of small output, are now distributed throughout the world.

One of the more important variants of the original process depends on the use of enriched air, instead of common air. This has been used on a considerable scale by a company operating works in Switzerland and in Germany. The oxygen content of the air utilised is increased to 50 per cent., and to prevent loss of oxygen the whole operation is carried out in a closed circuit. The product, instead of being absorbed in towers, is generally removed by cooling, as liquid nitrogen peroxide. Although under certain conditions the increase in yield of fixed nitrogen obtained from the enriched gas was considerable, and though many tons of liquid nitrogen peroxide were made by the process, certain serious difficulties were encountered, and several explosions have recently occurred in these plants.

* Chem. Soc. T., 1919, 115, 1050.

* The substance of a paper read by Dr. J. A. Harker, F.R.S., before Section B (Chemistry) of the British Association, Hull, 1922.

The nitric-acid works on the Birkeland-Eyde system, erected during the war in France, are now closed, in order that the power may be used for its original purpose—viz., railway electrification.

SYNTHETIC AMMONIA PROCESSES

Originally worked out by Haber and his colleagues, among whom I should specially mention Dr. Le Rossignol, who is an Englishman born in Jersey, and Dr. H. C. Greenwood, the brilliant young investigator whose death three years ago we all deplore, the process was translated into a technical success by the Badische company, and is now employed on a huge scale in its works at Oppau, on the Rhine, and in the much larger works only recently completed at Merseburg, in Saxony.

But to day this is by no means the only process for the manufacture of ammonia from its elements. The accompanying table shows that there are now quite a number of other synthetic-ammonia processes, and summarises the more important facts regarding their individual characteristics.

The original German process operates at 200 atmospheres, now considered only a moderate pressure. In order to secure autothermic working, very large units are employed and the gas velocity is kept low, the reaction vessels being enormous flanged tubes of steel, nearly 40 ft. long and over 3 ft. external diameter, with walls 6 in. thick. The gases are preheated before being passed over the catalyst, and are recirculated through the system, after removal of the ammonia they contain.

In the process worked out independently during the war in the research laboratory of the Nitrogen Products Committee, at University College, London, much higher gas velocities were employed. It was found that under these conditions the yield of ammonia from a given quantity of good catalyst material can be increased enormously, and in the technical plant which was designed it was planned to obtain about 5 kg. of ammonia per hour for each litre of space filled with catalyst, instead of about 400 g. as in the original German system.

In the plant to produce 11,000 tons of nitrogen annually in the form of ammonium nitrate, erected at Sheffield, Alabama, by the U.S. Government in 1917–18, and working on lines not greatly differing from the German process, activated sodamide was used as catalyst material. This was difficult to prepare in bulk, and its activity, though at first fairly high, was permanently destroyed even by small quantities of water vapour. Therefore it was not surprising that this plant did not reach the stage of commercial operation. But, profiting by the lessons of this comparative failure, an American company, formed by the General Chemical Co. and

Forms of the Synthetic Ammonia Process

Country and Date	Process	Operating pressure Atms.	Approx. space-time-yield kg. lit. cat. hr.	Approx. percentage conc. NH_3	Method of removing NH_3	Source of hydrogen	Remarks

the Solvay Process Co., has erected near New York an improved plant on lines not dissimilar to those followed at Sheffield. For over a year this has now been producing liquid ammonia for the refrigerator industry at the rate of 10 tons per day.

The process invented by M. Claude, the special characteristic of which is that it operates at a very high pressure (about seven tons to the square inch), has been described in detail both by Claude himself and more recently by J. H. West (*cf.* J., 1921, 420 R). It differs mainly from the older Haber process in that under the very high working pressure adopted (about 900 atms.) the percentage combination attained in the gases after a single passage is about 40 instead of 10–11, giving about 25 per cent. of ammonia in the issuing stream. The yield of ammonia per litre of catalyst per hour in technical operation reaches the high value of about 5 kg. Multiple-stage working is adopted instead of recirculation of the gas, and the dimensions of a full-sized unit plant giving a technical output of 5 tons per day appear almost absurdly small in comparison with the monumental structures employed in the German process. M. Claude is now using a new form of catalyst tube, made by a well-known firm of steelmakers in Sheffield, of a new material having very remarkable properties at high temperatures. These tubes stand up extremely well to the trying conditions, and promise to give a safe industrial life much longer than anything previously attained. In the Badische process the cost of preparing and purifying the hydrogen used amounts to from 65–70 per cent. of that of the ammonia produced. It is therefore evident that hydrogen production is of paramount importance, and it is to the preparation of cheap hydrogen by a new process from the gases of the coke ovens at Bethune that Claude is at present devoting his attention.

In the Casale process, as now running at Terni, near Rome, the hydrogen is obtained electrolytically from large cells of a new type operated by hydro-electric current obtained from the great waterfalls near by. Some of this hydrogen is burnt with air, and thereby the required mixture of hydrogen and nitrogen is produced. Much attention is now being given to the question of the bulk generation of electrolytic hydrogen. New types of cell of large capacity have been worked out by inventors in this country and in Switzerland, Italy, and America.

Several proposals are on foot in different parts of the world to use electrolytic plants on a very large scale for producing hydrogen required in the manufacture of synthetic ammonia. There is good reason to believe that under existing conditions, and with coke at its present price, hydrogen produced in bulk at a favourable site from cheap hydro-electric power will easily be able to compete with that obtained by other methods. To ensure this, however, the type of cell employed requires to be much cheaper than previously, in order to keep down the capital cost of the electrolytic plant, which otherwise would be almost prohibitively large.

CYANAMIDE PROCESS

The cyanamide process, which, though stated by many authorities to be obsolete, or at any rate obsolescent, had at the end of the war an aggregate capacity in tons of nitrogen distinctly greater than that of any other method of fixation. It is quite true that since the armistice many of the works erected or enlarged during the war period have been closed. In some cases their situation was unfavourable for post-war commercial operation, and some of those whose output was used as a source of ammonia for munition purposes are unable, under present conditions of cost of labour and raw materials, to operate for the commercial manufacture of fertiliser.

The largest cyanamide works in the world, capable of producing about 200,000 tons annually, and erected during 1918 by the American Government at Muscle Shoals, in the wilds of the cotton-growing district in Alabama, is one of these. We in England used sometimes to say, five years ago, that Uncle Sam was rather slow in making up his mind to come into the war, but there is no doubt that when he did come in he put his hands into both pockets and spent money like water. The American nitrogen programme, including the expenditure on unfinished plant, scrapped at the time of the armistice, cost no less than $140,000,000. Muscle Shoals alone, exclusive of the hydro-electric scheme now being proceeded with, cost nearly twice as much as Gretna. During the past two years all sorts of proposals have been made as to its future, and at present it is still uncertain whether the Government will lease it to Henry Ford or some other private interest, or will keep it, and the synthetic plant at Sheffield, wrapped up in cotton wool, ready for the next war.

So far as can be ascertained, there has been no new development of outstanding importance in the manufacture of cyanamide itself, although detailed improvements have been made; but, nevertheless, even under the present difficult conditions, cyanamide is still almost certainly the cheapest form of combined nitrogen. In Germany, notwithstanding the recent big synthetic-ammonia developments, plans are now on foot for an immediate approximate doubling of the capacity of the great cyanamide plants at Presteritz, belonging to Messrs. Frank and Caro. Though the German nation cannot pay its just debts, there appears to be still plenty of money for private enterprise.

But cyanamide, when made, is at best an unsatisfactory fertiliser for many soils. When, in the course of an investigation a few weeks ago, the writer had an analysis made of what was probably a rather old sample of cyanamide, to his surprise he found that the nitrogen content was practically all in the form of dicyanodiamide. If such transformation is common, it is no wonder that the action in the soil is sometimes found to be injurious, rather than beneficial. Many efforts have been made within the last few years to find some process by which cyanamide nitrogen can cheaply be transformed into some other compound. As pointed out in the Report of the Nitrogen Products Committee, to transform it to ammonium sulphate is a relatively expensive process. Until lately the researches to this end made in many different laboratories have met with but small success.

An American company is now manufacturing from cyanamide, for export, a concentrated mixed fertiliser in the form of mono-ammonium phosphate, sold under the trade name of "Ammophos." This would appear to be a promising material, but is too costly for many applications. But within this last year independent investigators in Sweden and Switzerland, working along parallel lines, have succeeded in perfecting processes whereby, by the action of carbonic acid, free cyanamide is first prepared from a solution of calcium cyanamide, and subsequently transformed to urea. In the Swiss form of the process, excess of the sulphuric acid employed in the second stage of the transformation is afterwards used to act upon phosphate rock, which is changed to mono-calcium phosphate. The final product is a neutral body known in France and Switzerland as "Phosphazote," having its nitrogen content as urea, and its phosphorus in the water-soluble form. The cost of its manufacture is stated to be by no means high, and, unlike cyanamide, the substance has no deleterious action on the skin or on the bags in which it is packed. It has now been manufactured in Switzerland on a fair scale for about six months, the product going mostly to France for vine culture. The relation of the two constituents can be varied within limits, but the usual form in which the fertiliser is sent out contains 11–12 per cent. of nitrogen as urea and 11–12 per cent. of available phosphoric anhydride. These two new processes, which apparently are in course of rapid development, may prove to be a means of habilitating cyanamide as a product of fixation, and hence may shortly assume considerable importance.

CYANIDE PROCESS

It is only possible to refer very briefly to the cyanide process, by far the oldest practical fixation method, which still attracts many investigators. A British company is continuing its experiments at Birmingham, and in America cyanide is now being made on a considerable scale from cyanamide as a source of hydrocyanic acid for use in plant fumigation. In the opinion of some American experts the costs of producing cyanide by existing methods, such as the Bucher process, are excessive, and the cyanide process is not likely to be competitiv until further research is carried out on the fundamental reactions involved in the preparation of sodium cyanide. These have never been properly studied, and are more complex than was formerly supposed. Investigations with this object are being undertaken by the Fixed Nitrogen Research Laboratory of the American Government.

AMMONIUM NITRATE

After the Oppau explosion mixed salts containing ammonium nitrate will probably be under the ban of many fertiliser dealers, although the substances may nevertheless be perfectly safe, if their possessors are not sufficiently careless or foolish to attempt to remove them by the stimulus of a big blasting cartridge.

THE POSITION IN GERMANY

In 1913 Germany consumed about 200,00 tons of nitrogen, of which about 110,000 tons was imported in the form of Chilean nitrate. The bulk of this large consumption was used in agriculture for the intensive cultivation of crops. Prof. Matignon, of the Collège de France, states that from May 1, 1921, to April 30 of this year, the smaller Germany of to-day consumed 290,000 tons, or 45 per cent. more than in 1913, without the demands of her agriculturalists being entirely met. Furthermore, the whole of this increased total was produced within the country from the fixation and by-product industries.

Even that is not the whole story. The limit of capacity of production of the German works was far from being attained in 1921. Although the German Government pleads bankruptcy, the Badische company appears to have had little difficulty in finding money to repair the enormous damage caused by the great explosion at Oppau last September. It is stated that the works is now on the point of being ready to produce again at full capacity.

At the end of the present year Germany will have at her disposal an internal capacity for the production of fixed nitrogen of about 500,000 tons annually, a total so colossal that she will be entirely independent of all importation. In case of another war, she will thus be assured of the basic materials for a gigantic production of munitions, together with enough fertiliser to enable her to grow a very large share of her own food. It may be justifiable for the Allies to allow our late enemies to put themselves so soon after the war into so strong a position; but, on the other hand, it may be that those whose function it is to see to it that some, at any rate, of the provisions of the Peace Treaty are carried out, are unaware of what is now happening.

Let them beware that whilst Gretna and almost all our own munitions works are calmly being dismantled, the world is not caught napping a second time.

THE BRITISH ASSOCIATION

THE ninetieth meeting of the British Association, held in Hull from September 6 to 13, will be remembered as one of the most pleasant and useful in the long history of the Association. The arrangements were excellently planned, and the attendance of 1730 must be regarded as very satisfactory, particularly in view of the refusal of the railway companies to extend to members the same facilities that are given to race-goers and other pleasure-seekers.

Since the meeting in Edinburgh last year, the Association has received a most generous gift of £10,000 from the Hon. Sir Charles Parsons, and a legacy of £450 from Mr. T. W. Backhouse. Sir Charles Parsons has also financed the production and publication of "A Retrospect, 1831-1921," compiled by the Secretary, Mr. O. J. R. Howarth (*cf.* J., 1922, 272 R). With these welcome aids to its somewhat slender financial resources, the Association should soon be in a position to increase the grants to research committees, and to extend the scheme of exhibitions to students enabling them to attend the meetings, which was initiated during the past year. Sir Edward Thorpe, the retiring president, has drawn the attention of the Council to the hardship inflicted on students of science by the greatly increased cost of text-books, and to alleviate the difficulty Sir Robert Hadfield has given a donation of £50 per annum for three years. The Council has decided to allot the money to necessitous students of the poorer provincial universities and technical institutions.

Prof. H. H. Turner, Savilian Professor of Astronomy in the University of Oxford, has retired from the office of General Secretary, and Mr. F. E. Smith, F.R.S., Director of Scientific Research at the Admiralty, has been elected to fill the vacancy so created. Sir Robert Hadfield and Prof. W. A. Bone have retired from the Council, but Chemistry remains well represented by Sir William Pope, Dr. E. F. Armstrong and Prof. A. Smithells.

Arrangements are well in hand for next year's meeting in Liverpool (September 9 to 16), where Sir Ernest Rutherford will preside, and Dr. A. Holt, Mr. Edwin Thompson and the Town Clerk will act as Local Secretaries. Everything points to a very successful meeting, including several departures from precedent which should add to the convenience of members. The invitation to hold the 1924 meeting in Toronto has been definitely accepted ; the Dominion Government has voted the sum of approximately £11,000 to assist visitors from Great Britain ; and the meeting will probably be held during the first week of September, after members have had an opportunity of travelling around.

The only change in the organisation of the Sections is the introduction of Forestry as a sub-section of Section K (Botany).

Sir Charles Sherrington's presidential address, entitled "Some Aspects of Animal Mechanism," dealt mainly with recent advances in the physiology of the nervous system and the time-honoured problem of ontology. Although we can now explain the *how* of the mechanism of some aspects of animal life, we are still as far off as ever from understanding the nature of the connexion between nervous processes and the corresponding phenomena of consciousness. In an Evening Discourse, entitled "The Atoms of Matter : their Size, Number and Construction," Dr. F. W. Aston described in simple language the results of, and inferences from, recent work in the prolific field of radio-activity, and refreshed us all by giving two new illustrations of the dimension and speed of molecules. He said that if a hole were made in an evacuated electric-lamp bulb of a size to allow the molecules present in air to enter at the rate of one million per second, one hundred million years would elapse before the bulb was full. Again, if a tumblerful of water were distributed throughout all the waters on the globe, then each tumblerful taken from these waters would contain 2000 molecules of the original tumblerful.

CHEMISTRY

Although the meetings of Section B, in common with those of most other sections, did not attract such large audiences as did last year's meetings in Edinburgh, the attendance was nevertheless very good, and there is no doubt that the programme arranged by the Recorder, Prof. C. H. Desch, with the help of the Organising Committee, was much appreciated. The success of the gatherings was due in no small degree to the ability and geniality of the President, Principal Irvine, who, moreover, set a very high standard in his presidential address ; the Section does not often hear such a masterly account of new researches of great scientific, as well as of potentially industrial, importance.

General regret was felt at the unavoidable absence of Prof. A. F. Holleman, who was to have read a paper on "The Rule of the Conservation of Substitution-Type in the Benzene Nucleus," but in place of this a valuable pioneer paper, not previously announced, on "Solid Disperse Systems in Air" was read by Dr. R. Whytlaw-Gray of Eton College. The papers of Prof. J. W. McBain, Dr. J. S. Owen and of Principal Irvine's co-workers also dealt with the results of original research. The joint discussion with Section K (Botany) on Photosynthesis was well staged, and though it brought out prominently the somewhat widely differing outlook of chemists and biologists, it doubtless proved as useful to the protagonists as it was interesting and stimulating to the large audience. Very useful papers were contributed to the discussion on the Nitrogen Industry, and that by Dr. J. A.

Harker obtained very wide publicity in the daily papers. In contrast to this, the discussion on "Valency and Polarity in Organic Compounds," to which Prof. R. Robinson and Dr. J. Kenner made weighty contributions, was somewhat too abstruse for many of those present; but no criticism of this kind could apply to the very lucid expositions on the "Hydrogenation of Fats" given by Dr. E. F. Armstrong and Mr. E. R. Bolton. Reports were presented by the Committees on Colloids, Fuel Economy, and Absorption Spectra, but none of these was discussed.

Hull is a very favoured locality from the point of view of chemical industry, and the excursions to works, organised by Mr. A. R. Tankard, local secretary to the Section, proved very popular. The special thanks of the Section are due to the directors of the following companies for their generous hospitality: The British Oil and Cake Mills, Ltd. (seed-crushing and solvent extraction, soap, margarine); G. & T. Earle, Ltd. and the Humber Portland Cement Co.; Reckitt & Sons, Ltd. (ultramarine, starch, metal polishes, etc.), and the Frodingham Iron and Steel Co., Scunthorpe.

We give below further abstracts of papers presented, together with a *résumé* of a paper on the resistance to fire of concrete, read before Section G (Engineering) by Prof. F. C. Lea and Dr. R. E. Stradling of Birmingham University, and some remarks from the joint discussion on Vitamins held by Sections I and M (Physiology and Agriculture).

The Composition of Esparto Cellulose

By E. L. Hirst

Esparto grass, after removal of waxes, lignins, etc. in the ordinary course of paper-making, gives a material which is homogeneous and similar in appearance to cotton cellulose, but differs markedly from it in giving on distillation with 12 per cent. aqueous hydrochloric acid an amount of furfural corresponding to the presence of 18—20 per cent. of a pentosan.

Esparto cellulose is not acetylated so readily as cotton cellulose, but by slightly modifying Barnett's method, in which sulphuryl chloride is used as catalyst, almost quantitative yields of acetates have been obtained without appreciable loss of the pentose-content as shown by furfural estimations. This acetate mixture has been subjected to the action of acid methyl alcohol in sealed tubes at 130° C., when it is found that after prolonged digestion practically the whole of the material dissolves and the solution then contains methylglucoside together with a proportion of a methyl pentoside. That the pentose is identical with xylose has been confirmed by isolating from esparto cellulose a pentosan which on hydrolysis is converted into a reducing sugar identical with ordinary xylose. In the course of quantitative experiments esparto cellulose has thus been converted into methylglucoside and methylxyloside in such a manner that 90 per cent. of the whole material can be accounted for. The analytical results indicate that the over-all yield of methylglucoside is 95 per cent. and that of methylxyloside 68·5 per cent. of the theoretical amount, calculated on the assumption that only glucose and xylose residues are present. The loss in yield, as indicated by the results of control experiments, is due to the destruction of pentose owing to furfural formation during the digestion in the sealed tubes.

The evidence therefore points to esparto cellulose being, to the extent of 90 per cent. at least, a definite chemical substance composed of glucose residues and xylose residues present together in the proportions of 80 per cent. and 20 per cent. respectively.

Determination of Compressibilities up to High Pressure and Applications to High-Pressure Chemistry

By E. D. Williamson

A new form of pyknometer has given satisfactory results, particularly in determining compressibilities at the lower end of the pressure range. By means of a movable electrical contact, the instrument allows of continuous readings without removal from the pressure chamber.

In the study of the chemical effects of pressure on systems of more than one component, it is necessary to know the compressibility of each solution in order to compute the volume changes on which these effects depend. The volume changes can be readily calculated from the slopes of the density-composition curves. Even in the case of a simple system, such as a salt and water, it is necessary to make a number of other measurements in addition to those of compressibility. For instance, good density-composition data must be obtained at atmospheric pressure. Also, some form of equilibrium determinations, such as those of vapour pressure or EMF, must be made in order to calculate the initial differences in "free energy" (used in the same sense as by G. N. Lewis) between the solid salt and salt in solution. For the case of H_2O—NaCl almost all the necessary data for the complete elucidation of the system under pressure have been obtained, and a beginning has been made with some others.

Hydrogenation of Fats

This discussion was opened with an address by Dr. E. F. Armstrong, who said that fat-hardening presented problems which brought in almost every aspect of the chemist's work and nearly every trick of his art. Fat-hardening was discovered in theory by Sabatier and in practice by Dr. Normann whose small-scale experiments paved the way for the elaboration of the process on an industrial scale in England. The enormous number of patents, very few of which were of any value, which had resulted was typical of chemical industry, and he regarded this as one of the drags upon the wheels of progress which ought to be removed. Fat-hardening had been much delayed by the difficulties experienced in manufacturing hydrogen, but many of these had now been overcome. Inventors of processes for making hydrogen seldom took into consideration all three factors involved, viz., the capital cost of the plant, operating costs, and the cost of maintenance and repairs. In localities where cheap power was available, there was no difficulty in making cheap hydrogen by the electrolytic method, and he understood that it was being produced on the continent with the aid of cheap water power at 2s. 6d. per 1000 cb. ft. The process adopted by the Badische company was preferable when hydrogen was required in very large quantities, but the ordinary catalytic process was best for small plants. Dr. Armstrong then described the preparation of the nickel catalyst used in hydrogenation and emphasised the points that the efficiency of the catalyst depended upon the existence of maximum surface, and that the oil to be hydrogenated must be clean. The remainder of the address was devoted to an explanation of the manner in which the catalyst brings about the hydrogenation, viz., by the intermediate formation of an unstable additive compound of the nickel and the fat. (*Cf.* J., 1920, 249 R; 1922, 67 R, 304 R.)

Aerosols, or Solid Disperse Systems in Air

By R. Whytlaw-Gray and J. B. Speakman

Dilute smokes analogous to the solid-liquid systems of colloidal solutions can be formed, (*a*) by heating substances of high boiling-point in a rapid air stream (paraffin wax, acetanilide, *ortho*-phthalic acid, and diphenylamine disperse readily); (*b*) by the arc discharge from metallic electrodes in an air current, forming with most metals an oxide dispersoid, and with silver, gold, and platinum a metallic one; (*c*) by chemical interaction between highly diluted vapours or gases, *i.e.*, zinc ethyl and air or ammonia and hydrogen chloride. An ultramicroscopic method has been developed of counting the number of particles in a given volume of these smokes and by working with a large volume of dispersoid (1 cb. m.) the changes that take place have been followed and shown to be due to aggregation. Different substances form aggregates or complexes of various structures, those of zinc and cadmium oxides giving irregular flexible threads in which the particles appear as beads on a string and exhibit remarkable Brownian motion.

The curves obtained by plotting the number of particles per c.c. against time showed in all cases a steep initial drop corresponding with the period of most rapid aggregation.

The weight of the particles in a given volume was found by filtration through asbestos and weighing the small filter on a micro-balance sensitive to 0·0002 mg. and the resulting weight-time curves showed that the weight falls off much more slowly than the number of particles. By combining the two sets of curves it was possible to calculate the sizes of the particles: these were found to increase with time and then become constant.

Liquid and solid disperse systems are produced in a large number of chemical operations, such as the passage of gases through liquids and the decomposition of solids by heat, and this possible source of error in measurements of high accuracy does not seem to have been considered.

The Study of Soap Solutions

By Prof. J. W. McBain

In view of the large number of current theories which are irreconcilable with the conclusions to which the study of soap solutions has led it is necessary very carefully to prove the evidence for the existence of the ionic micelle.

1. The following methods agree in showing that hydroxyl ion is only a minor constituent of soap solutions (about 0·001*N*):—Electromotive force with hydrogen electrode; catalysis; conductivity; ultra-filtration with direct analysis of the filtrate.

2. The osmotic activity is about half that of a salt. Trustworthy measurements have been obtained by the following methods:—Freezing-point; dew-point; minimum pressure required for ultra-filtration; vapour pressure.

3. The conductivity is that of a salt; this is indicated by hundreds of concordant measurements with many kinds of soap.

4. Half the conductivity must be ascribed to a constituent of very high equivalent conductivity but of negligible osmotic pressure, the ionic micelle. Its conductivity is several-fold that of all the fatty ions contained in it.

5. By ultra-filtration the ionic micelle is found to be colloidal, and, in addition, the undissociated neutral colloid, consisting of still larger particles, may be separated from the ionic micelle. Sodium and potassium electrodes confirm the concentrations of sodium and potassium ions assumed. Migration determinations are also in agreement. Hydrolysis is impossible in the case of cetyl sulphonic acid, whose behaviour is closely similar.

6. An important result is the theory of gel structure. The only differences between a transparent jelly and a sol are mechanical—elasticity and rigidity. The colloidal particles in both are identical in nature and amount, but in the gel they are arranged in ultra-microscopic filaments or aggregates. The equilibria and the resistance to the passage of the electric current are unaltered on gelatinisation.

7. "Electrical endosmosis" and "cataphoresis" in a transparent soap jelly are quantitatively identical with electrolytic migration in the corresponding soap sol.

8. The theoretical conclusions are of general applicability to very large groups of organic and inorganic solutions in aqueous and non-aqueous solution.

Raw Materials for Synthetic Ammonia: The Manufacture of Hydrogen and Nitrogen

By J. H. West

There are two main sources of commercial hydrogen—coal and water. Electrolytic hydrogen is very pure, but owing to the high capital cost of the plant and the great consumption of electric energy, the cost of production is prohibitive unless cheap water-power is available. Many coals contain about 5 per cent. by weight of hydrogen, equivalent to about 21,000 cb. ft. per ton of coal, but only about one-quarter of this amount is set free on distillation of the coal in retorts or coke ovens. Coke-oven gas, where available, is an excellent source of hydrogen, when the latter is separated from the other gases by Claude's liquefaction process. The interaction of steam and hot coke gives water gas containing about 50 per cent. of hydrogen and 42 per cent. of carbon monoxide, the yield being about 55,000 cb. ft. of gas per ton of coke. The carbon monoxide in water gas may be caused to react with steam, giving carbon dioxide and hydrogen.

The process devised by Dr. A. Jaques and the author combines the distillation of coal in a retort, the formation of water gas from the resulting coke, and the conversion of the carbon monoxide produced in these two operations into carbon dioxide and hydrogen by reaction with steam in presence of a catalyst, in one apparatus, thus giving a maximum yield of hydrogen. Nearly all the hydrogen in the coal is liberated by passing the crude coal gas through a hot zone in the producer, so that all tar, oils, and hydrocarbons, such as methane, are cracked or split up into hydrogen and carbon, the carbon reacting with steam to form water gas. The process is carried out in a modified form of Tully complete-gasification plant, and the only products are gas and ashes.

Nitrogen can be made in an ordinary liquid-air plant, the separation from oxygen being effected by fractional distillation. Another method is to burn out the oxygen of air with hydrogen. In other words, a measured quantity of air is added to the hydrogen and the mixture is passed over a catalyst, so that combustion takes place quietly, and a mixture of hydrogen and nitrogen in the desired proportions results.

In the Haber process water gas is mixed with air producer gas, so that sufficient nitrogen remains in the mixture after treatment for conversion of the carbon monoxide, the final adjustment to the exact proportions being made by adding a little pure nitrogen obtained from liquid air.

The Häusser Process of Nitrogen Fixation

By C. J. Goodwin

The commercial success of the manufacture of synthetic ammonia in conjunction with the Ostwald process of obtaining nitric oxides and nitric acid by combustion of the ammonia, has created the impression that in the near future such ammonia will be the principal raw material for nitric-acid manufacture. Colour is lent to this view by the economic failure of the arc process, except under exceptionally favourable conditions, and by the price conditions obtaining in the markets for nitrate of soda and sulphuric acid. Economically, and on general principles, such an assumption seems unsound provided there is an assured output for all the synthetic ammonia produced, because, even if the loss on conversion is small, it would be irrational to make ammonia in plant involving high capital costs if nitric acid could be made directly in cheaper plant at the same cost. Recent developments in the Häusser process have brought the commercial realisation of this statement within sight. The details of Häusser's researches and trials were recently communicated to this *Journal* (1922, 253—259 R). The normal development of this method of nitrogen fixation was suspended during the war, and in this country the Nitrogen Products Committee in its final report (publication of which was delayed until 1920) rightly concluded that other processes would give more immediate and satisfactory results.

In the present paper it is shown that the impending trials with a 1200 to 1500 litre bomb are likely to lead to commercial yields. Modern alloys and unstainable steel have assisted in overcoming difficulties in wear and corrosion, and the volume of the absorption tower system has been reduced to one-sixtieth of the normal by absorption under 2½ to 4 atmospheres pressure in chromium-nickel-steel or silicon-iron towers. A yield of 150 grams of nitric acid per cubic metre of coke-oven gas is anticipated. The plant requires no external energy for driving compressors, etc. It is possible that by using a special gas engine or a kind of Humphrey pump, a greater proportion of the calorific power of the gases or liquid fuels might be converted into useful energy, but such a plant would necessarily be more complicated. Finally the importance of using gases of high calorific value as giving higher temperatures and yields is emphasised, and methods are indicated by which coke-oven and similar gases can be enriched to meet these conditions. It is suggested that Häusser plants can be usefully developed either as adjuncts to synthetic ammonia plants, at coke-oven plants, or in places where liquid fuel is cheap and the cost of making nitric acid is relatively high. Such plants can be relatively small, whereas other methods involve production on a very large scale to render them commercially successful.

Some Aspects of the Relationship between Water-Power and Nitrogen Fixation

By E. B. Maxted

The fixation of nitrogen by any of the three principal processes, namely as nitric oxide in the high-tension arc, as cyanamide, and as synthetic ammonia, involves in each case two economic factors, which may conveniently be grouped under the heading of power and of materials respectively. On the predominance of the one or of the other of these two classes will depend the practicability of any one of the processes under given geographical conditions. From this standpoint, the arc process is necessarily confined to countries suitable for the development of cheap hydro-electric power, whilst the production of cyanamide, by reason of the balance between the material and the power factors, is capable of establishment either at the source of cheap power or at the site of the necessary raw materials.

The synthesis of ammonia, by virtue of its low power-factor, possesses the unique advantage of being independent of peculiar geographical conditions, provided that the hydrogen utilised is made from fuel. It is, however, of interest to regard the synthesis of ammonia as a possible outlet for water-power, the hydrogen being in this case made electrolytically, and from this standpoint to obtain data concerning the relationship of electrolytic hydrogen produced from water power to hydrogen produced from fuel; further, to see what economic advantage, if any, is obtained by applying water power to the synthesis of ammonia in this way, rather than for the fixation of nitrogen in another form, such as calcium cyanamide, in each case under the conditions which exist in Great Britain.

The potential resources of water-power in this country have recently been surveyed by the Water Power Resources Committee of the Board of Trade. In the course of this survey, water resources estimated to be capable of producing about 250,000 kw. were examined in detail. This figure is not exhaustive, and is exclusive of the Severn Estuary scheme. By far the larger proportion of potential water power sites of any considerable magnitude are located in Scotland. An important factor in the present case consists in the maximum power available at a given site. Of the ten Scottish loch and ver sites reported on favourably by the engineers tained by the above committee, only one was timated to produce over 30,000 kw., and only two er 20,000 kw., the average power of the ten sites ing about 10,000 kw. In Wales, of the five sites ported on, only one was estimated to have a otential output greater than 5000 kw.

On the basis of the above survey, it would appear hat water-power on a considerable scale could be eveloped in Great Britain and that, under pre- ent conditions, it should be possible to produce ydro-electric energy from several of the more suit- ble sites for about £4—£5 per kilowatt-year, the reater part of this cost representing interest on he capital cost of the installation. If a power con- umption of 135 kw.-hr. per 1000 cb. ft. of hydrogen roduced by electrolysis be assumed—a figure which onforms to the results obtained in practice—the ost of power should be about 1s. 7d. per 1000 cb. ft. f hydrogen, the value of the oxygen being disre- arded. This figure does not compare unfavourably ith the cost of hydrogen made from fuel. The rincipal disadvantage of the electrolytic process onsists in the relatively large floor space required, nd in the multiplicity of cells necessary. This is eing met to a certain degree by the gradual intro- luction of large unit cells; and the extent to which this enlargement is practicable, together with the ven more important desirability of a relatively high operating current-density, will probably deter- mine the industrial future of electrolytic hydrogen, t any rate for cases in which the oxygen is not tilised. The utilisation of relatively large supplies f cheap oxygen in chemical industry presents, oreover, in this connexion an important field for esearch.

The problem may also be considered from a lightly different standpoint. Let it be assumed hat power of a given magnitude, for instance, 0,000 kw., is available at a given site; and let this ower be utilised completely, firstly for the syn- hesis of ammonia (the hydrogen being generated lectrolytically), and, secondly, for the production, or instance, of calcium cyanamide. In the first ase, some 5000—5500 tons of nitrogen per annum ould be fixed as ammonia, about 7500—8000 of the 0,000 kw. available being used for electrolysis. If, n the other hand, the 10,000 kw. were used for the xation of nitrogen as cyanamide, the weight of itrogen fixed per annum would be about the same, he important difference being, however, that, in he case of synthetic ammonia, about 33,000 cb. ft. er hour of waste oxygen would be available from he hydrogen and nitrogen plants—assuming the tter gas to be made from air by a process of low emperature separation—whereas, in the case of yanamide, the whole of the anthracite and lime equired would have to be brought to the site of the actory and there handled. This would be balanced o a certain degree by the greater simplicity of the yanamide method, and by the necessity for fixing he ammonia by means of an acid.

Consideration of the nitrogen problem from the bove standpoint is of interest in that it brings the ynthesis of ammonia into line with the other pro- esses of nitrogen fixation in regard to a choice etween fuel and water-power for their operation. lthough the presentation of the matter in this ght is not intended as a definite argument for the referential manufacture of such large quantities of ydrogen by electrolysis, it would appear that the utilisation in Great Britain of hydro-electric power for such purposes is not impossible.

The Resistance to Fire of Concrete and Reinforced Concrete

By F. C. Lea and R. E. Stradling

The authors considered the problem under two headings, viz., the possibility of making a concrete which shall retain its strength after exposure to high temperature, and the possibility of preventing steel from reaching such a temperature that its strength is reduced to or below that required to carry the loads. In testing the action of fire on concrete, the authors experimented on the expansion of quartz and set cement, and found that at about 575° C. quartz changes to the β form and undergoes a linear expansion of about 0·4 per cent. The expansion of set cement is normal, and approximately equal to that of steel, up to 93° C.; between 100° C. and 491° C. it contracts, but expands again above the latter temperature. The authors conclude that water is continually driven off throughout the heat treatment, but at different rates for different temperature ranges, the greatest being between 98° and 102° C. Between 300° and 500° C. the rate is fairly constant, but falls off after the higher temperature has been passed. At temperatures above 400° C. the calcium hydrate is dissociated into quicklime and water.

Experiments were also carried out on the reduction in strength of sand-cement mortars and concrete, under the application of heat. Various mortars composed of Leighton Buzzard sand and cement were used, and it was found that with a 1:1 mixture for temperatures below 400° C. there was a gain in the tensile strength of the specimen, the maximum gain being about 22 per cent. at 100° C. Increase in temperature above 400° C. led to loss in strength, and at 830° C. this loss amounted to 91·1 per cent. With mixtures containing more sand, the range of temperature within which a gain of strength occurred was less, and the loss of strength was more rapid at higher temperatures. Concrete made of ground brick and cement was found to gain in strength between 0° and 650° C.; above the latter temperature there was a loss in strength, which, however, did not take place so rapidly as in the sand-cement mortar, being only 55 per cent. at 1030° C. The authors also found that if the specimens after heat-treatment were exposed to the atmosphere for some time they lost strength quite out of proportion to the amount of heating; that cracks would appear on the surface; and that the block might crumble to pieces. This is attributed to hydration of the quicklime, formed during heating, by atmospheric moisture.

Concrete fails owing to the relative movement of the sand grains and the cement, brought about by the different coefficients of expansion, and this type of failure can be partially obviated by using rather different materials. When this is done the failure on heating is due to breaking down of the cement itself. In reinforced concrete, when the temperature is raised above 100° C., contraction occurs in the concrete whilst the steel reinforcements expand. This tends to break down the adhesion between the concrete and the steel, either by the complete sliding of the steel through the concrete or by the cracking of the concrete itself.

The authors make several suggestions for overcoming this defect, but state that large-scale experiments would be required to test them.

Vitamins

Prof. J. C. Drummond pointed out that plants were to be regarded not only as machines for storing solar energy, but as laboratories in which certain substances were prepared that the animal body was unable to make for itself. We knew the constitution of some of these substances, *e.g.*, the amino-acids, tryptophane, and cystine, but there were others, the identity of which was still obscure, commonly known as vitamins A, B, and C. Whereas two of these were produced only by green plants, it appeared that the third could be manufactured by such low forms as yeasts and bacteria growing in culture media. On the other hand, the recent studies which showed that rickets could be cured not only by vitamin A, but also by exposure to sunlight or ultra-violet light, suggested the possibility of a synthesis of vitamin A by animal tissues. Prof. Drummond uttered a warning with reference to the food of the industrial population of this country. The consumption of milk per head was much lower than that of other countries, and the use of margarine had largely replaced that of butter; the most dangerous feature of all was the widespread neglect of fresh green foods.

Captain J. Golding described experiments in which the importance of vitamin A was demonstrated in the rearing of pigs. Under the experimental conditions it was found that the limitation of growth and development of the young pig was dependent on the amount of the vitamin which had been transferred from the mother during suckling. It was evident that if this amount was in excess of immediate requirements, it could be stored in the fat of the young pig, and no signs of deficiency followed a deficient diet until this store was exhausted. Further results were given showing that prolonged deficiency of the factor A might do irreparable harm in the matter of reproduction. Whilst in practice the danger of vitamin deficiency was largely confined to sty-fed pigs, it also occurred in others. During last summer (1921) a big herd of young pigs kept on a dry upland pasture was found to be suffering from failure of growth and joint trouble. The pigs were at once cured by bringing them to a fresh green pasture or by giving them lucerne. Agriculturists were warned against artificial foodstuffs advertised as containing vitamins, for these were generally a cloak for a lack of nutrient materials. Apart from cod-liver oil, the farmer should look to his natural foods to supply vitamins.

Among other papers presented to the meeting were:—*Section A (Mathematical and Physical Science):* X-Rays and Beta Rays: M. le Duc de Broglie; The Law of Distribution of Particles in a Colloid Suspension: Prof. A. W. Porter; X-Ray Electrons: Prof. R. Whiddington. *Section D (Zoology):* Presidential address by Dr. E. J. Allen on The Progression of Life in the Sea (including observations on the production of Vitamin A by plankton diatoms); The Hydrogen-Ion Concentration of Soils and Natural Waters in relation to Animal Distribution: Dr. W. R. G. Atkins; Fresh-Water Fauna of Aberystwyth Area in relation to Lead Pollution: Miss K. Carpenter. *Section F (Economic Science and Statistics):* The Future of Unemployment Insurance: J. L. Cohen; Equal Pay to Men and Women for Equal Work (presidential address): Prof. F. J. Edgeworth. *Section G (Engineering):* Home-produced Oil Fuel: Dr. C. H. Lander. *Section I (Physiology):* The Efficiency of Man and the Factors which Influence (presidential address): Prof. E. P. Cathcart; An Estimation of the Practical Agricultural Importance of Vitamin A in Feeding Pigs: Capt. J. Golding; Further Studies on the Isolation of the Antineuritic Vitamins: Dr. A. Seidell. *Section J (Psychology):* Industrial Psychology and the Efficiency Engineer: Dr. C. S. Myers. *Section K (Botany):* On the Transport of Organic Substances in Plants (presidential address): Prof. H. H. Dixon. *Section L (Education):* Educational and School Science (presidential address): Sir R. A. Gregory. *Section M (Agriculture):* The Use of Lime in the North of England: J. A. Hanley; The Limitations of Laboratory Methods of Lime-Requirement Determination: N. M. Comber.

The presidential addresses have been published in a separate volume by John Murray (price 6s. net).

APPEAL ON BEHALF OF RUSSIAN MEN OF SCIENCE

THE following is the text of a letter, dated September 30, addressed by Sir James Walker, President of the Chemical Society, to its Fellows. We reproduce it here in the hope that it will evoke a response among members of the Society of Chemical Industry and among other readers of this *Journal.*

In September of last year, in consequence of the information received as to the deplorable conditions under which Russian men of science were placed, I issued an appeal to the Fellows of the Chemical Society to assist in the alleviation of the acute distress prevailing amongst their colleagues in Russia.

I have to announce with great satisfaction that in response to this appeal the sum of £214 2s. 7d. was received, besides numerous valuable parcels of clothing, underclothing, boots, and books. Of this sum £170 has been devoted to the purchase of clothing, which has been distributed amongst our colleagues in Ekaterinburg, Moscow, and Petrograd. In addition to this, three cases containing clothing and books have been despatched to Moscow and Petrograd.

The difficulty with which we were confronted, namely the uncertainty as to whether parcels sent from England would reach their proper destinations, has now happily been overcome, definite proof having been received in every case that the goods have reached those for whom they were intended.

In a letter written by one of the workers of the European Student Relief Society to the Friends' Relief Committee, the following passage occurs:—

"The Chemical Society in England recently sent out some scientific journals, etc. through the Friends. They have been entrusted to me for distribution, and when I told some of the Moscow professors of their arrival, their eagerness to see them was like the eagerness of the children in the famine areas to get bread. You can assure all donors that every journal will be properly circulated in the faculty concerned and be retained in the library."

It will be seen from this how urgent the need still is for scientific books; and from information received from the Committee of Russian Men of Science (a member of which visited this country last spring) the need for every kind of scientific apparatus appears to be equally pressing.

Notwithstanding the useful work that has been accomplished by the different organisations formed to relieve the wants of men of science in Russia, there remains much to be done, for there is every reason to fear that the necessity will be no less acute during the coming winter than it was last year. I therefore issue this appeal to Fellows of the Chemical Society and to British chemists generally to render every assistance within their power, in a confident hope that a generous response will be forthcoming.

In addition to donations of money to be devoted to purchasing requisite articles, gifts of clothing (which, if used, must be in good condition), and recent chemical literature, will be welcome. The Chemical Society will continue to act as the receiving depôt, and cheques (made payable to Mr. S. E. Carr, and crossed "Russian Fund"), together with parcels of clothing, boots, books, etc., should be addressed to the Assistant Secretary, The Chemical Society, Burlington House, Piccadilly, W. 1.

JAMES WALKER,
President.

CORRESPONDENCE

THE TRAINING OF THE CHEMICAL ENGINEER

Sir,—I have read with much interest the reports of Dr. Ruttan's address on the training of the chemical engineer (*cf.* J., 1922, 282 R, 323 R). I am, I believe, the only person in England at the present time who has taken the course of study, which he describes, at the Massachusetts Institute of Technology, so that perhaps my remarks may interest your readers.

I expected great things of the course when I entered upon it; but as the weeks passed, with industry after industry expounded to us, principle after principle elucidated, I was amazed at the value of it all. It could do no less than introduce the students to the seven industries embraced by it: actually, owing to the method of our study, *i.e.*, by "unit operations," it prepared us, not merely for those seven, but for *all* the industries in which chemistry is involved.

The course started just before the United States entered the war, and was broken off in the middle of its first session. After the war it was restarted, in a slightly modified form. In its first post-war year, some of the co-operating companies merely tolerated the students. When I took the course, in its second post-war year (1921), they received us with open arms, a sure sign that our presence was to their advantage as well as to ours.

I understand that English colleges teach chemical engineering by "providing the student with plant and demonstrating to him processes on a semi-large scale," which, Dr. Ruttan says, has not been successful (*loc. cit.* 282 R). Having experienced the other method, that of teaching by "unit operations," with factories as laboratory and classroom, I humbly and fervently commend that method to our English professors. A good general outline of the idea is given in two valuable articles by W. K. Lewis and R. T. Haslam (the guiding spirits of the course), in the *Journal of Industrial and Engineering Chemistry*, 1921, 13, 465, and 1922, 14, 647.—I am, Sir, etc.,

GEOFFREY J. GREENFIELD.

Langley Park Coke Works Co.,
Durham.
September 10, 1922.

PERSONALIA

Dr. L. Birkenbach, of Munich, has been appointed to succeed Prof. Wilke-Dörfurt in the chair of chemistry at the School of Mines (*Bergakademie*), Clausthal.

Mr. Charles Crowther, the new Principal of the Harper-Adams Agricultural College, Newport, Salop, was for many years lecturer and then for six years professor of agricultural chemistry in the University of Leeds.

Following the death of Prof. W. Wislicenus, Prof. Wieland of Freiburg i/B has assumed the editorship of *Liebigs Annalen der Chemie*. The publication committee consists of Professors A. Wallach, Groebe, Zincke, Willstätter and the editor.

Among those who received the degree of D.Sc. (*honoris causa*) of the University of Leeds, on the occasion of the meeting of the British Association in Hull, were Prof. Sir Charles Sherrington, the Duc de Broglie, Institut d'Optique, Paris, and Prof. P. Weiss, director of the Institut de Physique, Strasbourg.

Prof. R. T. Haslam has been appointed director of the research laboratory of applied chemistry in the Massachusetts Institute of Technology in succession to Mr. R. E. Wilson, who has joined the research staff of the Standard Oil Co., of Indiana. Dr. G. B. Waterhouse has been appointed to succeed Prof. H. O. Hofman as head of the department of metallurgy in the same institution.

Dr. R. C. Farmer has been invited to take up the position of Deputy Director of Explosives Research at the War Office Research Department, and will commence duty in October. Dr. Farmer was formerly Chemical Adviser to the Explosives Department under Lord Moulton, and was a member of the Nitrogen Products Committee and the Chemical Committee of the Munitions Inventions Department. Since the armistice he has been a director of Messrs. W. J. Bush and Co., Ltd., and is now resigning this position.

* * *

Prof. Alfred Getz, professor of mining in the Norwegian Technical High School, Trondhjem, died in August, aged 60 years.

We record with great regret the death, on September 12, of Dr. William Kellner, formerly Chemist to the War Department, and a member of this Society since 1885.

NEWS AND NOTES

FRANCE

Proposed Franco-German Potash Monopoly

The special correspondent of the *Observer* in Paris announces the failure of the negotiations that have recently been taking place between the French owners of the Alsatian potash mines and the German Potash Syndicate which were undertaken to re-establish the world-monopoly that existed before the war, when all the mines were in German territory. It is pointed out that the failure was almost inevitable owing to the enormous advantage that the low exchange-rate of the mark would confer on the German producers.

Industrial Notes

Chemical Industry.—The failure of the negotiations between the representatives of the Alsatian potash mines and those of the Potash Syndicate is apparently due to the fact that the German producers offered only a one-tenth share in the monopoly, on the ground that the German mines have a productive capacity twenty times that of the French. This offer is unacceptable to the French, who contend that they have considerably increased their output and secured important markets abroad. The German representatives naturally will not give way, as German potash is selling at 132·30 francs per metric ton f.o.r. at the mine, whereas the French price is 450 fr.

Investigations have recently been carried out on the production of alloys to withstand the high temperatures and pressures used in the Claude synthetic-ammonia process. It has been found that a steel of the following composition will resist the conditions mentioned for 4000 hours:—Ni 60, Mn 2, Cr 12, C 0·5, and Fe 25·5 per cent.

Metallurgy.—At present the metallurgical outlook is very good. The dissolution of the Comptoir des Fontes Hématites has again raised the question of the utility of such organisations. The general opinion is that they are useful if they confine themselves to regulating production and distribution, but harmful if they develop into trusts that attempt to control markets. It is also felt that "comptoirs" might extend their activities to the export trade, provided that in tendering for contracts they would act as promptly as individual firms, and that similar organisations exist abroad. Considerations of this kind suggest the need for an international agreement between the leading metallurgical countries and for more efficient co-ordination of their efforts to meet the world's requirements.

During the first seven months of 1922, 2,689,132 metric tons of pig iron and 2,413,170 t. of steel were produced in France.

Coal.—The state of the coal market continues good, and although the end of the coal strike in the United States will mean renewed competition from British coal, the approach of winter, the high exchange value of the pound sterling, and the greater industrial activity in France, are factors that strongly favour the French coal industry.

Saar coal, which contains about 33 per cent. of volatile matter, yields brittle coke unsuitable for metallurgical use, and the question of surmounting this difficulty has been receiving attention in order to make France less dependent on supplies from the Ruhr district. Experiments have shown that the brittleness of the coke can be overcome by coking the raw coal with coal that has been partly distilled in a special retort so as to reduce the content of volatile matter to 12 per cent. It is not intended to use this process at the mines, as this would mean costly additions to existing plants, but to explain it to the iron and steel manufacturers, who mostly produce their own coke. The successful application of this process would lead to extensive development of the Saar coalmines.

La Societe de Chimie Industrielle

This society held its Second Congress in Marseille during the first week of July. The attendance numbered about 400, and among the foreign guests were Dr. Emil Mond, Prof. W. A. Noyes, Prof. A. C. Langmuir, Dr. C. L. Parsons and Senator Paternò. Monsieur H. Giraud, president of the Marseille Chamber of Commerce, took the chair at the opening meeting, when addresses were delivered by M. Paul Kestner, president of the Society; M. A. Gardair, chairman of the organising committee; Prof. Cavalier; M. H. Giraud; and by M. Deschiens, who in reading the annual report mentioned some of the results of work done during the year. At the instance of the Society the exportation of radio-active minerals from Madagascar to foreign countries was prohibited; the Customs classification of fats was revised; the suggestion that coke ovens should be heated with producer gas instead of with town's gas was referred to the Central Committee of French Coalmines; and representations concerning the mobilisation of technical men in wartime were favourably received by the Minister of War. A striking address was delivered by Prof. C. Matignon on the present state of the German nitrogen industry (*cf.* *i.*), and M. Sabatier was presented with the Society's gold medal. Many papers were read before the fifteen technical groups into which the congress was divided, and visits were made to local works and to the exhibition of French colonial products.—(*Chim. et Ind., Aug.*, 1922.)

AUSTRALIA

The White-Lead Industry

The manufacture of white lead in Australia has made great progress, for, whereas practically the whole of the requirements was imported seven years ago, now production almost meets the demand. This advance is largely due to the establishment of a branch factory of Lewis Berger and Sons, Ltd., manufacturers of paint and varnish, in Rhodes, near Sidney, in 1916, and which now employs 350 workers. The Dutch process is used and the raw material is lead of 99·9 per cent. purity from Broken Hill. The capacity of the works is 9000 tons per annum.

NEW ZEALAND

Discovery of Franklinite

Great interest has been aroused by the discovery of franklinite, hitherto not known to occur in New Zealand, in the fiord country of Southland. The Government mineralogist has confirmed the identification of the mineral. Franklinite contains about 67 per cent. of iron oxide, 17 per cent. manganese dioxide and 16 per cent. of zinc oxide, and is named after the Franklin district of New Jersey, where it is mined and shipped to Pennsylvania for the production of zinc and spiegeleisen. Commercial utilisation is only possible if the ore is readily accessible and available in large quantity.—(*Ind. Austr., June* 8, 1922.)

UNITED STATES

Annual Prize of 25,000 Dollars

At a council meeting of the American Chemical Society, held during the Society's recent meeting in Pittsburgh, a letter was read from Dr. W. H. Nichols to Dr. Edgar F. Smith (president) offering on behalf of the Allied Chemical and Dye Corporation a prize of $25,000 to be awarded annually to the chemist residing in the United States who, in the opinion of a special jury appointed by the Society, has contributed most to the benefit of chemical science and the world. The scheme will come into effect on January 1, 1923.

"Journal of Physical Chemistry"

At the same meeting of the above-named council, it was resolved that the *Journal of Physical Chemistry* shall in future be published under the joint auspices of the American Chemical Society, the Chemical Society of London, and the Faraday Society. The arrangements were made on the occasion of a recent visit of Dr. C. L. Parsons to London. It has been agreed that the management of the journal shall be left entirely to a board of eight members, who will be nominated by the societies concerned, and who will elect the editor-in-chief and probably also a managing editor. Members of the board will be appointed for a term of two years, one-half will retire each year, and no member shall serve continuously for more than four years. The societies will incur no financial liability, and their members or Fellows will be offered the journal at a reduced subscription rate. Mr. Francis P. Garvan, president of the Chemical Foundation, has guaranteed the payment of $10,000 per annum for five years to assist the publication.

CANADA

Soapstone in Ontario

The Mines Branch of the Canadian Department of Mines has issued a preliminary account of a large deposit of a mineral resembling soapstone which occurs at Wabigoon, near Dryden, Ontario, and in close proximity to the Canadian Pacific Railway. This deposit, which is stated to be the most promising of its kind in Canada, consists of two well-defined bands of mineral, separated by 100 ft. of hard grit rock, and the smaller of the two has a proved length of 500 ft. and a width of 35 ft. The rock is dark greenish grey, soft, homogeneous, but not greasy to the touch. Its percentage composition has been found to vary within the following limits:—SiO_2 41·94—51·44; FeO 7·24—7·71; Fe_2O_3 2·05—3·68; Al_2O_3 4·79—7·57; MgO 25·39—26·43; CO_2 0·11—5·09; H_2O (above 105° C.) 6·56—6·71. Crushing strength ranges from 10·269 to 12·140 lb. per sq. in.; modulus of rupture from 1827 to 1920 lb. per sq. in.; fusion temperature 1400° C. It is suggested that the mineral might be suitable for making refractory bricks for the smelting furnaces of sulphate pulp (kraft) mills; at present, although the consumption is large, all the soapstone bricks required are imported from the United States. The stone might also be used for making baking-oven bricks, foot warmers, griddles, etc.

BRITISH INDIA

The Rubber Plantation Industry

In 1921 there were 1016 rubber plantations in British India which covered an area of 196,990 acres and produced 4043 tons of rubber, nearly all of which was of the Hevea kind. The chief producing areas are situated in Southern India, Burma, and Assam. In 1920 the production was 6156 t., and the decline in 1921 is ascribed to low prices and the Moplah rebellion. The exports by sea declined by 21 per cent. to 4917 t., of which the United Kingdom took 63, Ceylon 21, the United States 9, and the Straits Settlements 6 per cent. Imports of rubber were very small.—(*Ind. Tr. J., Aug.* 17, 1922.)

SOUTH AFRICA

The Whaling Industry in Natal, 1921

According to a report of the Durban Chamber of Commerce, the whaling industry of Natal is seriously affected by the prevailing financial depression, the price of whale oil having declined by 65·3 per cent. to £31 5s. per ton in August, 1921. Whale oil was in but small demand in Europe, although exports to the United States continued, and unless the cost of production can be considerably reduced many of the whaling companies may not resume operations. The 1071 whales captured during 1921 yielded 6255 tons of oil (£155,000), 2447 t. of fertilisers (£25,000), and 1045 t. of boiled bone (£8000).—(*U.S. Com. Rep., Aug.* 14, 1922.)

GERMANY

Hydrogenation of Oils in Presence of Oxygen

In the *Berichte* (1922, pp. 2193–97), Dr. W. Normann criticises the assertion that the presence of oxygen is essential in fat-hardening. His experiments with nickel cyanide, nickel chloride on kieselguhr, powdered nickel, and palladium chloride show that hydrogenation proceeds in the total absence of oxygen, and that the presence of even a few tenths of one per cent. of oxygen is distinctly harmful.

Ammonium Bicarbonate as Fertiliser

The production of ammonium sulphate for use as a fertiliser involves the consumption of large quantities of imported sulphuric acid. The cost of the acid makes the price of the fertiliser high; the acid itself possesses no fertilising value, but tends to increase the acidity of the soil. Ammonium bicarbonate is now recommended as an alternative nitrogenous fertiliser, the production of which only requires ammonia, water, and carbon dioxide, a cheap by-product. The cost of this product should thus be low compared with that of ammonium sulphate. Tests made at the Research and Control Station of the Oldenburg Board of Agriculture have given favourable results both on sandy and on acid moorland soils.

New Applications of Schoop's Metal-spraying Process

Strongly adherent, homogeneous coatings of lead, tin, zinc, aluminium, brass or copper can now be sprayed without the use of compressed oxygen, a small pointed flame of acetylene and compressed air being sufficient. Not only is the cost of transport and hire of cylinders obviated, but the process is more economical than the older one. For many years coatings of enamel, quartz or glass have been produced by Schoop's process and recently very hard, chemically resistant coatings of a mixture of metal and glass enamel or similar substances have been successfully obtained. Another new application of the process is in the production of coatings of "stainless" steel on metallic objects whereby they may be made non-rusting as well as hard; and further experiments are now in hand which, if successful, will result in the production of machine tools having an outer skin of hard alloy ("stainless" or tungsten steel) on a body of other suitable softer metal.—(*Chem.-Z., Sept.* 2, 1922.)

The Nitrogen-Products Industry in Germany

In a long article published in the July issue of *Chimie et Industrie*, Prof. C. Matignon discusses the present situation of the German nitrogen industry, in which over one milliard marks are invested. But for this industry, in 1921 Germany would have had to import 1,500,000 metric tons of Chilean nitrate, worth 27 milliards of paper marks; and although this quantity corresponds to an output of 230,000 t. of nitrogen, the total productive capacity of the German factories is far from being attained. By the end of 1922 the total capacity will be 500,000 t. of combined nitrogen, of which 300,000 t. will be produced by the Badische synthetic-ammonia factories, so that, assuming that the coke ovens and cyanamide factories work at only half capacity, the German output of fixed nitrogen will then be at least 400,000 t., *i.e.*, more than half the world's pre-war consumption of 692,000 t. In time, therefore, Germany will be able not only to meet the increasing needs of her own agriculture but also to export nitrogenous fertilisers, which, favoured by the low value of the mark, will compete easily with Chilean nitrate.

GENERAL

The Society's Annual Dinner in London

The Second Annual Dinner in London will be held in the Connaught Rooms, Great Queen Street, W.C., on Friday, October 13, at 7 for 7.30 p.m., and it is hoped that a large number of members and their friends will be present. Ladies may be invited, and the cost of tickets, obtainable from the General Secretary, is 10s. 6d. each, exclusive of wines.

The Society's General Council for Canada

The following constitute the General Council for Canada for the year 1922–23:—Chairman: Prof. R. F. Ruttan; representatives of the Local Sections: Toronto, M. L. Davies, L. E. Westman; Montreal, A. R. MacLean, H. W. Matheson; Ottawa, F. J. Hambly, A. E. McRae; Canadian Pacific, A. E. Archibald, J. A. Dawson; Shawinigan Falls, R. A. Witherspoon, F. E. Dickie. The Secretary is Mr. Alfred Burton, whose address is 114, Bedford Road, Toronto, Ont., Canada.

Generation and Utilisation of Cold

This subject will be discussed at a joint meeting of the Faraday Society and the British Cold Storage and Ice Association on Monday, October 16, in the Institution of Electrical Engineers, Victoria Embankment, W.C. 2. The Council of the Faraday Society has extended a special invitation to members of the London Section of the Society of Chemical Industry to attend the meeting, the detailed programme of which is given elsewhere in this issue.

Proposed Institute of Paint and Varnish Technologists

It is intended to inaugurate a society bearing this title and with aims similar to those of the sister society in the United States. The functions of the proposed Institute will be to disseminate practical and scientific knowledge by reading and discussing papers to be published in a journal, to improve technical education, to form a technical library, to maintain close contact with Government departments, public and other bodies interested in the products and problems of the industry, and to promote research. Support has already been promised by a number of scientific and technical workers in this field, and members of allied organisations are invited to become members. Those who desire to attend the inaugural dinner, to be held shortly in London, or to assist in forming the Institute are asked to communicate with Mr. H. D. Bradford, 42, Ribblesdale Road, London, S.W. 16.

An International Scientific Congress in Utrecht

Under this title the *Chemiker-Zeitung* (Aug. 26, 1922) describes a meeting, held on June 21—23, of chemists hailing from England (3), United States (3), Austria (8), Germany (9), Holland (8), Denmark (4), Czechoslovakia (2), Latvia (1), Switzerland (1) and Russia (1). According to *Science* (Sept. 6, 1922), the meeting was planned not only to promote the interests of chemistry but to renew old friendships and form new ones between men and nations recently at war. Fourteen short papers on chemical topics were read and of these a paper on "Free Radicals," by Prof. P. Walden, was of especial interest. The social functions included a reception by the Dutch Chemical Society, at which an address was given by Prof. Wendt, president of the Royal Academy of Sciences, and replied to by Prof. W. A. Noyes (U.S.A.). The idea of holding the meeting was conceived by Prof. F. G. Donnan and Prof. Ernst Cohen (Utrecht); the organisation was in the hands of the last-named and two Dutch colleagues and the guests were very hospitably entertained. It is suggested that the time is now ripe for greater international co-operation among men of science.

Medicinal Plants in the Malay Peninsula

In a work on the "Minor Forest Products of the Malay Peninsula," published by permission of the Federated Malay States Government, Dr. F. W. Foxworthy, Forest Research Officer, gives lists of poisonous and medicinal plants. Large numbers of the local plants, he states, are used in native medicine, but only a few are recognised in European pharmacy. Some of the species included in the list of poisonous plants are also of medicinal value.

The list of the principal plants used locally for medicinal purposes contains no less than 343 names, and is taken mainly from an official bulletin entitled "Malay Drugs" published by Mr. H. N. Ridley in 1906. The table gives the family to which each plant belongs, the botanical name, the common name (usually the name given by the Malays), the part used, and the diseases, etc. for which the extract from the plant is used. Occasionally some plant acquires prominence because of fraudulent claims as to its curative properties. This seems to have been the case some years ago with *Combretum sundaicum*, Miq., which was asserted to be a cure for the opium habit. A careful examination of the plant failed to reveal any just grounds for this claim.

Among the native plants of actual or potential use are the following:—

Brucea sumatrana, Roxb. (Fam. *Simarubaceæ*).—Kosum is well known as a plant useful in the treatment of certain types of dysentery.

Taraktogenos Kurzii, King (Fam. *Flacourticeæ*).—The seeds yield Chaulmoogra oil, which is so useful for treating leprosy. This species has not yet been found in the Peninsula, but occurs in Siam and Burma. The Malay species of *Taraktogenos* and of the related genus *Hydnocarpus* are worth investigating to see if they can be used in the same way.

Strychnos spp.—Several species are found as climbers, although none is so valuable as *Strychnos Nux-vomica*; but two of them, *S. ovalfolia*, Wall., and *S. quadrangularis*, A. W. Hill, are used as constituents of a Sakia dart poison. Fourteen species of this genus are recorded from the Peninsula.

Strophanthus spp.—These are coarse shrubs or climbers, some of which may contain strophanthin or an allied glucoside; apparently they are not used at present.

Dr. Foxworthy's publication also contains references to tanning materials, oleo resins and wood oils, fruit or seed oils, essential oils, and dye plants and dye woods. It is the second part of a work dealing with the forest products of British Malaya, the first having been devoted to trees and timbers.

Water-Hyacinth Ash as a Source of Potash

In many tropical regions the water-hyacinth (*Eichornia crassipes*) is a troublesome weed, and as removal is often necessary it has been suggested that the plants might be burned and the ashes used as a source of potash or as a fertiliser. Previous analyses of ash from India and Burma have shown the following variations in percentage composition:—K_2O 11·3—34·1; CaO 7·8—12·8; Cl 5·7—21·0; SiO_2 20·7—49·4; P_2O_5 1·4—8·2. Thus the potash content varies greatly. A sample of ash prepared in Burma was examined at the Imperial Institute and found to contain much extraneous mineral matter. About 11 per cent. of the crude ash was soluble in water, and the chief constituents of value, calculated as percentages of the original ash, were as follows:—Soluble portion: KCl 7·54; NaCl 0·51; Na_2SO_4 1·56; insoluble portion: K_2O 1·51; $MgCO_3$ 4·16; $Ca_3(PO_4)_2$ 8·20. Ash similar to this sample would be suitable for local use as a potash fertiliser, the small content of phosphoric acid adding slightly to its manurial value. About 75 per cent. of the water-soluble matter consisted of potassium chloride, but extraction, though probably easy, would hardly pay, as 14 tons of ash yield only 1 ton of 80 per cent. KCl.—(*Imp. Inst. Bull.*, XIX, 4.)

Amalgamation of Tartaric-Acid Manufacturers in Italy

With the co-operation of the Banco di Credito, the three chief producers of tartaric acid in Italy, viz., the Società Anonima Appula, of Bari, the Società Industria Acido Tartarico, of Milan and Casale Monferrato, and the Società Italiana dei Derivati della Cellulosa, of Milan, have amalgamated to form a new company with a capital of 25 million lire.—(*Chem. Ind., Aug.* 21, 1922.)

Belgian Trade in Artificial Silk

The production of artificial silk in Belgium averaged 2700 metric tons per annum before the war, one-half of the output being exported to Germany, which was the source of many of the raw materials and chemicals required, and only 5 per cent. consumed in the country. In recent years the exports have gone largely to the United Kingdom and Switzerland, as will be seen from the following figures of imports and exports of artificial silk and waste-silk yarn in 1920 and 1921:—

	Imports		Exports	
	1920.	1921	1920.	1921
	Metric tons		Metric tons	
Germany	0·3	1·1	9·0	1·3
Spain	—	—	1·5	0·6
France	2·9	1·4	—	1·9
United Kingdom	1·4	1·1	7·8	29·4
Switzerland	1·4	1·0	5·3	111·5
Other countries	0·05	0·001	4·7	9·0
Totals	6·02	4·7	28·4	152·7

The demand from Spain, Portugal, Switzerland and Japan is stated to be brisk, and some large orders have been received from the United States. Competition is feared from Japan, as that country can export articles manufactured from imported artificial silk at prices 40 to 50 per cent. less than those of other countries. One Belgian firm is contemplating the establishment of a factory in Japan on account of the cheapness of Japanese labour, and another company is to build a factory in France for manufacturing acetylcellulose silk under a contract made with a British cellulose company and covering Belgium, France, England and Poland.—(*U.S. Com. Rep., July* 3, 1922.)

The Italian Beet-Sugar Industry

The area planted to sugar-beet in Italy during the spring shows a large increase as compared with the area planted last year, and this increase, together with the proposals to remove restrictions on trading in sugar and the reduction in the customs tariff on sugar, provides evidence that production now covers home requirements. Details of the area planted to sugar-beet, crop returns, and sugar output since 1913–14 are set out below:—

Season	Area planted	Yield of beets	Output of sugar
	Acres	Metric tons	
1913–14	203,402	2,749,907	305,564
1914–15	96,051	1,319,140	150,216
1915–16	127,761	1,457,571	150,396
1916–17	108,994	1,313,690	144,870
1917–18	111,504	883,038	92,624
1918–19	104,525	1,117,743	108,431
1919–20	145,075	1,800,917	167,767
1920–21	126,163	1,267,815	124,392
1921–22	180,310	1,685,000	217,532

No great extension of sugar-beet cultivation is possible in Italy, as the area of suitable land is limited and economic factors favour the production of cereals. Imports during the last six years have averaged 60,000 t. per annum (97,000 t. in 1921) and judging from the export in 1913–14, when 35,000 t. was exported out of a production of 305,000 t., from the present large population and the increased consumption, it seems unlikely that Italy will attain importance in the export trade in sugar for some time.—(*U.S. Com. Rep., June* 19, 1922.)

Consumption of Fertilisers in Italy

During the war the consumption of fertilisers in Italy declined greatly, but improved after the armistice, as will be seen from the following figures, showing the consumption in pre-war years, in 1919, and in 1921:—

	Annual average 1909–1913 Metric tons	1919 Metric tons	1921 Metric tons
Superphosphate	978,000	600,000	850,000†
Basic slag	118,000	2,600	2,600†
Potash fertilisers	13,690	*nil*	1,405†
Sodium nitrate	45,250	18,000	32,000
Ammonium sulphate	29,783	13,700	22,000
Calcium cyanamide	8,583	20,000	16,000
Calcium nitrate	710*	*nil*	2,500†

* 1913 only. † 1920 only.

The consumption of ammonium nitrate rose from 2000 t. in 1919 to 14,000 in 1920.—(*U.S. Com. Rep., Aug.* 14, 1922.)

The Java Sugar Crop in 1922

The production of sugar in Java during the current season is estimated at 1,712,500 tons (932,500 t. white and 780,000 t. brown sugar), which compares with the realised production of 1,627,000 t. (900,000 t. white and 780,000 t. brown sugar) in the previous season. From this season's crop 434,500 t. of white sugar and 345,000 t. of brown were delivered during the four months April to July, 1922.—(*Ind. Tr. J., Aug.* 24, 1922.)

Beet-Sugar Industry in Rumania

Prior to the war the nine beet-sugar factories in Rumania had an average production of 70,000 metric tons per annum, but in 1921 their output fell to 29,000 t., on account of the state of the factories and the reduced area under beet. It is estimated that, if transport facilities and fuel can be provided, the sugar-beet crop for 1922-23 will amount to 45,000 t. Producers state that the present market price in Rumania does not cover the cost of production.—(*U.S. Com. Rep., Aug.* 14, 1922.)

The Petroleum Industry in Trinidad

During the past year this industry has been very active. There was a considerable increase in the footage drilled by the various companies, and a consequent large increase in production of crude oil; in fact, production in 1921 was the greatest in the history of the Colony—viz., 82,395,595 gallons, as compared with 72,905,947 galls. in 1920 and 64,436,632 galls. in 1919. The number of new wells drilled was 84, an increase of 17 over the previous year. In 42 of these wells oil was struck. At the close of the year 1921 twenty companies were actively engaged in the winning of oil, as against 22 at the end of 1920. The Admiralty continues to purchase considerable quantities of oil fuel; both crude oil and refined products are shipped to private firms in the United Kingdom and there is a considerable trade with the other West Indian islands.

Coca Production in Java

The cultivation of coca was introduced into Java in 1880 and the crop is now grown on 63 estates over an area of 6000 acres, usually interplanted with coffee, rubber and cacao. The first leaves may be gathered when the plants are 8 months old and mature shrubs yield 700 to 850 lb. of leaves per acre. Javanese coca has approximately the same content of alkaloid as the Peruvian product, but the basic alkaloid of the former is cinnamylcocaine, whereas that of the latter is cocaine. The export in 1920 totalled 3,755,400 lb., of which the bulk was shipped to Amsterdam, 649,000 lb. going to Japan and 24,000 lb. to the United States.—(*U.S. Com. Rep., May* 22, 1922.)

Manufacture of Chlorate in Norway

Work was resumed at the Vadheim chlorate factory in Norway a few weeks ago and it is anticipated that the output will be from 600 to 800 metric tons of chlorate per annum. It is also intended to produce metallic sodium.—(*Chem. Ind., Aug.* 28, 1922.)

Pine-Tar, Resin and Turpentine in Portugal

The Portuguese output of resin is estimated at 4000 metric tons per annum and of this 750 t. is consumed in the country, mainly for making paper (250 t.), printing-ink (100 t.), varnish, colours, etc. (50 t.), dyes (250 t.), pharmaceutical and other products (100 t.). Turpentine of good quality is produced in large amounts. The production of pine-tar and turpentine since 1916 has been as follows:—

	Tar Metric tons	Turpentine Metric tons
1916–1917	3,000	950
1917–1918	4,000	4,200
1918–1919	6,000	2,000
1919–1920	6,300	1,800
1920–1921	12,400	3,600

During the 1919–20 season the production of resin was 9000 t., which yielded 6300 t. of tar and 1800 t. of turpentine.

Esparto Cellulose in Spain

A large factory is being erected in Benalua de Guadix, Granada, at a cost of 9 million pesetas, to manufacture esparto paper and powder. Power will be obtained from the River Dilar by means of hydro-electric generators developing 4400 h.-p. It is hoped that the entire production of esparto grass in Spain will be utilised shortly in the country and not exported, as it has been, largely to England, in which case the importation of cotton for manufacturing powder would be unnecessary.—(*Raw Materials Rev., July*, 1922.)

LEGAL INTELLIGENCE

Nuisance Committed by Smell from a Fertiliser Factory. *The Attorney General* v. *The Elstree Chemical Works* (1922), *Ltd.*

In the Vacation Court on August 30, Mr. Justice Swift heard a motion by the Attorney General at the relation of the Barnet Rural District Council for an injunction to restrain, until trial of the action, the Elstree Chemical Works (1922), Ltd. from committing a nuisance by emitting smells.

For the relators it was stated that the defendant company manufactured fertilisers from leather, wool and felt waste at a works in Elstree, and that this manufacture gave rise to a strong odour which caused a public nuisance. On behalf of the defendant company, the nuisance was not denied, but a request was made for time in which to abate it, as the business had only been carried on by the company since March and several attempts had been made to avoid producing the smell.

The injunction was granted, but its operation was suspended for one month to enable the defendant company to abate the nuisance. The parties then agreed to treat the motion as the trial of the action, the injunction being made perpetual, subject to the suspension for a month, and the defendant company agreeing to pay the costs.

OFFICIAL TRADE INTELLIGENCE

(From the Board of Trade Journal for September 14 *and* 21)

OPENINGS FOR BRITISH TRADE

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence), 35, Old Queen Street, London, S.W. 1, from firms, agents or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number.

Locality of Firm or Agent	Materials	Reference Number
Australia	Sheets and rods of ebonite and brass (tender for) ..	†
"	Sheet steel	290
Brazil	Cement, earthenware piping	6657/F.L./ E.C.
"	Steel	317
British India ..	Cement (tender for)	**
British West Indies, British Guiana ..	Galvanised goods, iron and steel, copper, fireclay goods	264
Canada	Chinaware	*
Egypt	Oil, paint, varnish, soap, lamp glasses (tender for) ..	9008/F.E./ G.P.
Finland	Iron, steel, copper, brass, tin, lead, zinc	6122/F.R./ E.C.
France and Belgium	Calcined magnesite, white spirit, manganese dioxide, ammonium chloride, acetone, carbon tetrachloride, yacca gum ..	301
Italy	Tinplate	270
"	Chemicals, colours, varnish, soap, perfumery, vegetable oils	302
Kenya Colony ..	Glass, glassware, pottery ..	225/25/T.G./ M.C.
Mexico	Semi-porcelain	319
Netherlands ..	Lubricating oils	272

TARIFF CUSTOMS EXCISE

Australia.—The text of a Memorandum explaining the provisions of the Customs Tariff (Industries Preservation) Act, 1921, designed to prevent "dumping," is reprinted in the issue for September 14.

France.—The import duty on ammonium sulphate has been suspended.

French Togoland.—The importation and sale are prohibited of "trade" spirits and harmful essences and chemicals such as star-anise oil, benzaldehyde, salicylic ether, hyssop, and absinth, but not of pharmaceutical alcohol for medical or scientific use.

Germany.—New monopoly taxes have been applied to imported spirits, ether and its products. An Act has been passed authorising the German Government to increase the import duties or impose new import duties if the economic necessity arises, and to reduce or withdraw duties that have been increased or imposed under the new law.

Gold Coast.—The export duty on cocoa has been reduced from ½d. to ¼d. per lb.

Hungary.—Special permits are required for imports of oleic and stearic acids, dégras, pitch, resin, cement, coal-tar oils, indiarubber, certain wares of glass and enamel, zinc white, zinc gray, sal-ammoniac, liquid ammonia, sodium sulphate, sodium carbonate, and certain colours. Phosphates no longer require an import licence.

Lithuania.—A translation of the new export tariff may be consulted at the Department of Overseas Trade.

Malta.—Opium and certain other drugs may not be imported from the United Kingdom unless for legitimate scientific and medical purposes.

Palestine.—Import duties at the rate of 4 per cent. *ad valorem* have been imposed on timber, constructional iron and steel, ordinary window glass, hollow bricks, Portland, Roman, Keene's and similar cement, asbestos sheeting, but not on plaster of Paris and patent plasters having a lime basis. Samples of patent medicines may be imported free of duty.

Papua.—The duty on exports of copra has been reduced from 25s. to 15s. per ton.

Portugal.—The import duty on newsprint paper has been reduced to 0·1 milavo per kg. A law has been passed authorising the introduction of a new customs tariff comprising "maximum" and "minimum" rates.

Solomon Islands.—Revised schedules of import duties and free goods may be consulted at the Department.

South Africa.—Ferrosilicon rods are duty-free under the British preferential tariff, but pay a duty of 3 per cent. *ad. valorem* under the general tariff.

Sweden.—An import duty of 1·50 öre per kg. has been applied to imported soft rubber tyres and outer covers.

United States.—A copy of the Tariff Revision Bill as passed by the Senate may be consulted at the Department.

Venezuela.—Salts of potassium and sodium, but not potassium or sodium hydroxides, have been placed on the duty-free list. The import duty on paper has been increased.

Yugoslavia.—The monopoly tax on petroleum has been increased to 400 dinars per 100 kg.

Appointment of Committee on Safety in Mines.—The following have been appointed to serve on a committee, under the direction of the Safety in Mines Research Board, to investigate the causes of, and the means of preventing, the ignition of firedamp and coal dust arising from the firing of permitted explosives:—Col. Sir F. Nathan (chairman), Mr. W. Rintoul, Dr. G. Rotter, Mr. H. Walker, and Prof. R. V. Wheeler.

REPORTS

FIFTH REPORT OF THE COMMITTEE APPOINTED FOR THE INVESTIGATION OF FUEL ECONOMY, THE UTILISATION OF COAL, AND SMOKE PREVENTION. *Pp.* 17. *London: The British Association for the Advancement of Science*, 1922.

Since the publication of the last report the fuel situation has been dominated by the effects of the coal crisis of 1921, and this is illustrated by reference to the present position of the iron and steel industry which, better than any other, reflects the effects of coal prices upon production. The production of pig iron in the United Kingdom fell from 8,034,700 tons in 1920 to 2,611,400 in 1921, and that of steel from 9,067,300 t. in 1920 to 3,625,800 t. in 1921. It is particularly unsatisfactory from a fuel-economy standpoint that the present prices of coking coals and of coke offer little inducement to iron- and steel-makers to start up the coke ovens attached to their own works.

Oil Fuel Supplies.—Statistics relative to the importation of petroleum products into this country during the past five years are collected, and it is shown that whilst the home production of shale oil is very small, increasing quantities of fuel oil are being imported almost entirely from countries outside the Empire. The possible production of benzol in the gas and coking industries is relatively small, and owing to the low present cash value of benzol as a heating agent in coal gas it does not pay to extract it for use as a motor spirit. The development of a satisfactory low-temperature carbonisation process is therefore greatly to be desired. Although it is still problematical whether it would be more profitable to carbonise coal at 600° C. or at slightly higher temperatures, large-scale trials have shown that at 600° C. suitable coals will yield 7·5 per cent. of tar and 2·5 galls. of motor spirit, together with 3500 cb. ft. of rich gas per ton of coal (*cf.* Fuel Research Board Report, J., 1922, 270 R). The future of this industry depends upon the suitability of the solid residue for domestic use, and from this point of view the recent suggestions of Sutcliffe and Evans (*cf.* J., 1922, 196 T) deserve further investigation both from the technical and commercial standpoints.

During recent years there has been marked progress in the design of burners for fuel oil; the consumption of air or steam by the burners has been reduced and heavy oils can now be sprayed into furnaces under pressure alone. Research is also being directed towards rendering internal-combustion engines capable of burning even the heaviest oils. The outstanding question to-day is how to adapt heavy fuel oil for use in low-compression internal-combustion engines, so that it may replace motor spirit.

The Chemistry of Coal.—The problem of the constitution of coal continues to attract the attention of investigators notwithstanding its magnitude and complexity. The absence of a recognised nomenclature for the various coal fractions is leading to confusion, and it is felt that the time has come when chemists should agree upon this matter in conference.

Attention is drawn to the economic importance of the brown coal deposits at Morwell in Australia, and to the possibility of concentrating such fuels by a preliminary heat treatment (*cf.* Bone, J., 1921, 499 A).

Domestic Heating and Cooking Appliances.—The radiant efficiency of a modern gas fire is about 50 per cent., based on the *net* calorific value of the gas. It has been proved at South Kensington that, within wide limits, this efficiency is independent of the chemical composition and calorific value of the gas burnt, provided that the rate of heat development by combustion is kept suitably constant for a given size of fire. The recent work of Fishenden (*cf.* J., 1922, 13 R) and of Barker on the efficiency of domestic appliances is reviewed, and it is recommended that the design of types of domestic appliances using solid fuel should be reconsidered with a view to determining whether greater fuel economy can be secured without sacrifice of convenience or unreasonable increase in capital expenditure. In existing kitchen-ranges a large excess of air is passed up the flue and means should be taken to reduce this by enclosing the fire except when it is required for kitchen heating. Other improvements which should be considered are the lagging of the oven door and the provision of a separately fired boiler for the hot-water supply. In an appendix to the report Mr. A. H. Barker describes methods of determining the thermal efficiency of cooking appliances.

Steam Raising.—With a view to improving boiler practice throughout the country the attention of manufacturers and of public education authorities is called to the need for better supervision and education of boiler-house staffs. Fuel economy would also be promoted if more detailed financial and technical data relative to the production of electric power were published by the Electricity Commissioners.

Smoke Abatement.—It is concluded that abatement of atmospheric pollution would be best secured by the institution by the Ministry of Health of a national Smoke Inspectorate on similar lines to the existing Alkali Inspectorate, which has admittedly worked with beneficial results to the industry concerned (*cf.* Report of Departmental Committee of the Ministry of Health, J., 1922, 1 R).

REPORT ON THE INDUSTRIAL, COMMERCIAL AND ECONOMIC SITUATION OF POLAND, DATED FEBRUARY, 1922. *By* R. E. KIMENS, *H.M. Commercial Secretary, Warsaw. Department of Overseas Trade. Pp.* 48. *H.M. Stationery Office*, 1922. *Price* 1s. 3*d*.

During 1921 internal trade in Poland was decontrolled, export restrictions were reduced, protective tariffs were introduced, and measures were passed for developing agriculture. Poland has acquired extensive forest areas under the Riga Treaty, and has obtained rich mining, metallurgical, engineering, and chemical industries by the incorporation of Upper Silesia that should eventually enable the country to rank among the chief industrial States of Europe. Although agriculture has not yet fully recovered, production is increasing, and given good harvests, machinery and imported fertilisers, a large quantity of produce will be available for export in future.

The output of coal during the first eleven months of 1921 was 6,865,289 t., or 7·2 per cent. more than the total output in 1920; imports from Upper Silesia were 1,931,300 t., so that in future there will probably be a surplus for export. There were no changes in the lead, copper, potash and sulphur industries, but deposits of pyrites containing 34 to 38 per cent. sulphur are being mined. Although statistics for the whole year are not available, it is probable that the output of iron ore, salt, and zinc has increased. Owing to Government control and high prices there has been no development in the petroleum industry, but the export of crude and refined products increased; about 53 per cent. of the capital invested in the industry is French and 14 per cent. British.

Many industries are gradually becoming self-supporting, and this may in time greatly affect the foreign trade. During the year the textile industry made a great recovery, about 75 per cent. of the plant being in working order at the end of 1921. In the metallurgical industry the output was only 20 per cent. of the pre-war production owing to lack of capital, shortage of fuel and food, and transport difficulties. All the coke required has to be imported from Teschen, as Upper Silesian coke is too poor to be used in blast furnaces. The production of pig iron was about 130,000 tons and of iron products 250,000 t.

Satisfactory progress was made by the chemical industry and production increased generally. Importation of heavy chemicals is decreasing and will be further reduced when Upper Silesia is incorporated. Foreign competition in pharmaceutical chemicals and dyes will be more difficult in future, as dye manufacture is progressing, and supplies of intermediates will be available in Upper Silesia; in certain branches local dyes competed successfully with British and German products. Nitric acid is made in two factories, the demand for hydrochloric acid is met by local production, and the output of sulphuric acid increased, although certain quantites were imported from Upper Silesia for making superphosphates. Reliable statistics for the chemical industry are not available at present, but are being compiled by certain branches of the industry. Sufficient soap is produced to supply the home market; there was no export in 1921 and importation is impossible owing to the low price of the local product. The glue and bone industry did well and attempts are being to export glue to Great Britain. Conditions in the tanning industry improved until October, but afterwards declined and stocks accumulated; a certain quantity of leather was imported from Great Britain, but this trade will probably not increase as the demand, except for high-class leathers, is more than met by local production. There is a good market for dry quebracho extract, the only tanning extract now imported. Trade depression affected the cement, ceramic, tile and brick factories. The glass industry is developing, although the quality of the products is usually very poor. Little advance was made by the starch industry, the output being still only 12·3 per cent. of the pre-war amount. The production of alcohol was slightly in excess of requirements and the sugar crop increased; it is probable that both sugar and alcohol will take an important place in the export trade in future.

The export trade during the first half of 1921 was over four times larger in volume than in the same period of 1920, mainly on account of increased exports of timber and petroleum. No official statistics of value are published, but it is believed that during the first half of 1921 the value of the exports was about 10·5 per cent. of the value of the imports. The volume of exports to Great Britain increased by nearly 500 per cent. during the first half of 1921, compared with the same period in 1920, but the volume of imports from Great Britain has remained stationary since the beginning of 1920. The superior quality of British goods makes them popular in Poland, and they would be preferred if prices were lower and terms of payment more favourable.

REPORT ON THE ECONOMIC SITUATION OF DENMARK, TO MARCH, 1922. *By* R. M. TURNER, *H.M. Commercial Secretary, Copenhagen. Department of Overseas Trade. Pp.* 52. *H.M. Stationery Office*, 1922. *Price* 1*s*. 6*d*.

Although depression and unemployment were the outstanding features of the industrial situation in Denmark during 1921, agriculture was generally prosperous, except in the latter months of the year, when prices fell.

Nearly all the factories which were erected when prices of material and labour were high have disappeared or been absorbed in older establishments. The margarine industry, comprising 65 factories and employing 800 men and 250 women, probably suffered less than most. The output in 1920 was approximately normal at about 55,000 tons, but prices fell steadily, and exportation was small. Serious losses on stocks were incurred by the oil-crushing industry, and exports diminished, only 4700 t. of coconut oil and 5900 t. of soya oil being exported, compared with 9700 t. and 11,600 t. respectively in 1920. Vegetable oils were shipped to France and the Mediterranean, but exports to Germany decreased. Production of milk and cream was unprofitable, and both the conserving and the potato-flour industries suffered severely.

The sugar-beet harvest was not very satisfactory in 1921, and the 1920 crop yielded only 52,740 metric tons of sugar compared with 152,252 t. in 1914. Most branches of the metal industry were run at a loss, and the leather industry, which was built up during the war, had a most disastrous year largely owing to the failure of the export trade. Brick-making suffered from German competition, but the cement industry has begun to regain its former position, thanks to increased exports to South America (125,700 t. against 37,000 t. in 1920). The porcelain industry was fairly well employed, and the manufacture of technical porcelain, particularly for electrical materials, appears to be maintaining its position in the home market. Manufacturers of fertilisers suffered great losses owing to the fall in value of stocks, and other branches of the chemical industry were affected by the general depression and by acute competition from Germany.

The value of the export of chemical products fell from £397,196 in 1920 to £292,056 in 1921. The yeast and spirit industry is well organised under a single group; in 1920, 3900 t. of yeast and 3·4 mill. litres (nearly 900,000 galls.) of 100 per cent. spirit was produced. Paper manufacturers were badly hit by large importations from Germany and Finland.

Imports during 1921 were valued at £71,682,243, exports at £64,626,168, and the adverse trade balance was reduced from £63,084,112 (1920) to £7,056,075, largely owing to the decreased volume and value of the imports and an increase in the volume of many exports. The values, in Danish money, of some of the chief imports and exports (Danish produce) are given below (21·4 kroner = £1)

	Imports		Exports
	1000		kr.
Tallow, oil, rubber, resin, tar, etc ..	83,415	..	23,629
Goods of rubber, tallow, oil, etc. ..	17,240	..	1,562
Paper and articles thereof	25,179	..	1,236
Chemical, technical articles ..	20,194	..	6,250
Fertilisers	60,482	..	2,610
Mineral fuels	145,827	..	4
Minerals, raw or roughly worked ..	16,893	..	13,338
Goods of clay, stone and glass ..	29,104	..	2,990
Wrought iron and iron goods ..	118,118	..	10,781

The value of imports of fertilisers increased by 23 million kr. to 60 mill. kr., the chief items and the respective decreases or increases (shown in parentheses) being:—Phosphate, raw, 23,104 tons (−81,253 t.); superphosphate, 52,500 t. (−3000 t.); Norwegian saltpetre, 49,200 t. (−13,000 t.); Chile saltpetre, 55,600 t. (−12,300 t.); basic slag, 445 t. (−3400 t.); potash fertilisers, 14,200 t. (+9600 t.). During a large part of the year British firms found it impossible to meet German, and difficult to meet Belgian and Czechoslovak competition. The Danish Export Association has been reorganised, and its functions have been transferred to a great extent to the Trade Information Bureau belonging to the Ministry for Foreign Affairs.

TRADE NOTES

BRITISH

Annual Report on the Uganda Protectorate

This report, covering the period April 1 to December 31, 1920, states that the general improvement which was a feature of the year 1919–20 (*cf.* J., 1921, 396 B) was not maintained. The area under, and export of, cotton rose to 207,100 acres and 8517 tons, respectively, but only 1284 t. of coffee was exported, and cacao-planting has been practically abandoned. Cultivation of para rubber is increasing in spite of low prices; the output for the ten months was 140 t., valued at £23,767. The acreage under sugar-cane is extending, and experiments on the value of different varieties of cane and on the manufacture of "jaggree" are in progress. Flax has been grown experimentally, but it seems unlikely that the crop will give rise to an export trade. The use of elephant grass and papyrus for manufacturing paper and power alcohol is being investigated in England. A first consignment of timber was shipped in 1920 and a regular supply can now be obtained. The total value of domestic produce exported during the period covered by the report was £4,134,136, the increase of 125 per cent. over the value for the previous twelve months being due to the high price of cotton.—(*Col. Rep.-Ann.*, *No.* 112, 1922.)

FOREIGN

The Fertiliser Industry in France

There is a good demand for phosphatic fertilisers and several superphosphate factories have already sold most of their output, mainly to home agricultural syndicates and traders. Anticipating a rise in prices, farmers are attempting to cover their requirements for the approaching season, but buyers in southern France are at present holding back. Supplies of bone meal are still short as the demand far exceeds the supply. The demand for slag is strong and stocks are low; it is hoped that the steel-works will soon be able to supply it in large quantities and thus enable exportation to be resumed. Stocks of ammonium sulphate are exhausted and Great Britain is now the only source of importation.—(*Chem. Ind.*, *Aug.* 28, 1922.)

REVIEWS

Werkstoffe: Handwörterbuch der Technischen Waren und ihrer Bestandteile. *Unter mitwirkung Zahlreicher Fachwissenschaftlicher Mitarbeiter. Herausgegeben von* Prof. Dr. Paul Krais, *Erster Band A bis F. Zweiter Band G bis R. Dritter Band S bis Z. Leipzig: Johann Ambrosius Barth,* 1921. *Price,* £3 16*s.*

This compendious work owes its origin to Dr. Zschimmer, a former director of the well-known glass works of Schott and Co., in Jena, who had conceived the idea of bringing out a "Lexicon of Technical Materials." For some reason which does not appear, Dr. Zschimmer was unable to carry out this project, and on the advice of Prof. Dr. B. Rassow, the publisher entrusted its compilation to Dr. Paul Krais, of Dresden, who, with Dr. Groscheiff, is responsible for the plan of the work. In view of the wealth of material to be dealt with it was obviously desirable to form a clear definition of what was to be understood by the term "Werkstoff," and, for the purpose of the dictionary, this was defined to include "all natural or prepared technical substances constituting the material or material portion of a wholesale ware, no matter whether it is artificially produced or not." Edible, potable and medicinal substances were explicitly excluded, as were plants and animals, fertilisers and feeding stuffs, cosmetics and furniture, clothes and leather work, as well as jewellery and articles of virtu. Having regard to the nature of the work some objection may be taken to certain of the limitations, but it was absolutely necessary that a line should be drawn somewhere, and the projectors of the undertaking must be held to be the best judges where to draw it.

It might be supposed that a work of so comprehensive a nature had no special attractions for the chemist. Such a surmise is very far from the truth. It is significant of the mode in which chemistry and chemical facts enter into the nature, application and use of the most widely varied substances that the book resolves itself practically into a chemical dictionary with so much of chemical physics added as may be thought necessary to complete the account of the particular substance described. The method of treatment may be gleaned from the following highly condensed account of the scheme prepared by the editor and Dr. Groscheiff. Name of the substance in German: its etymology; its French and English equivalent; its chemical nature; its morphology; its thermal properties; its density; its mechanical-technical properties; its optical properties; its electrical and magnetical properties; its radio-active properties; its behaviour towards Röntgen and cathode rays; its acoustical properties; its chemical behaviour; its physiological action; its valuation by physical, chemical and technical proofs; its technological relations; its commercial applications, mode and extent of production, method of distribution and price, with information as to where it can be obtained in Germany.

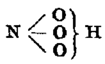
The book, as stated in the preface, is not a dictionary of technology in the usual sense. It enters into no details of manufacture, although here and there bibliographical references are made, usually to German sources, where such details may be found. As regards prices the data given are invariably prior to 1914; they seem of little value, either immediately or prospectively, and have at most a merely historical interest. The same is true of the statistics of production, which are only of relative importance.

The work, like so many similar undertakings, has suffered to a great extent by the war. Its publication has been much delayed, and much of its subject-matter is already out of date. It is, however, a useful production, and contains, in concise form, a wealth of information, although certain of e data are not very recent or the most authoritave. As is usual in German publications of this ind there is a tendency to restrict the information German sources, to the exclusion of foreign ork, even when this is more recent and more curate.

T. E. Thorpe.

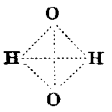
NORGANISCHE Chemie. *Ein Lehrbuch zum Weiterstudium und zum Handgebrauch.* By Prof. Fritz Ephraim. *Pp. viii.+727. Dresden and Leipzig: Theodor Steinkopff*, 1922. *Price* 21*s.* 6*d.* (*bound* 24*s.*)

Prof. Ephraim's textbook differs in many ways rom others of the same size. It is more compreensive, and the author is able by presupposing lementary knowledge, by an unusual arrangement f material, and by an admirable conciseness of style, cover a surprisingly wide field. Compounds of the rare" elements are considered in some detail, nd the tables of physical properties also make the ook valuable for reference. Recent advances, specially German, are included—even the Badische xplosion of 1921! The account of Werner's theory s notably clear and detailed, and the theory of isond hetero-polyacids of Miolati and Rosenheim eceives careful consideration. The introduction of hese conceptions lights up some obscure regions—s in the case of the constitution of such compounds s $18BaO$, V_2O_5, $3P_2O_5$, $60WO_3$, $150H_2O$, but in uch formulæ as



$N\left\langle\begin{matrix}O\\O\\O\end{matrix}\right\}H$

and



he extension of the valency conception seems lmost at its breaking limit.

The arrangement of the material under the *negative* radicals (oxides, sulphides, carbonates, etc.), although permitting of a concise treatment, is less suitable for elementary students, since the facts then become somewhat blurred. The present book, however, is specifically written for more advanced students, and these will find it very attractive and stimulating. The arrangement is not so new as the author seems to think; it was adopted by Sir William Ramsay in the "Systematic" part of his two small volumes on "Modern Chemistry," which are masterpieces of their kind.

Prof. Ephraim has carefully avoided loose generalisation, and although the experimental details are necessarily extremely brief, he makes little use of expressions such as "breaking rings," "splitting off water," and the like, which take the place of genuine descriptive language in some textbooks.

There are several typographical errors, and one or two very questionable statements were noted, but in a book covering so much ground these are surprisingly few. The reviewer can recommend this book to all chemists as both interesting and useful. Advanced students will find it of very great value: they will discover something new on nearly every page.

J. R. Partington.

Chemistry of the Non-Benzenoid Hydrocarbons and their Simple Derivatives. By Benjamin T. Brooks. *Pp.* 612. *New York: Chemical Catalog Co., Inc.*, 1922. *Price* $7 *net.*

Dr. Brooks has done well to assemble, in one volume and in systematic sequence, an orderly presentation of the non-benzenoid hydrocarbons, their properties, relationships and principal derivatives. It is a form of classification seldom adopted owing to the historically somewhat haphazard manner in which the material has been accumulated, and to the more customary, if illogical, practice of discussing the *cyclo*paraffins and essential-oil constituents after a survey of the aromatic series has been made. Thus a wholesome rearrangement of attitude towards organic chemistry is encouraged by a study of the treatise. Moreover, the somewhat monotonous aspect of paraffin hydrocarbons as considered in earlier books is now relieved by the importance of these materials from the standpoint of the rubber, petroleum and essential-oil industries. Accordingly, the opening chapters include interesting sections on the origin of petroleum oils, the details of cracking, and recent results of oxidation. A long chapter entitled "The Ethylene Bond" embraces the modern views of Lewis and of Langmuir as applied to the carbon atom, and of J. F. Thorpe in connexion with *spiro*-compounds, followed by the work of Harries on ozonides. Alicyclic unsaturated hydrocarbons are next assembled, whilst six chapters entitled "Cyclic Nonbenzenoid Hydrocarbons" deal respectively with the sub-hexyl, *cyclo*-hexane, *para*-menthane, *ortho*- and *meta*-menthane, bicyclic and tricyclic, and super-hexyl series. The concluding chapters deal with physical and physiological properties, the whole volume being well produced, agreeable to manipulate, and adequately enriched with references to recent literature.

M. O. Forster.

A Comprehensive Treatise on Inorganic and Theoretical Chemistry. By J. W. Mellor. *Vol. II.* F, Cl, Br, Li, Na, K, Rb, Cs. *Pp. vi.*+894. *London: Longmans, Green and Co.*, 1922. *Price* 63*s. net.*

The first volume of this treatise has been already reviewed very favourably (1922, 227 R), and there is no doubt that the second volume fulfils all the expectations raised by the first. In Chapter XVII, the history of the halogens, their occurrence, preparation and properties are dealt with very fully. In this and the succeeding chapters an immense mass of data is given. The language is terse, but the treatment is critical, and the author has been successful in writing a book which nowhere simulates a compilation of the dictionary type. In Chapter XVIII, in the same manner, there are described the compounds of the halogens with hydrogen; in Chapter XIX, the oxides and oxyacids of chlorine, bromine, and iodine; and in Chapter XX the alkali metals. One of the special characteristics of the book is the completeness of the references, which are given for every statement, and appear at the end of the chapters. The number of these probably explains the absence of an authors index which, with the comparative sparseness of the subject index, is the only poor feature of the book.

Dr. Mellor is to be congratulated on the plan of the treatise and on the excellence of the first two volumes. On completion the work will fully justify the designation of a comprehensive treatise and do much to stop the present unfortunate tendency to regard inorganic and the so-called physical chemistry as separate and distinct branches of the science. The author's "Introduction to Modern Inorganic Chemistry" and "Modern Inorganic Chemistry" will form with this "Comprehensive Treatise" a uniform series of books which is unique in this or any other language. The Treatise promises to outrival the well-known German works, and is likely to be for many years the standard book for use by advanced and research students.

Robert H. Pickard.

Potash. *By* Sidney J. Johnstone. *Monographs on Mineral Resources with Special Reference to the British Empire. Imperial Institute. Second Edition. Pp.* 122. *London: John Murray,* 1922. *Price* 6*s. net.*

This monograph on potash, like those on other mineral resources issued by the Imperial Institute, is admittedly and intentionally only a compilation. As such the monographs, when compiled with reasonable completeness and accuracy, have a very considerable value. Mr. Johnstone's monograph will take a high place in the series in this regard. He has materially added to the information contained in the first edition and produced for its size the most complete up-to-date summary of the world's resources of a material essential alike to the manufacturer, agriculturalist and chemist. Not only are the mineral resources of potash considered, but the yields resulting from animal and vegetable sources and as by-products of other industries, are also classified and discussed.

After a general statement of the world's output, the author devotes a chapter to the deposits of soluble potash minerals. His summarised account of these in Germany, France (Alsace), Spain, Abyssinia, Nigeria and Peru, to select only certain of the countries listed, is notably up to date. The succeeding chapter deals also with soluble potash, but refers to that extracted from brine, etc. from salt lakes and pans in America, Asia and Africa. Chapter IV deals with deposits of potassium nitrate of mineral origin, the South American, Rhodesian and Russian resources receiving full treatment. In Chapter VI the potassium nitrate deposits of organic origin, such as those contained in the soils of old village sites in India, South and Central America, Egypt and elsewhere, are recounted and the method of recovery described. The author advisedly devotes few words to the extraction of potash from sea-water, and passes on to the consideration of the insoluble potash minerals, alunite, felspars, leucite, etc. The reader is thus led naturally to the recovery of potash from the dust and gases of cement kilns and blast furnaces, where it has been volatilised from the clay, ore or fuel employed. The methods of recovery from insoluble minerals as well as flue-dust and gases are discussed, but not exhaustively, and it is perhaps not surprising to find certain notable omissions. In Chapter IX, vegetable sources of the alkali, such as seaweed, wood-ash, sunflower-stalks, bracken, and many others are described, but it is curious that the author should dismiss in a few lines the Russian supplies of carbonate which were of such extreme importance to this country and the United States of America during the war, especially for glass-manufacture and chemical needs. Residues from beet-sugar manufacture are discussed in Chapter X. An account of the animal sources of potash, such as wool-washings (suint) and karroo ash, is given in the final chapter, and the book concludes with a moderately full bibliography. The absence of an index in a compilation of this kind is unfortunate.

Finally, it may be observed that, whilst the author nowhere actually says so, and whilst he details all the adventitious sources of potash and describes the war-time expedients, he appears to regard the deposits of soluble potash salts as the mainstay of industry in the future—a point of view with which the reviewer cordially agrees.

P. G. H. Boswell.

REVIEW

Vol. XLI] OCTOBER 16, 1922 [No. 17

THE STRUCTURE OF STEELS FROM THE STANDPOINT OF COLLOID CHEMISTRY

F. C. A. H. LANTSBERRY

WOLFGANG OSTWALD has shown that there are eight possible varieties of the colloidal state :—

(1) Solid + Solid.
(2) Solid + Liquid.
(3) Solid + Gas.
(4) Liquid + Solid (suspensoid).
(5) Liquid + Liquid (emulsoid).
(6) Liquid + Gas.
(7) Gas + Solid (smoke).
(8) Gas + Liquid (fog).

Since the great bulk of metals and alloys are originally produced in the molten state it is possible for them to be obtained in the form of a molecular solution and ultimately to exist in six of the possible forms of the colloidal state.

It is well known that molten metals dissolve gases which are evolved both before and after solidification. Metals and alloys also contain slag and other enclosures, some of which become liquid below the fusion-point of the metal, whilst others remain solid well above the temperature of fusion.

Some very interesting facts are known about the solubility of gases in metals. The familiar instance of steel may be quoted, which at the moment of solidification evolves the bulk of the dissolved gas and gives rise to unsound castings. Fortunately, however, the addition of silicon in small quantities to the molten metal increases the solvent power for gases, and results in the production of sounder castings. This is quite on a par with the protective action of certain colloids. This view is confirmed by the fact that elements, such as silicon, titanium, and aluminium, whose compounds show a distinct tendency towards assuming the colloidal state, have the greatest effect in promoting soundness in steel.

The existence of non-metallic enclosures in steel is of great importance, and provides a subject about which very little is really understood. For the purpose of this note these enclosures may be divided into two classes :

(1) Those which are solid above the temperature of fusion of the steel (certain slags and alumina).

(2) Those which have a melting-point below that of the steel (sulphides).

Confining our attention for the moment to the liquid state, it is fairly certain that at some temperature the materials of the first class will become molten, so that whatever is said of the second class will be true of the first up to the point at which solidification of the enclosures commences. In any case the quantity of slag existing in steel is very minute and might almost be neglected entirely for the purpose of this note.

The influence of sulphides, however, is of very great importance, so much so that sulphur has been a nightmare to the steelmaker for generations. It is known that sulphur in excess of 0·08 per cent. tends to make steel "hot short." Another interesting fact is the change in character of the enclosures when even a small quantity of manganese is added to the steel. In an alloy containing no manganese the sulphide exists as a yellowish enclosure, but the presence of 0·2 per cent. of manganese changes the colour to a pale bluish-gray. It is fairly certain that in a steel containing no manganese the sulphur exists as ferrous sulphide, but that in a steel containing 0·5 per cent. manganese and 99 per cent. iron the sulphur should exist as manganese sulphide (MnS) is very difficult for the chemist to understand. But whatever may be the exact composition of these sulphide enclosures, it is quite certain that they may give rise to troubles in manufacture quite apart from the "red shortness" about which there is considerable exaggeration, because bars containing over 0·1 per cent. sulphur can be hot-rolled into quite small bars. The sulphide areas when segregated into large masses may cause considerable wear of tools in machining operations. This is illustrated in Figs. 1 & 2, which represent steels that are not materially different in sulphur-content, but whereas the steel illustrated in Fig. 1 caused so much wear of the tools as to be practically unmachinable, that illustrated in Fig. 2 machined quite sweetly and produced articles showing an excellent finish. The essential difference between the two lies in the size of the sulphide enclosures. In passing it may be remarked that this is the main difference between English and American machining steels. It would therefore appear to be of considerable technical importance and of extreme scientific interest. In the first place it is known that the sulphides are insoluble in steel below its melting-point, or at least that the solubility is not greater than required to fulfil the theoretical concept that complete insolubility is impossible. It is also certain that there is no tendency for the sulphide enclosures to segregate at temperatures below the melting-point of the steel. Our knowledge of the behaviour above the melting-point of the steel when both constituents are liquid, is not even so extensive. At temperatures immediately above the melting-point of the steel we know that there is little or no mutual solubility, a point which is proved by the tendency towards segregation in the casting of large masses. At the same time we have the fact of the enormous variation in size of the sulphide enclosures in steels of various origin. This is undoubtedly brought about to a considerable extent by the extreme agitation which occurs during the various processes of manufacture.

But we have no knowledge of the solubility relationships of steel and sulphides in the liquid state. In the case of phenol and water we know that at the ordinary temperature these two materials are practically insoluble, but as the temperature is increased so the mutual solubility increases until at a certain temperature (depending upon the relative proportions of the constituents) complete solution occurs. On cooling complete solubility persists until the same critical temperature is reached, when the mixture becomes opalescent. At this point it can easily be proved that the phenol has assumed the colloidal state, but as the temperature is lowered coagulation occurs, until finally the mixture separates into two distinct layers. It is quite possible that at high temperatures steel and the sulphides show a similar behaviour, and if this be correct we have at hand a possible means of controlling the size of the sulphide enclosures and so rendering them innocuous. It is true that we cannot apply the ultramicroscope to the study of these problems, but during the last few years methods have been developed of studying the electrical conductivity and viscosity of molten metals and alloys, and this gives us a ready mode of attack, for both these properties show very definite characteristics when the colloidal state is attained.

The relations existing between carbon and iron are very interesting when regarded from the colloid point of view. Carbon exists in steel as a carbide of iron, Fe_3C, known as cementite. At all temperatures below 680° C. the limiting solubility of this cementite in iron, known metallographically as ferrite, corresponds to about 0·04 per cent. carbon. On heating, no change takes place in these solubility relationships until a temperature of 700° C. is attained, when the cementite suddenly goes into solution in the ferrite. At this temperature the solution occurs in the pearlitic portions of the steel, and as the temperature is increased the solid solution produced dissolves either ferrite or cementite according as one or other constituent is in excess. If ferrite is in excess the concentration of the solid solution decreases with increase of temperature, but when cementite is in excess the concentration increases until a maximum is attained at a concentration of 1·7 per cent. carbon and a temperature of 1135° C. We see, therefore, that in steels the stable condition at high temperatures is that of a solid solution, whilst at low temperatures this solid solution has split up into its constituents, the ultimate stable condition in the cold being undoubtedly iron and graphite. During this splitting up the solid solution passes through several very definite transition stages which can be trapped and subjected to microscopic examination. The solid solution austenite is shown in Fig. 2. Apart from the polygonal outlines which are characteristic of single-phase alloys, the material is structureless. In pure carbon steels it is exceedingly difficult to obtain this structure, but by etching at high temperatures the structure has been developed. (Fig. 3.)

The normal structure obtained by properly quenching steel is shown in Fig. 4. This characteristic structure is known to metallographists as martensite, and its peculiar appearance has been ascribed to surface stress marks by some authorities and by others to the effects of twinning along the octahedral planes. By less drastic quenching or by reheating at about 400°C., a very dark etching constituent appears known as troostite (Fig. 5), whilst still less drastic quenching or more tempering gives sorbite (Fig. 6).

If the quenching be omitted and slow cooling adopted pearlite is obtained; the structure of this material is shown in Fig. 7. By very slow cooling indeed the two constituents segregate completely and cementite and ferrite are obtained side by side (Fig. 7). Examined from the point of view of the colloid chemist these changes may be explained as follows:—

Cementite is regarded as the dispersed phase and ferrite as the dispersion medium. At high temperatures the degree of dispersion is great enough to produce the molecular solution austenite. As the material cools a temperature is reached at which the dispersed phase assumes the colloidal state and troostite is obtained. Troostite shows a maximum solubility in acids and is irresolvable even under the highest powers of the microscope. Troostite may, therefore, be rightly regarded as a colloidal solution in which cementite is the dispersed phase. As the temperature falls the phenomenon of coagulation occurs and sorbite is produced. Examination of sorbite under the

microscope indicates that it has the structure of a suspensoid. On still slower cooling pearlite is obtained and the structure recalls very strongly the phenomenon of periodic precipitation. Fig. 8 shows the Liesegang rings obtained by the precipitation of silver chromate in gelatin. These recall the appearance of pearlite in a very striking manner. We see, therefore, that colloidal chemistry gives an explanation of the reason for the peculiar laminated structure of pearlite, an explanation which will hold good for all other eutectics. It is unfortunate that the ultramicroscope does not lend itself to the study of alloys, but as pointed out earlier, other methods are available, and no doubt advantage will be taken of them in time to find out if that which at the present time is merely conjecture can be demonstrated by experiment.

THE "THERM" SYSTEM OF CHARGING FOR GAS

SIR WILLIAM POPE

As the result of a view expressed by the Fuel Research Board some years ago, the Gas Companies now sell gas by the "therm"; the consumer is thus charged at a fixed rate for each 100,000 British Thermal Units obtainable by burning the gas. Since coal gas is used as a source of energy, it seems but just that it should be sold on an energy basis, and that its cost should be fixed by reference to the amount of some form of energy, such as heat, obtainable from it; the heat unit of a therm is quite a suitable one to use.

The new method of charging for gas replaces the former one in which a charge per 1000 cubic feet was made; to charge for gas by volume, without defining its heating value, is just as reasonable as it would be to sell milk by the pint without limiting the amount of water which might be added to it before the sale. That it is more rational to charge for gas by the therm than by the 1000 cubic feet is not to be doubted. To-day, however, the daily Press—and notably the *Daily Mail*—is said to be inundated with complaints to the effect that the new mode of charging for gas has resulted in an increase in the gas bills and in an illegitimate profit to the producing companies.

Whilst entirely agreeing that to charge by the therm marks a distinct advance, I am inclined to think that the gas undertakings have made a most unfortunate choice of the time at which to make the change. The rising coal market and the heavy expense caused to the gas-making industry by the coal strike of last year greatly increased manufacturing costs. Whilst the selling price of gas is now undoubtedly falling throughout the country, it is fairly certain that in most cases the price is higher to-day than it should be; the consumer of gas, who often understands neither the volume nor the energy unit, will not be content until the sum total of his gas bill *in money* approximates more nearly to pre-war figures.

The attempts which have been made to popularise the therm by public advertisement have probably not served their purpose because the announcements are couched in terms incomprehensible to those who have not received the rudiments of a scientific education. It has been stated recently in the literature of gas technology that modifications are now being made in the existing gas-meter register so that the gas user may read his consumption directly in therms; this will be better appreciated than long dissertations explanatory of the therm. It might even be well if, until this modified register is universally installed, gas undertakings were to indicate upon their gas bills the consumption not only in therms but also in cubic feet, so that the public could make direct comparisons with their gas accounts of previous quarters; this would obviate the need for a calculation the nature of which is not universally understood. Naturally, it should be insisted that equal prominence is given to the number of therms and of cubic feet, and to the cost of each of the two units, the therm and the 1000 cubic feet.

Gas legislation of 1920 may have been faulty in defining the methods by which standard basic prices, dividends permissible, etc. are to be fixed, but upon this aspect of the question I am not prepared to write. It is of the greatest importance, however, that the progress made by the Fuel Research Board, in instituting the sale of gas upon a heat basis, should not be prejudiced by extraneous factors; it seems highly desirable that the Board of Trade should call for an inquiry into the question for the purpose of defining the nature of those factors which have arisen fortuitously but which undoubtedly operate against the popularity of a distinct advance, that, namely, of securing by legislative action the merchanting of gas on the basis, not of its bulk, but of its usefulness to the consumer.

* * *

In a letter to *The Times* of October 7, Sir George Beilby, Director of Research to the Fuel Research Board, explains the reasons which induced the Board, after devoting a year and a half to the study of the question, to recommend the adoption of the thermal system of evaluating coal gas. He states that there are two other matters of importance to the consumer which have not been sufficiently considered, viz., the need of a calorimeter, now available, to record continuously and automatically the heating quality of the gas, and the necessity for securing that the consumer shall burn his gas in the most economical manner. For this purpose it was recommended that the gas companies should readjust consumers' burners free of charge, whenever the calorific value of the gas was changed.

GENERATION OF STEAM BY ELECTRICITY*

F. T. KAELIN†

THE purpose of this paper is to bring before the engineering profession the conversion of electric energy into heat energy by means of an improved and inexpensive apparatus, the electric steam-generator. To produce steam by electricity appears at first sight a reversal of common-sense, but this process has its economic *raison d'être* in the fact that it can utilise hydro-electric power that would otherwise be wasted. In times of business depression the engineer is forced to consider all kinds of improvements, such as increasing efficiency of production, elimination of waste in material, labour and power; and the electric steam-generator is a handy and simple means of contributing toward this end. There are more than 300 installations in Italy, Switzerland, Sweden and France, and a small number of generators has been in use for a short time in Canada and the United States.

The low cost of the electric steam-generator compared with that of other electrical plant for converting electricity into heat, and the comparative cheapness of the wiring and control apparatus necessary, are very favourable considerations. It can be shown that even when the load factor is comparatively high, *e.g.*, in pulp and paper factories, which purchase big blocks of power and consume it, mainly for pulp-grinding, during only six days of the week, it is economically feasible during the seventh day to turn the power into steam, which is always required either for heating or manufacturing.

In the electric steam-generator the electric current passes through a resistance either of metal or formed by the water to be evaporated, and all electric energy is converted into heat energy. One kilowatt-hour is equivalent to 3412 British Thermal Units; the total heat content of 1 lb. of steam at an absolute pressure of 150 lb. per sq. in. is 1193 B.Th.U.; assuming the temperature of the feed water to be 150° F., the total heat to be supplied will be 1193—(150−32) = 1075 B.Th.U. One kilowatt-hour will therefore produce 3412/1075 = 3·17 lb. of steam. The heat losses are very small.

During the past ten years generators have been made with capacities up to 1000 kw., and only within the last two years have sizes of 2000 kw. or more been constructed.

There are two main classes of electric steam-generators: (*a*) those in which the current passes through a combination of metallic resistors, and (*b*) those in which the water itself forms the resistance. In (*a*) the resistors in the form of wire and ribbon made of some high-resistance alloy may be mounted in tubes similar to those of fire-tube boilers. The arrangement allows the use of alternating or direct current, as the heating elements do not come into direct contact with water; in all other cases in which the resistors are in contact with water and the current passes partly through metallic resistors and partly through water, only alternating current can be used because direct current would decompose the water.

Generators in class (*b*) are built on an entirely different principle. The electric current passes through steam-tight insulating bushings to a system of stationary electrodes partly submerged in water, the water to be evaporated serving as the electric resistance. The outstanding advantages of this type are its simplicity of construction, compactness, easy control, and very low cost per kilowatt capacity. Practically any water that is satisfactory for ordinary boilers is also suitable for the electric steam-generator. The resistance of water has a negative temperature co-efficient, *i.e.*, the resistance decreases as the temperature and pressure increase. The writer has made many tests to determine the relationship between resistance and temperature for various kinds of water, and has used apparatus specially constructed for currents up to 10 ampères and 6000 volts. at atmospheric pressure. Fig. 1 shows a set of curves giving the relation of temperature and resistance for raw water from the St. Maurice River and for condensate water mixed with about 25 per cent. of raw water from the same source

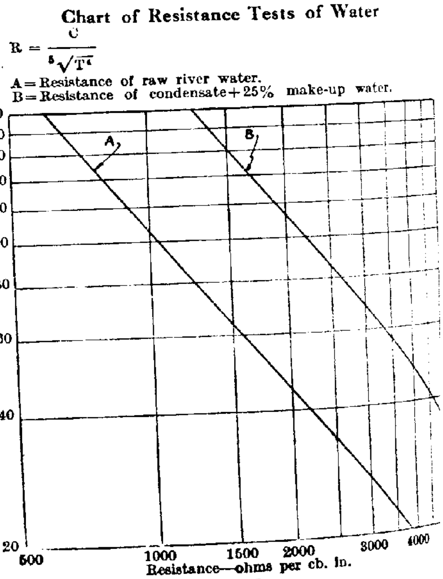

FIG. 1

Using a logarithmic scale, the curves appear as straight lines, and in many other tests, of which the results are not shown in the diagram, it was found that these lines were all very nearly parallel. This would indicate that the same general law applies to all kinds of water. The curves have been verified above 100° C. by tests on steam-generators under pressure.

---

* Abstract of a paper read before a joint meeting of the Montreal Section of the Society of Chemical Industry, the Engineering Institute of Canada, and the Institute of Mining and Metallurgy, at Montreal, on Jan. 19, 1922 (*cf.* J., 1922, 94 R.).

† Chief Engineer, Shawinigan Water and Power Co.

Figure 2 shows a section of a 5000 kw. generator, consisting of a vertical cylindrical tank with an extension at the bottom. The upper part is flanged, and to it is bolted a dished cover which contains three openings for the porcelain bushings that insulate the three copper conductors leading to the electrodes.

Electric Steam Generator
Three-phase single unit system

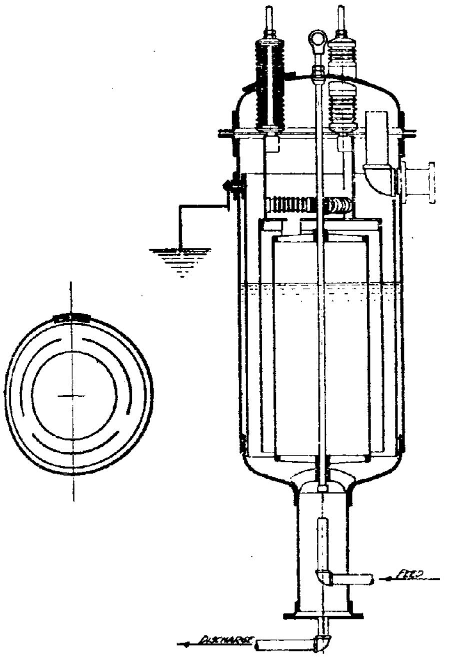

Fig. 2

The insulator bushing consists of three parts: two corrugated sleeves, one of which is outside and the other inside the tank, and a tube inside these sleeves, the whole being held together by the shoulder and nut of the conductor passing through. The arrangement shown in Fig. 2 is for 1300 amps., 2200 volts, 3-phase, 60 cycles, and for a working pressure of 165 lb. per sq. in.; the electric current passes through from both sides of the electrode to the inside and outside cylinders, and to a much smaller extent directly from electrode to electrode.

This type of generator requires but little floor space; the 5000 kw. generator with electric control apparatus can easily be placed in an area 10 × 12 ft., and the 18,000 kw. generator, equal to 1800 boiler horse-power, with all its accessories, needs a floor space of about 15 × 22 ft., and a head-room of 25 ft. for ease in dismantling.

As the heat in the steam-generator is produced in the water, there are no parts subjected to a higher temperature than that of the steam; hence no dangerous stresses are produced by temperature differences. Another element of safety is that interruptions to feed-water supply can be easily met by shutting down the generator. The operation of the electric steam-generator is at least as safe as that of the coal-fired boiler.

PHOTOSYNTHESIS

The following is a short report of the discussion on Photosynthesis which took place at a joint meeting of Sections B (Chemistry) and K (Botany) at the recent meeting of the British Association in Hull. Prof. H. H. Dixon, President of Section K, presided over a large attendance.

In opening the discussion, Dr. F. F. Blackman said that he proposed to deal with the active system of photosynthesis and its organisation in the living cell, and bring together evidence which supported the thesis that here we had to do, not with a simple photochemical reaction, but with a complex system in which other components, that might be described provisionally as protoplasmic components, played an essential part.

The first point developed was that there were numerous lower plants which obtained all their carbon by the reduction of carbon dioxide in the dark without the intervention of radiation, and synthesised all their organic compounds from that source; instead of radiant energy, there was utilised the chemical energy of the oxidation of nitrogen, sulphur, and hydrogen, or their compounds. In those chemosynthetic organisms there was not a gain of energy, but only an exchange of oxidation potential: the gain to the organism was substance for growth. It might be asked whether this power was entirely absent in the higher plants, and what connexion the chemical machinery of it had with the chemistry of photo-reduction of carbon dioxide.

The second point was the fact, now thoroughly investigated, that the seedlings of many plants at a stage when they have developed chlorophyll to a full green colour might be quite incapable of reducing carbon dioxide in light, and gave out as much of that gas from respiration in light as in dark. Some other component or property lagged behind the chlorophyll in its development and the slow, steady rate of its development was the same in darkness or light.

A third point of interest was the efficiency of photosynthesis in the golden-leaved varieties of certain shrubs. Here the amount of chlorophyll might be as low as 4 per cent. of the normal green form, and yet under medium conditions the reduction of carbon dioxide might be as great as in green leaves. The fact had been established that the golden leaf needed more light than the green to carry out the same rate of reduction of carbon dioxide. It looked as if with these extreme variations of chlorophyll what counted was the cube root of the amount of chlorophyll present—a single dimension of the colloid *micellae* and not the total mass—which might be taken as an indication of the organisation of the system.

A fourth point considered was the relation of photosynthesis to temperature. It was established that for a high rate of photosynthesis it was not sufficient to have intense radiation and concentrated carbon dioxide, but a high temperature was also essential. For each temperature there was a specific maximum of activity which could not be exceeded unless the temperature was raised. The specific maximal values increased rapidly for rising temperature and had a temperature-coefficient of about 2 for a rise of 10° C. This temperature relation was quite different from that of a pure photochemical reaction, and it provided a further indication that we had to deal with a complex system in which dark reactions played a controlling part.

The fifth point to be raised had to do with the organisation of the active system. Prof. Warburg had been investigating the action of the narcotic phenylurethane upon the rate of photosynthesis and had found that the process underwent great depression of rate with perfect recovery on removal of the narcotic. The relation of the depression to the external concentration of the drug gave a typical adsorption isotherm indicating that the narcotic acted by adsorption on a surface from which it displaced temporarily some reacting substance of the active photosynthetic system.

Taking all these pieces of evidence together, we were forced to conclude that the chloroplast contained an active system of several components related together in a complex organisation.

Prof. E. C. C. Baly said that the conversion of a substance A into substance B might be represented as the sum of the three equations:—

$$\begin{aligned} A + E &= A' \\ A' &= B' + F \\ B' &= B + G \end{aligned}$$

where E, F and G were quantities of energy and A′ and B′ represented the reactive forms of A and B. The reaction was exo- or endo-thermic according as $F+G-E$ was positive or negative. In any case a quantity of energy, E, must be supplied in order to start the reaction, and this might be done by means of (i) heat, (ii) light, or (iii) a material catalyst. The energy could only be supplied in "quanta," and if E were large only the use of a radiation of short wave-length made the number of quanta to be introduced sufficiently small to be practicable. For the conversion of a molecule of carbonic acid into formaldehyde and oxygen, 150,000 calories was necessary, and this could be supplied in a single quantum by radiation at wave-length 200 $\mu\mu$. Carbonic acid had an absorption band at this frequency, and formaldehyde ought therefore to be produced when a solution of carbon dioxide in water was exposed to ultraviolet light. This had now been shown to take place.

In order to bring about the reaction by means of *visible* light, it was necessary to have present a coloured substance with basic properties, and Malachite Green had been found to fulfil the conditions. There seemed little doubt that the formation of formaldehyde in the leaf proceeded as follows:—

(i) [Chll.A+H_2CO_3]+light → [Chll.B+CH_2O].
(ii) [Chll.B+Carotin → Chll.A+Xanthophyll.
(iii) Xanthophyll+light → Carotin+Oxygen.

The photosynthesised formaldehyde was extraordinarily reactive and was best represented by the formula CHOH. It polymerised rapidly to a mixture of carbohydrates, in which were found hexoses, and evidence was not wanting in favour of the formation of more complex substances. In the presence of nitrite it was converted into formhydroxamic acid, and hence into amino-acids and a mixture of cyclic bases in which piperidine, pyridine, coniine and glyoxaline had been detected. The active (energised) forms of the amino-acids condensed with the cyclic bases to give substituted amino-acids, and these were the immediate source of proteins.

Mr. G. E. Briggs described some experiments to determine the relation between the radiant energy absorbed and the carbon dioxide assimilated by the green leaf (*Phaseolus vulgaris*) in different parts of the visible spectrum. For three different parts of the spectrum the carbon dioxide assimilated was measured, and the energy absorbed by chlorophyll *a* and chlorophyll *b* was estimated from data obtained, due allowance being made for the energy diffusely reflected by the leaf. The results were of the following order:—For the yellow-red (570—640 $\mu\mu$) 15 calories per c.c. of carbon dioxide; for the green (510—560 $\mu\mu$) 7; and for the blue (430—510 $\mu\mu$) 22+, these being maximal values. Since the heat of formation of the most probable products of assimilation ranged from 5 to 6 and more calories per c.c. of carbon dioxide it was probable that both chlorophyll *a* and chlorophyll *b* took part in the photochemical reaction.

Referring to Prof. Baly's suggestions as to the part played by the different pigments in the photosynthetic process, Mr. Briggs said that as the quantity of each pigment underwent relatively little change during prolonged assimilation, no energy was supplied from that source; and, further, that since as much oxygen was evolved as carbon dioxide was absorbed in the red and the green parts of the spectrum (regions where no energy was absorbed by the xanthophyll) as well as in the blue, it was not necessary to postulate a photochemical reaction involving xanthophyll in order that oxygen might be liberated.

Prof. I. M. Heilbron and Mr. C. Hollins put forward some speculations on phytosynthesis. The large number of plant products in which the predominant carbon nucleus was C_5 or a multiple of it suggested that this unit had a special significance. The photosynthesised reactive hexose might be supposed, in addition to its further condensation to sugars, cellulose, glucosides, etc., to furnish by dehydration ω-hydroxymethylfurfural. This by oxidation and decarboxylation could give a stabilised C_5-compound, which, either as the furan derivative or (by opening of the ring) as dihydroxyglutaconic dialdehyde, might be a source of pentoses and of their condensation products. Simple schemes were suggested to show how two, or three, molecules of a "pentose" could give rise, by ordinary condensation reactions, to anthocyans (C_{15}), terpenes (C_5, C_{10}, C_{15}, etc.), coniferyl alcohol (C_9) and the numerous related compounds (including lignin), coniine (C_8) and the phonopyrrole-carboxylic acids (C_8, etc.). The degradation of hexose into "pentose" represented the respiration of the plant. Against the suggestion of Robinson (British Association, 1921) that anthocyans resulted from the condensation of two hexose and one triose molecules were to be set the absence of nonoses in nature and the failure of all attempts to obtain benzene derivatives from hexoses.

Prof. R. Robinson thought that the accumulation of active formaldehyde and formhydroxamic acid scarcely accounted for the almost inexhaustible variety of plant products. The alkaloids were probably produced from hexoses rather than built up atom by atom from formaldehyde. He was unable to accept the suggestions of Prof. Heilbron and Mr. Hollins as to the significance of the C_5-unit. Practically all the compounds in C_{5n} belonged to the terpene family and were derivable from isoprene. Apiose, the sugar corresponding to isoprene, was a simple condensation-product of dihydroxyacetone and glycollaldehyde. The anthocyans he preferred to consider as $C_6+C_3+C_6$ rather than $C_5+C_5+C_5$. Although nonoses had not been found in nature, Emil Fischer had obtained a nonose which was fermentable.

Dr. E. F. Armstrong emphasised the fact that cane-sugar was the first sugar formed in the plant. If hexoses were produced intermediately their existence was but transient.

Prof. Baly, in reply to the discussion, said that Mr. Briggs' experiments, though valuable, could not be interpreted quite so simply as was assumed. The relation between radiation absorbed and quantity of reaction resulting was very complex, and, indeed, in only one case so far (viz., the conversion of oxygen into ozone) was the Einstein theory satisfied. The measurement of photochemical efficiency was thus an abstruse problem and the experimental results were far from justifying Mr. Briggs' conclusions concerning the individual rôles of the leaf pigments.

NEWS FROM THE SECTIONS

MANCHESTER

The new session of the Manchester Section was inaugurated on October 6 by an address given by the President of the Society, Dr. E. F. Armstrong, on "Practice and Theory in an Industrial Problem." Dr. E. F. Ardern, chairman of the Section, presided over a large attendance. An abstract of Dr. Armstrong's remarks is given below.

The main object of my remarks is to illustrate to you the extreme breadth of chemical problems, and the necessity for breadth both in the training and in the mind of the chemist if he is to succeed in his profession. The illustration I have chosen is that of the hydrogenation of fats. The difficulties encountered by Sabatier, Normann and other early workers in this field demonstrate the hundreds of ways in which the chemist has to exercise his ingenuity; how he has to be master of all trades, and how considerations of all kinds, in addition to those of the text-book equations, enter into his daily life. Twenty or twenty-five years ago nobody knew how to make pure hydrogen in quantity and cheaply. Therefore the would-be hardener of fats had to find out how to make hydrogen. Electrolytic hydrogen naturally appeared attractive, but the costs of the plant, the prime costs, and the lack of any outlet for the oxygen ruled it out of court. Alternative fancy methods, *e.g.*, the action of acids on iron, also broke down on the grounds of cost; and the only method which to the manufacturer seemed to promise success was that of removing carbon monoxide from water gas. Now, even the manufacture of water gas in those days was in a very crude state. You could buy producers, but the life, the cost of repairs, and so on, left much to be desired. Therefore the would-be carrier-out of the chemical process found, in the first place, that his energies were dragged right back to what was almost a gas-engineering, at any rate a chemical-engineering, problem of his producer plant. The many and great difficulties connected with this problem were originally solved, more or less empirically, by hard work, the chemist on the spot making practical, careful trials, and keeping data added by the engineer. In later days the physical chemist has come to our assistance, and by a proper use of thermodynamics, etc. has done much to enable the ideal conditions of the laboratory to be foretold before they were applied to the plant. But in the main such work, valuable as it is, merely served to confirm the results which were arrived at empirically by the hard-working men on the spot. The next problem was the very important one of the cost of the hydrogen. It is worth while stopping to analyse the items which enter into that cost. There is, first of all, the actual running costs of the plant, the cost of the iron ore, the cost of labour, the cost of the heat to generate the producer gas, and so on. Then there are the repair costs, and the capital costs, interest, depreciation, rating, and so on. It is no use neglecting, in practice, any one of these costs, and every new method has to be criticised from these points of view. You may have a perfectly ideal process which will break down entirely because the plant has to be renewed once a month. We had the misfortune during the war to work a process in which the plant, otherwise ideal, had to be renewed once a fortnight; this difficulty was fatal. The electrolytic process of making hydrogen suffers from a high capital cost, unless it is carried out in a country with unlimited cheap water-power. Running costs are of considerable importance sometimes, but they alone are never determinative.

To turn now to the problems presented by the oil and the catalyst. Before fat-hardening was introduced the unsaturated oils were worth very much less than the saturated oils, and one could afford to spend quite a lot of money in hardening them and still make a lot of money from the hardening process. To-day, through some vagary of the world's markets, the unsaturated oils are worth so much in comparison with the saturated ones that in hardly a single case can one afford to spend even half the money necessary for hardening. The process is out of action through the vagaries of the market. The wise man at the head of a company will have to take a long view of past and future markets before he decides to indulge in the capital expenditure necessary to put up a plant of this sort, so that directly we are up against the cost of the oil the chemist has to turn himself into an economist, or associate himself with the economist, and think of his problem from that point of view. Of course, the actual production of the oil is outside our range, although it should be within it; because it is very much better for us to receive a carefully made, relatively clean oil, and to deal with that, than it is for us to receive a carelessly made, dirty oil, and try to put right a harm which has been done. So really the chemist's care ought to go right back to the original production of the oil and not to come in when the oil is delivered to him. In the works the oil has to be cleaned to the maximum extent possible.

Then there remains the catalyst. Here the training of the chemist comes into play, and it is to get the catalyst in a suitable state that his skill is required. The early writers on this subject, much of the patent literature, and such technical papers as there are, of course, bring in higher mathematics and every form of modern high-class chemistry, but I think it is very much better for the practical man to approach it from the other end, that of simplicity. The active nickel surface is obtained by saturating kieselguhr with the nickel salt, precipitating with alkali, washing, and reducing the oxide to the metal. It is very simply said, but it is difficult to choose conditions which do not harm that very delicate surface. No theories are required in preserving that surface. First of all, one must use salts that can be easily washed away, nitrates rather than sulphates, for if they are not washed away they can be burnt away. The catalyst must not be overheated, because the globules of metal soften and begin to coalesce far below the melting-point. The actual problem of heating the active catalyst is purely a common-sense one which requires a great deal of thought and care. Although it sounds very easy to describe in a few words, the solution took a great many years of research to find. Then we have catalyst poisons. There is a wonderful literature based on catalyst poisons and a very wonderful jargon. It all amounts to this, that if you have anything which spoils the surface, you obviously reduce the activity of the catalyst. There is no mystery about it, it is obvious simple fact, but it has been wrapped up in a great deal of mystery. The next stage is to bring together the cleaned oil, the purified hydrogen, and the clean catalyst under suitable conditions. We must have chemical control in order to be able to stop at any particular point. The reaction takes place quite fast, and a good many tons of material are worked up at a time. You cannot see when the oil has attained a certain hardness, so you have to take it out and test. The determination of hardening-value takes some time; the determination of the melting-point takes a long time; the determination of the refractive index is the only quick method, and the melting-point may be deduced from the refractive index by means of a correlative curve.

Fats, I might say, are sold, as they always have been, on a titre. The titre has nothing whatever to do with the hardening number or the refractive index of any fat, so the unfortunate fat-hardener is never quite certain he is going to stop at the right titre. If he tries to get over this difficulty by mixing A tons of one titre a little above the mark with B tons of another titre below the mark he does not get the titre he hopes to arrive at. So the chemist has to set up a lot of very elaborate controls in order to comply with an utterly irrational selling-method based upon an archaic custom of the tallow trade. You would think these salesmen and buyers would listen to the chemist; but no, that difficulty is the only one which he is not able to solve. I quote you this, in all earnestness, as typical of British practice, and I think everyone will endorse our feeling that this is an example of some of the real difficulties with which the British nation has to contend.

Having briefly sketched the practice, I will now say a little about the theory of this reaction, because it also brings in every branch of chemical affairs. There are at least two theories to explain why a reduction takes place. One theory is that adsorption of hydrogen occurs at the surface of the nickel. I do not know what adsorption means, but in some mysterious way it is supposed to provide the active hydrogen which brings about saturation. The other theory is that combination between nickel and oleic acid is brought about through partial valencies and that then the unstable complex breaks down. We have a beautiful experimental proof of the formation of such a complex, and the investigations of Rayleigh, Hardy, Adam, and Langmuir, all tend to support the additive-compound theory.

It is hardly necessary to say that such work as I have been describing is the result of team work. Team work is only possible where there is loyalty, self-sacrifice, and good feeling, and I am quite certain that British industry needs work of this kind. My experience, limited as it is, has left me with a feeling that the very training we chemists get, the analytical training, *i.e.*, the training of suspicion, has made us much less ready to mix together, much more critical of our fellow chemists, than is desirable in the best interests of the profession. I think the greatest good this Society has been doing, is doing, and can do, is to keep on bringing us together to discuss problems in the most friendly way possible, so that members may learn what is both in and at the back of one another's minds.

MEETINGS OF OTHER SOCIETIES

THE IRON AND STEEL INSTITUTE

The autumn meeting was held last month in York under the presidency of Mr. Francis Samuelson. In a paper on the bases of modern blast-furnace practice, Mr. A. K. Reese defined the object to be sought as the attainment of the greatest possible quantity consistent with quality, a statement demurred to by Prof. H. Louis, who maintained that the aim should be the greatest possible economy consistent with quality; economy and quantity were not always associated. The paper was very comprehensive, treating the subject from four aspects: (1) preparation of materials, (2) furnace design, (3) auxiliary equipment, and (4) method of operation. Under (1) the author emphasised the need of perfect uniformity in the size and density of the materials charged; under (2) that the output capacity of a blast furnace is proportional to its effective bosh area; and under (3) the importance of rough-cleaned gas and regularity in the volume of its admission.

Mr. C. W. H. Holmes described an investigation of the factors influencing the grain and bond in moulding sands, the factors being the various processes to which such sands are subjected, and the properties investigated being the strength of the bond and the ratio of the mechanical grades of sand. Mr. L. E. Benson related how he had nitrogenised specimens of "armco" iron and steels by annealing them at 500° C. in a salt bath containing 17 parts of sodium nitrate to 3 of potassium chloride, the rate of absorption of nitrogen being about 0·02 mm.

per hour in the case of "armco" iron. In answer to criticism, he stated that there was no positive evidence that a nitride was formed.

The results of researches carried out in the laboratories of Vickers, Ltd. were described by Mr. J. H. S. Dickenson in his paper on the flow of steel at red heat and the scaling of heated steels, a subject of especial interest to makers of steel apparatus, such as that used in synthetic-ammonia production, which has to withstand high temperatures and pressures for long periods. The author has determined that temperature at which the rate of flow of a steel does not exceed a practically negligible amount when subjected to a uniform stress of 8·5 tons per sq. in. A graph was shown comparing the results of tests applied for periods varying from a few seconds to many weeks, and another which emphasised the very great influence of time in determining the maximum temperature at which a steel can support a given load, and therefore also the load which the steel can bear at any temperature.

In some practical notes on the manufacture of high-speed steel in the basic-lined electric furnace, Mr. H. K. Ogilvie stated that at Coventry the use of ferro-tungsten was preferred to that of tungsten powder, and that the use of high-speed turnings as raw material for the furnace was found to be uneconomical. Other papers presented were:—"On the Diminution of Lag at Ar1 through Deformation": J. H. Whiteley; "Changes in the Volume of Steels during Heat Treatment: (1) Air Hardening Nickel-Chromium Steels": L. H. Aitchison and G. R. Woodvine; "Magnetic Properties of Heat-treated Carbon Steels": E. D. Campbell and E. R. Johnson; and "A Brinell Machine Attachment": E. D. Campbell.

At the annual meeting to be held in London, in May, 1923, a resolution will be submitted to alter the period of office of presidents from two years to one year.

THE INSTITUTE OF METALS

Swansea, the metallurgical centre of the South-West, offered its hospitality to the members of the Institute on the occasion of its autumn meeting (Sept. 20–22), and those who took advantage of it must have been impressed by the evident desire of the local people to foster the *entente cordiale* which is springing up between the scientific and the practical pursuers of the art of metallurgy. This desire is clearly shown by the efforts which have been, and are being, made to develop the new University College on sound and broad foundations. The excellent laboratories that are being erected and equipped in Singleton Park—the gift of the Municipality—under the direction of Prof. C. A. Edwards (metallurgy), Prof. J. E. Coates (chemistry) and others: the many scholarships that are being offered to students: and the close *liaison* that is developing between the academic staff and the manufacturers—all point to the thoroughness with which the ground is being prepared and to the plentiful harvest that will surely follow. The Institute of Metals has its eye upon Swansea, and intends to form a local section there as soon as possible. The following papers were presented to the meeting:—

The Sixth Report to the Corrosion Research Committee of the Institute of Metals on "The Nature of Corrosive Action and the Function of Colloids in Corrosion": G. D. Bengough and J. N. Stuart. The report attempts to present a general review of corrosion phenomena based on the study of several different metals, and to examine how far the electrochemical theory of corrosion can interpret those phenomena. The difficulties encountered by this theory are indicated, and it is shown that it gives a satisfactory account of the facts only under certain conditions: many facts can only be explained by recognising the important part played by colloids in corrosion. A theory of the mechanism of colloid action is put forward and some experimental results are reviewed in the light of this theory. On the electrochemical theory the action of oxygen is that of a depolariser; it can be shown that atmospheric oxygen has very little depolarising power at ordinary temperatures. Two chief types of corrosion are distinguished: (1) the general type, usually characteristic of acid corrosion, and (2) the local type, usually characteristic of corrosion in water and salt solutions. The second type is generally characterised by the formation of an adherent scale on the metal, and this scale may contain colloid.

A short Note on the Effect of Superheated Steam on Non-Ferrous Metals used in Locomotives: Sir Henry Fowler. This paper discusses the compositions of the various alloys used for the bushes in which piston tail rods slide, for piston-rod packing, and valve-spindle packings. After various experiments it was found that a phosphor-bronze (Cu 88, Sn 11, and P 1 per cent.) was most satisfactory. The composition of the McNamee rings was 70 per cent. lead, 30 per cent. antimony; this alloy gave complete satisfaction so long as the working temperature was kept below 340° C. A critical point was apparent about that temperature and the rings were liable to fuse. For by-pass valves a complex nickel-brass alloy gave successful results, but owing to the cost was replaced by castings of malleable iron or steel.

White Metals: A. H. Mundey, C. C. Bissett, J. Cartland. The principal classes of white metals are reviewed, together with their composition and physical properties, chiefly in relation to their manufacture and uses.

The Effects of Overheating and Remelting on Aluminium: W. Rosenhain and J. D. Grogan. The work described was undertaken to ascertain whether certain forms of treatment in the melting and remelting of aluminium would cause deterioration approximating to the condition generally described as "burnt" aluminium. High melting and casting temperatures, and even prolonged heating at a high temperature, gave no evidence of any serious deterioration in the quality of the metal. Repeated rolling and remelting were also without appreciable effect.

The Constitution and Age-Hardening of Alloys of Aluminium with Copper, Magnesium and Silicon in the Solid State: Marie L. V. Gayler. The quaternary system of alloys containing aluminium, copper, magnesium and silicon has been regarded as the ternary system aluminium-copper-magnesium silicide, since magnesium and silicon were added in the proportions of the compound magnesium silicide. The solubilities of copper and magnesium silicide in solid aluminium were determined at 500° C. and 250° C. Alloys of various compositions were quenched from 500° C. and allowed to age-harden at room temperature. The results showed that the age-hardening of these alloys is due to the difference in solubility at high and low temperatures of both copper and magnesium silicide. Derived differential curves of alloys which had been quenched but not aged showed three critical points. The highest critical point is suggested to be due to the precipitation of the copper compound, and the next to that of magnesium silicide.

First Report to the Aluminium Corrosion Research Sub-Committee of the Corrosion Research Committee of the Institute of Metals on Experiments on the Oxide Method of Determining Aluminium: J. E. Clenell. The drawbacks of the method for determining aluminium as oxide are discussed and improvements are suggested. Of the various methods examined, that in which thiosulphates are used for precipitation gives, on the whole, the best results. By working according to the standard method described, a practically complete precipitation of aluminium is obtained.

The Copper-rich Aluminium-Copper Alloys: D. Stockdale. An attempt has been made to settle some of the doubtful points concerning copper-rich alloys. Two general methods of fixing the various points were used, viz., the taking of cooling curves and the micro-examination of quenched specimens. The results showed that, contrary to Curry's statement, small quantities of aluminium do not raise the freezing-point of copper. The liquidus presents a minimum at 8·3 per cent. aluminium and shows a maximum at about 12·5 per cent., though the alloys in this neighbourhood all freeze at about the same temperature, 1047° C. The solidus shows the existence of eutectic over a range of alloys containing 7·5, 8, and 8·5 per cent. aluminium; alloys with 10 to 14 per cent. aluminium exhibit cooling curves typical of pure metals. At 16·5 per cent. a second eutectic makes its appearance, whilst the 18 per cent. alloy freezes like a pure metal. The positions of the lines bounding the phase fields formed by the constituents α, β, γ have been carefully determined, and the existence of the γ phase and transformation of the γ to δ phase have been confirmed. The temperature of the eutectoid transformation, determined by quenching experiments, is near 537° C.

The Cleaning of Aluminium Utensils: R. Seligman. In the absence of the author this paper was taken as read. It dealt in general with the cause of corrosion of aluminium utensils and showed that the presence of sodium silicate prevented the corrosive action of the soda. Certain cleansers sold under trade names were recommended.

New Forms of Apparatus for Determining the Linear Shrinkage and for Bottom-pouring of Cast Metals and Alloys, accompanied by data on the Shrinkage and Hardness of Cast Copper-Zinc Alloys: F. Johnson and W. G. Jones; The Hardness of the Brasses and some Experiments on its Measurement by means of a Strainless Indentation: F. W. Harris. These two papers were taken together. The apparatus was designed to be sufficiently simple and robust in operation for use in industrial work. The motion of a shrinking test-bar is conveyed through two steel arms, gripped rigidly by the cast bar, to a micrometer, the head of which is attached to one arm and the anvil to the other. Results of hardness tests on chill cast and annealed bars in both papers are in common agreement, and show an elusive maximum. The hardness curve of sand-cast bars, as shown in Harris's paper, does not give a definite maximum hardness. The author shows that the "absolute" hardness number of a metal is given by strainless indentations. These are obtained by repeated annealings of the metal to remove the strain round the impression and the replacing of the ball in the original indentation and again applying the load. This is repeated until the point is reached when the indentation is of sufficient superficial area to enable the metal to support the load by virtue of its own intrinsic resistance to distortion.

The Structure of Eutectics: F. L. Brady. It is shown that each eutectic grain consists of an inner portion, fine in grade and of uniform fineness, and a boundary of varying thickness, the grade of which is much coarser and of different arrangement. Two possible causes of this structure are discussed. The forms of eutectics may be divided into classes according to certain physical properties of the components; the division proposed shows the considerable connexion that exists between the physical properties, especially surface tension and the structure.

The Antimony-Bismuth System: Maurice Cook. The equilibrium diagram of the antimony-bismuth alloys is shown to consist of an unbroken liquidus curve, whilst the solidus is horizontal up to 60 per cent. antimony. The microstructures of slowly-cooled and quickly-cooled alloys reveal an apparent duplex structure which can be rendered homogeneous with sufficiently long annealing. The results lead to the conclusion that an isomorphous series of alloys is formed.

Note on the Cause of Red Stains on Silver-plated Work: A. Jefferson. The author discusses the possible origin of the red stains sometimes observed on articles electroplated with silver. Hypotheses regarding the origin of these stains were put to the test; ultimately, it was found that the application of rouge was responsible for the red stain; insufficient material at hand, however, prevented the matter being further examined.

Intermetallic Actions. The system Thallium-Arsenic: Q. A. Mansuri. In this paper the author claims to establish the facts that thallium and arsenic alloy in all proportions but do not form any solid solutions. An eutectic is formed at 215° C. between thallium and arsenic, and forms the solidus. The liquidus consists of the primary separations of thallium and arsenic, broken by a gap showing the presence of two layers of liquid.

INSTITUTION OF CHEMICAL ENGINEERS

At the thirteenth meeting of the Provisional Committee, held on September 20, the solicitors announced the receipt from the Board of Trade of a letter stating that the application for a licence to register the Institution under the provisions of Section 20 of the Companies' (Consolidation) Act, 1908, had now been entertained.

The secretary reported that over 180 applications for membership had been received, and that the names of those applicants which had passed the Selection Committee would be brought before the first Council as soon as formed.

The report of the sub-committee on the relations between the Chemical Engineering Group and the Institution of Chemical Engineers was considered and action was postponed until a later date. A vote of thanks was carried unanimously to the Registrar and Council of the Institute of Chemistry for their kind assistance in explaining fully their office organisation.

NEWS AND NOTES

UNITED STATES

The New Customs Tariff

The McCumber-Fordney Tariff Bill was signed by President Harding on September 21 and came into operation on the following day. As passed, the Bill contained no embargo on dyestuffs, coal-tar and synthetic organic chemicals, and foreign potash is to be admitted free of duty. Provision is made for increasing the duties imposed if foreign competition is shown to be injurious to a home industry. In general the rates of duty are increased by 15—20 per cent., but those on certain chemicals, metals, etc. are much higher. The following are some of the rates fixed:—Coal-tar intermediates, 7 cents per lb. *plus* 55 per cent. *ad valorem*; coal-tar dyes, 7 cts. *plus* 60% *ad val.* based on the American valuation; citric acid, 17 cts. per lb.; essential oils, animal oils and greases, ethers and esters, 20 cts. per lb. *plus* 25% *ad val.* The free list includes ores of tin, cobalt and copper, various crude drugs, fertilisers, potassium chloride and crude potash salts, thorium ores, sodium nitrate, sulphur, turpentine, rosin and wax, etc.

Peace-time Uses of War Chemicals

The United States Chemical Warfare Service has recently discovered that the use of hydrogen cyanide as a fumigant can be replaced by that of cyanogen chloride, which is a powerful lachrymatory when used at only one-tenth of the lethal concentration. Encouraging results are also being obtained in experiments on the admixture of a "sneezing" gas with illuminating gas as a means of detecting an escape of the latter, the sternutatory being destroyed when the gas is burned. Progress continues to be made in the use of poisonous gases against insect and rodent pests, notable work having been done recently in combating locusts in the Philippines; and attempts are being pursued to find a gas for destroying the cotton boll-weevil. Very successful experiments have been made by the Louisiana Department of Agriculture in spraying powdered calcium arsenate on cottonfields by means of the air blast from the propeller of an aeroplane; in this way it was found possible to treat 20 acres of cotton per hour much more thoroughly than by means of apparatus worked on the ground, and to reduce by one-half the amount of material needed.—(*Chem. and Met. Eng., Sept.* 13, 1922.)

Anthrax in the Tanning Industry

An analysis of 123 cases of anthrax occurring in the tanning industry of Pennsylvania during the twelve years from 1910 to 1921 showed that the number of cases represented roughly 12 per cent. of the employees directly exposed to infection, *i.e.*, those handling, soaking and liming raw stock. The mortality among these 123 cases was over 21 per cent. Accurate statistics for a five-year period revealed a yearly morbidity rate of nearly 2 per cent. From a study of the sources of infection it is concluded that certification (that imported hides are from districts free from anthrax) offers little if any protection to the tanner. It is therefore suggested that all undisinfected imported stock should be treated at central governmental disinfecting stations before dispatch to the tanners. Experience has shown that the best treatment consists in the continuous, intensive use of anti-anthrax serum, applied subcutaneously or intravenously, combined with excision of the local lesion and injection of a concentrated solution of phenol (25 to 50 per cent.) around the wound. Early diagnosis, prompt treatment and rest are essential for successful treatment. —(*J. Ind. Hygiene, June,* 1922.)

Census of the Dye and Coal-tar Products Industry

The U.S. Tariff Commission has issued a preliminary summary of the census of dye and coal-tar chemicals for 1921, based on the output of 200 firms that manufacture coal-tar products. Adequate supplies of coal-tar during the year were ensured by the increased production of by-product coke, which corresponded with a smaller output from beehive ovens. The statistical information given includes that set out below in tabular form.

Coal-tar products	No. of makers	Output lb.	Inc.(+) or Dec.(—) per cent.	Sales. lb.	Value of Sales. $
Intermediates (232)	107	70,899,912	— 73	33,637,326	8,483,463
Coal-tar dyes ..	74	39,008,690	— 56	47,513,762	39,283,956
Colour lakes ..	43	6,152,187	— 44	6,424,612	2,863,189
Medicinals ..	34	1,545,917	— 68	1,876,246	2,930,324
Flavours ..	17	901,245	+440	933,662	1,002,018
Perfumes ..	15	119,335	+ 20	119,691	175,815
Synthetic phenolic resins	3	1,643,796	— 65	1,674,456	1,352,166
Synthetic tanning materials	4	1,902,597	— 39	1,721,359	141,005
Research chemicals	—	2,012	+ 9	901	18,334
Photographic ,,	5	183,798	— 58	170,221	248,041

The production of dyes in 1921, grouped according to methods of application was as follows:—Acid dyes 7,751,698 lb. (19·87% of the total output); basic dyes 1,852,243 lb. (4·75%); direct cotton dyes 6,787,634 lb. (17·4%); sulphur dyes 10,239,255 lb. (26·25%); vat dyes (including 6,673,968 lb. of indigo) 7,019,120 lb. (17·99%); mordant and chrome colours 3,773,438 lb. (9·67%); lake and spirit-soluble dyes 697,444 lb. (1·79%); unclassified dyes 887,858 lb. (2·28%).

Cadmium in 1921

The production of cadmium in the United States began in 1906 with a small output by the Grasselli Chemical Co., and afterwards increased steadily, reaching a maximum in 1917. In 1921 production of cadmium metal declined to 65,101 lb., valued at $63,799, but that of cadmium sulphide attained the record of 65,446 lb., valued at $71,336. Electroplating with cadmium by the udylite process (*cf.* J., 1921, 628 A) was in use by 18 firms late in 1921 and contracts were made for installations in 9 other plants.—(*U.S. Geol. Surv., Apr.* 10, 1922.)

CANADA

Industrial Notes

The establishment of American branch factories in Canada continues this year to a greater extent than ever. The Anaconda-American Brass, Ltd. has been incorporated in the Dominion with a capital of $1,000,000, with head office at New Toronto, Ontario. The Lion-Meade Tyre Co., capitalised at $2,500,000, is building a factory at Wrightville, Hull, Quebec. A large factory for the production of asbestos goods, at Asbestos, Que., is being erected by the Johns-Manville Co., of New York; over $1,000,000 is being spent on the building and equipment, and the very extensive deposit of high-grade asbestos at Thetford Mines has been acquired. Among other American industries that have recently set foot on Canadian soil are cutlery manufacture, at Hamilton and Welland, electric bulbs at Oshawa, automobile plants at Sarnia and Windsor, silk mills at Cowansville, silk-dyeing and finishing at Drummondville, and textile-dyeing at St. Johns. The number of new industries initiated at Hamilton, Ont., during this year is 13, as compared with 24 for the whole of last year.

It is announced that Bryant and May, Ltd. has acquired the majority of the stock and controlling interest in the Canadian plant of Maguire, Paterson and Palmer (Can.), Ltd. at Pembroke, Ont., and the establishment will be under the same general management as the Canadian Match Co.

Projected Nitrogen-Fixation Plant

The Electro-Chemical Company of Canada intends to erect a plant for the fixation of atmospheric nitrogen at Queenstown, Ont., within a few yards of the power-house of Chippeawa Canal, on the Niagara River. The process employed will be that covered by the patents of J. S. Island. The company proposes to start with a plant of 3000 kw. which, it is said, when running at capacity, will have a potential output of 3174 tons of nitric acid (commercial 64 per cent.) annually. Experimental plants have been in operation at Brantford and Niagara Falls, Ont. Calcium nitrate will be the chief product.

Mining and Metallurgy

British Columbia.—Large deposits of kaolin have been found in the Cariboo District, south of Williams Lake and about half a mile from the Pacific Great Eastern Railway.

The Granby Consolidated Mining, Smelting and Power Co. is producing copper at 9·7 cents per pound. This is the lowest cost in the history of the company and compares with 11·63 cts. in 1921 and 15·94 cts. in 1920. It is hoped to reduce the cost still further after the new hydro-electric installation has been completed.

The spelter trade of British Columbia is very active, and large shipments are being made to the Orient and Europe. All the stock of lead and spelter which had accumulated after the war, owing to price conditions and irregular exchanges, has been cleaned up. A year ago Japan commenced extensive purchasing of spelter, which was followed by European buying, with the result that the demand for lead and zinc in foreign markets is almost exceeding the supply.

It is announced that legislation will be submitted during the next session of the British Columbian Legislature with a view to the establishment of iron and steel works. A company has been organised with a capital of $12,000,000, and, according to the announcement, the provincial government will unite with the Imperial and Canadian governments and guarantee, as its share, bonds not exceeding $4,000,000. The Coast Range Steel Co. has been incorporated with a capital of $15,000,000, and it is understood that representatives of the company have discussed the matter with the facilities committee of the Imperial Board of Trade and the British Columbian government. The proposed plant will have a production of about 120,000 tons finished steel per annum.

Northern Ontario.—Rich silver ore has been found on the property of the Wigwam Silver Mines, at Wigwam Lake, in the Gowganda district. The company is controlled by Montreal interests.

The magnitude of the development of the gold mines of Northern Ontario is attracting world-wide interest, resulting in efforts being made by well-known mining capitalists to obtain control of developed properties. It is reported that the Teck-Hughes mine will pass into the control of the Consolidated Goldfields of South Africa. Interests associated with the International Nickel Co. are also reported to be endeavouring to secure some properties. The Kirkland Lake Mining Co. has struck rich gold ore on its property. The mine adjoins the Teck-Hughes, and the main shaft is down 1000 feet. Important strikes are reported from the Holtyrex district, north-east of McIntyre and Hollinger. The value of the ore was $9·60 per ton.

Alberta.—A large consignment of McMurray tar-sand has been shipped to Swansea, Wales, for extraction of bitumen at an experimental plant. Several small-scale plants have been built and operated in Alberta for the treatment of these bituminous sands, but, so far, no authentic figures have been given of yields and approximate costs.

FRANCE

Industrial Notes

Chemical Industry.—The destruction by fire of Merck's factory at Darmstadt will affect the supply of fine chemicals in France. After the conclusion of hostilities the reappearance in the French market of Merck's products was received almost with a sigh of relief, so bad had the substitutes been found to be. This does not necessarily mean that French fine-chemical manufacturers cannot make products as good as those of Merck, but rather that they are too heavily handicapped by excessive manufacturing costs, for which the high prices of raw materials are responsible. To take one instance: the price of alcohol, a basic raw material, is always maintained at an exorbitant level.

The rumour that, in accordance with the Wiesbaden " agreement," a group of French dye-works is negotiating with German chemical firms for the supply of chemicals, is viewed with great concern by French chemical manufacturers, as such a policy would eventually lead to the closing down of their works.

The demand for ammonium sulphate and calcium cyanamide is very keen, but there are practically no inquiries for nitrate.

Metallurgy.- The demand for metallurgical products has slackened, although stocks, particularly of pig iron and semi-finished products, have been almost exhausted by orders from Great Britain and America. Prices, however, seem fairly stable. There is great activity among makers of iron and steel goods, especially agricultural machinery, but owing to foreign competition the production of machine tools is suffering severely. The announcement that a metallurgical trust, under the control of Herr Stinnes, was being formed between firms in Lorraine and Germany, came as a great surprise. As the French metallurgical firms find difficulty in obtaining adequate supplies of coke and the German firms are confronted with short supplies of iron ore, it seems natural that efforts should be made to arrive at some kind of industrial " understanding "—not to use the word " trust," for so far the problem has been considered without any idea of an *entente*. At present the French are investigating means of producing a good metallurgical coke to replace Ruhr coke, and the Germans have started to make plant for producing pig iron, now imported from France. Under the projected agreement, (1) the Germans would not need to build such plant; (2) the Ruhr would furnish the Lorraine works with a steady supply of coke, after "reparation" coke had been delivered; (3) the Hagondage, Knutange and Rombas works in Lorraine would supply the German metallurgical industry with semi-finished products; and (4) German capital would be represented to the extent of 25 per cent. of the capital of the Lorraine companies. The Lorraine firms mentioned deny that they have come to any agreement with the German firms, but the general impression is that strong influences on both sides are working to discover some common ground on which to base an understanding. The idea of German financial intervention is, of course, out of the question.

GERMANY

German Dyestuffs for the United States

After consultation with the Allied Powers, Germany has agreed to deliver to the United States dyestuffs to the value of $256,000,000 on account of the cost of the American Army of Occupation in Germany.—(*Ind.- u. Handels-Z., Sept.* 30, 1922.)

Discovery of Iron Ore

At the general meeting of the German Geological Society, held recently in Breslau, Herr Krusch, of Berlin, reported that a new iron ore worth exploiting, called "white iron ore" and consisting of nearly pure iron carbonate, had been found in bands of 2 metres in thickness in the low-lying moorlands of North Germany.

The Fire at Merck's Factory

The fire which broke out on September 15 in the establishment of E. Merck in Darmstadt was confined to the store-rooms and was soon brought under control. The factory itself did not suffer. No explanation is forthcoming as to the origin of the outbreak, but the loss incurred is covered by insurance. —(*Chem. Ind., Sept.* 15, 1922.)

Agreement Among German Glassmakers

According to the *Berliner Tageblatt*, the Union of German Factories for Glass Instruments in Ilmenau, and the Union of Thermometer and Glass Instrument Factories in Roda, have formed a community of interests ("IG"), and it has been agreed that glass tubes made by the firms of Schott (Jena), Fischer (Ilmenau), and Greiner and Fredrich (Stutzerbach) shall be sold only to members of the two Unions.—(*Bd. of Trade J., Sept.* 28, 1922.)

Dutch Clinker

In many Dutch and German streets, particularly the former, a beautiful bluish clinker is used for street-paving. Little is known of the nature and origin of this material, but usually it is the so-called Dutch clinker which, by the use of suitable raw material and fuel, is obtained after long baking in the form of very durable bricks. According to P. Thor (Tonindustrie-Zeitung) these are still made mainly in simple clamp-kilns, though ring-kilns with a temporary reducing atmosphere have been successfully introduced in northern Holland. The best fuel is a cut peat of medium calorific value and the firing period lasts from 15 to 20 days, according to the size of the kiln.

The New Börner Airship

In the issue of *Kraft und Stoff* for August 19, S. Hartmann describes the Börner airship, in which an external envelope of nitrogen is used to protect the mixture of coal gas and hydrogen contained in the balloon. Duraluminium is used in the construction of the vessel which, filled with 300,000 cb.m. of gas, could carry a useful load of 90 to 100 metric tons on a continuous voyage of 5000 to 6000 km., and could travel to New York in 48 (?) hours. —(*Chem.-Z., Sept.* 9, 1922.)

Rapid Evaluation of Motor Fuels

The Chemische Fabrik A.-G. has placed on the market a simple apparatus for rapidly estimating the value of a motor fuel. The method is based upon the work of the late Karl Dietrich, and utilises the comparative insolubility of purified "dragon's-blood" resin in benzine and paraffin hydrocarbons, and its solubility in benzol, alcohol, and halogen derivatives of the paraffins. The procedure consists of shaking a piece of "dragon's-blood" test-paper with a sample of the liquid fuel in a glass vessel; benzine remains colourless, but benzol and alcohol become dark red. The test is carried out more accurately by placing the end of a piece of filter paper in the liquid, which is coloured preferably with "dragon's-blood." The height of capillary ascent of the liquid and the characteristic zones of colour formed on the paper afford information concerning the composition of the fuel, and this may be confirmed by determining the refractive index of the fuel.

Mineral Production, 1913-20

The following statistics give a general view of the course of mineral production in Germany in the period 1913—1920. The ores for which output figures are given, in thousands of metric tons, are not only important as sources of metals but as raw materials of the chemical industry.

	1913	1917	1919	1920
Copper and arsenical ores :—				
Output of crude copper ore	947·8	960·1	616·8	576·2
Output of crude arsenic ore	25·8	39·1	26·1	38·4
Number of employees ..	13,292	15,122	12,196	10,849
Lead, silver and zinc ores :—				
Output	2,884·8	2,812·7	1,703·4	1,772·7[*]
Number of employees ..	21,282	18,223	17,047	18,018
Pyrites :—				
Output	268·6	803·7	381·4	436·3
Number of employees ..	821	1,920	1,604	1,821
Tungsten ore :—				
Output	15·8	106·8	20·6	1·4
Number of employees ..	148	613	370	69
Bauxite :—				
Output .. .. .. [†]	—	10·8	9·4	13·4
Number of employees ..	—	190	173	310
Tin, cobalt, nickel, bismuth and sulphate ores :—				
Output	34·3	138·0	123·3	65·5
Number of employees ..	585	1,020	1,326	1,071

[*] In Upper Silesia the output of ore was 10,32,700 t.

[†] The output for 1913 is included in the production of tin, cobalt, etc. ores.

The very small output of tungsten ore in 1920 was due to the resumption of importation, imports being six times as great as in 1913; and the reduced output of ores of tin, cobalt, etc. was the result of foreign competition. Of all the ores mentioned, zinc-ore production shows the largest decrease compared with that of 1913, viz., 54 per cent. Formerly the production of zinc metal was only 11 per cent. behind that of the United States, much imported ore being smelted; but in 1920 there was an excess of 2247 t. of exported over imported ores, and the production of metal fell to 77 per cent. below that of the United States. The partition of Upper

Silesia has entailed the loss of 66·1 per cent. of the output of zinc ore and 60·2 per cent. of the production of metal.

BRITISH INDIA

First Forecast of the Sesamum Crop

This official forecast includes, for the first time, the crop under sesamum in Burma. The total area planted to this crop in British India, exclusive of the United Provinces, is estimated to be 2,329,000 acres, which compares with 1,543,000 acres (excluding Burma) at the same time last year. Except in Bengal, the weather at sowing time was favourable and the present condition of the crop is good, although rain is wanted in certain areas.—(*Ind. Tr. J., Sept.*, 7, 1922.)

SOUTH AFRICA

Motor Fuel from Maize

The Diamond Motor Spirit Co., Ltd., has been formed in England, and will be registered shortly in South Africa, for the purpose of manufacturing industrial alcohol from maize. A site for the factory has been selected in East London, and the erection of buildings and plant will be begun at the end of the year. The total cost is estimated at £100,000, and the production is estimated at 8000 to 10,000 gallons of spirit per day. It is hoped to retail the spirit profitably at 1s. 6d. per gallon.—(*S. Afr. J. Ind., Aug.*, 1922.)

Nicotine Content of S. African Tobacco

In view of the proposal to establish a tobacco-extract factory in the Piet Retief district, Transvaal, the nicotine content of tobaccos from different localities in South Africa has been investigated under the direction of Dr. C. F. Juritz. It was concluded from the investigation that the air-dried leaves of the heavier tobaccos, such as those grown at Barberton, Piet Retief, and Potchefstroom, contain from 3 to 5 per cent. of nicotine, and the leaves of the lighter tobaccos not much above 2 per cent. and often less than 1 per cent. Leaves of the common wild tobacco (*N. glauca*) appear to contain much less than 1 per cent., but those of *N. rustica* have yielded 6 to 8 per cent. and even more of nicotine. The alkaloid occurs in all part of *N. rustica*, but mainly in the leaves, and mature plants show the highest content.—(*S. Afr. J. Ind., Aug.*, 1922.)

JAPAN

Rejection of the Dye Embargo

The Japanese Government has declined either to grant an embargo on imports of dyes or to increase the duty to protect the home dyestuffs industry. Japanese dye manufacturers asked for the duty to be increased from 35 to 70 per cent. *ad valorem* and for the imposition of import licences to cover the following colours made satisfactorily in Japan:—Rhodamine B, Methyl Violet, Bismarck Brown, Fast Red A, Malachite Green, Direct Black, Naphthol Brown, Cotton Violet, Sulphur Black, Sulphur Brown, Magenta, Orange A, and Congo Red. At present Japanese dyestuffs find a market only in adjacent countries and then only at very low prices. The home market is overstocked with German dyes, against which American, French, and Italian products are competing, and sales are limited by the depression in the textile industry. About one-half of the Japanese consumption of dyestuffs is imported, the total value of the requirements being roughly $15,000,000 per annum. Recently the value of imports from Germany and Italy has amounted to about $7,000,000 per annum, and from the United States to about $500,000.—(*Chem. and Met. Eng., Aug.* 9, 1922.)

GENERAL

Oil Technology at Birmingham University

It is officially announced that the chair of mining in Birmingham University has been subdivided into two professorial chairs. One professor will devote his time to coal and metal mining, and the other will be wholly engaged in the department of petroleum and oil engineering, for which large sums have recently been received from leaders in the industry. It is intended to build up an important school of oil engineering which, with the exception of the Imperial College of Science, London, will be the only one of its kind in the British Empire. Prof. R. R. Thompson, formerly Director of Lands and Mines in Trinidad, has been appointed to the chair of oil mining, and Mr. K. N. Moss to that of coal and metal mining.

Home-Grown Sugar

Working arrangements have been made for the future amalgamation of Home Grown Sugar, Ltd. and of the English Beet Sugar Corporation, Ltd., which owns the Kelham and Cantley beet-sugar factories, respectively. In accordance with these arrangements, the British Sugar Beet Growers' Society, Ltd. announces that, this year, the sugar-beet crops grown for Kelham will be worked at the Cantley factory. By working the crop, now grown on more than 8000 acres, in one factory, which will thus be able to work at full capacity, it is hoped to ascertain the lowest economic cost of production for future guidance. Proposals for improving and extending the Kelham factory for the same purpose are under consideration.

Dry Cooling of Coke

A correspondent to the *Times Trade Supplement* of September 9 outlines a new method of quenching coke which has been operated at the gasworks at Zürich. The glowing coke is placed in a closed tank through which a stream of non-inflammable gas is circulated by means of an electric fan; the gas may be flue gases or air from which the oxygen has been removed by previous contact with hot coke. The heat taken up by the gas is utilised in raising steam, and the gas is re-circulated through the tank until the temperature of the coke falls to about 500° F., at which the coke does not break into flame on exposure to air. The first year's working at Zürich showed that one ton of coke yielded an average of 886 lb. of steam at 57 lb. pressure, with feed water at 40° F., so that 1 lb. of coke yielded 450 B.Th.U. in the form of steam. Large quantities of heat and therefore of fuel may thus be saved; the coke produced is of better quality; and less labour is required because the plant is automatic. As the coke is discharged intermittently, a supply of steam has to be provided while the tanks are being refilled.

Peppermint Oil in China and Japan

China and Japan are the only countries in the Far East which produce peppermint oil in important quantities. In China the chief centre of production is Kwantung province, the oil is extracted at Canton, and about 2500 lb. per annum is exported, mainly to Hongkong. The plant is also grown in Kiangsi province, but very little oil is exported. In Japan, the largest centre of peppermint cultivation is Hokkaido, where over 20,000 acres are planted. The districts of Bizen, Bingo, Bitchie, Shitsuka and Okujoto are also large producers. The export from Japan in 1920 was 185·3 tons of peppermint oil, valued at 1,812,366 yen, and 221·5 t. of menthol, valued at 5,489,815 yen (yen = 2s. 0½d. at par). The United States is the chief consumer of Japanese menthol and peppermint. Japanese peppermint oil has an unusually large content of menthol; the dementholised oil has a disagreeable taste and odour and compares unfavourably with the product of other countries (*cf.* J., 1919, 404 R; 1921, 106 R).—(*Ch. of Comm. J.*, June 9, 1922.)

New Manganese Deposit in Hungary

The deposit of manganese ore recently discovered near Urkut lies on the southern spurs of the Bakony Forest, north of Balaton Lake. It will be developed partly by open and partly by underground workings. The initial plant is already being erected, so that the works will probably be in operation by the middle of 1923.

PERSONALIA

Dr. P. Uhlenhuth has been appointed director of the Institute for Experimental Therapy Emil von Behring in Marburg a/Lahn.

Dr. G. P. Teodorescu, of the University of Berlin, has been appointed professor of analytical chemistry in the Polytechnic, Bukarest.

Prof. A. Lottermoser has taken up his duties as director of the laboratory for colloid chemistry, recently established in the Technical *Hochschule*, Dresden.

The Hanbury Gold Medal of the Pharmaceutical Society has been awarded to Prof. E. Perrot, of the Faculty of Pharmacy in the University of Paris, for his researches in the natural history of drugs.

The Council of the Chemical Society has elected Prof. J. F. Thorpe to succeed Dr. M. O. Forster as hon. treasurer, and Dr. J. T. Hewitt to fill the vacancy so created in the list of vice-presidents.

Dr. F. B. Power, director of the biochemical department of the Bureau of Chemistry of the United States Department of Agriculture, has been awarded the Flückiger Medal of the Swiss Pharmaceutical Society.

* * *

Prof. F. T. Trouton, F.R.S., emeritus professor of physics in the University of London, died on September 21, aged 58 years.

Major-General J. Waterhouse, formerly Assistant Surveyor-General of India, died on September 28, aged 81. The deceased received the Progress Medal of the Royal Photographic Society in 1890 for his spectrographic investigations on the action of dyes on dry plates, and served as president of that Society from 1905 to 1907. In 1895 he was awarded the Voigtländer Medal of the Vienna Photographic Society.

REPORTS

REPORT OF THE GOVERNMENT CHEMIST UPON THE WORK OF THE GOVERNMENT LABORATORY FOR THE YEAR ENDING MARCH 31, 1922. *Pp.* 33. *London: H.M. Stationery Office*, 1922. *Price* 1*s.* 6*d.*

The total number of samples examined at the Central Laboratories in London and at the chemical stations in the provinces was 302,562, or 6113 less than during the previous year. Additional work has been imposed on the Department in connexion with the Safeguarding of Industries Act, the Dangerous Drugs Act, and the Dyestuffs (Import Regulation) Act. The report contains detailed statistics relative to the work done for various Government Departments, together with summarised results of some of the analyses made and observations upon matters of outstanding interest.

During the examination of dairy produce it was noted that the proportion of fat in different samples of cheese varied between 9·9 and 38·8 per cent., but no exception could be taken to this, as there are no regulations relating to the marking of unskimmed cheese. There were also large variations in the fat content of condensed milks owing to the adoption of different degrees of evaporation during manufacture.

Work connected with the analysis of waters is increasing because of the investigations being conducted upon the effect of drainage from tarred roads and of other types of pollution upon fish and fish food. Sea-waters are being examined in connexion with the oceanic research scheme of the Fisheries Departments, and efforts are being made to devise a more rapid method of determining the salinity that can be applied readily at sea.

The analyses of several fertilisers and feeding-stuffs were found to differ from the guarantees given upon invoices. One compound manure, sold without a guarantee, was found to contain only 2·6 per cent. of nitrogen and only such a proportion of phosphates and potash as would be found in ordinary soil. Cement, plaster, burnt wood, paper, string, glass and gypsum were found in materials purporting to be feeding-stuffs.

In connexion with the assessment of beer duty 29,642 samples were tested. There were only 702 samples of imported beer, as compared with nearly 10,000 in the year before the war. Arsenic in excess of the legal limits was found in 24 samples of brewing materials, 2 samples of malt and sugar, and 3 samples of beer and wort.

The question of the presence in chocolate of fat other than cocoa butter has continued to receive attention, and the method of determination previously described has given satisfactory results (*cf.* J., 1921, 372 R).

Fourteen samples of drugs were found to contravene the provisions of the Dangerous Drugs Act. Over 3000 samples were examined under the Safeguarding of Industries Act; in many cases the analysis was complicated, the nature of the examination required being frequently entirely different from that employed commercially.

The characteristics of denaturants and colouring substances for alcohol intended for industrial use have been specially investigated during the year. For the purpose of controlling the use of duty-free spirits many samples of denaturants, spirits, residues from stills, and manufactured articles were examined. Samples of imported and home-produced fusel oil were examined to ascertain whether they contained less than 15 per cent. of proof spirit or whether they were dutiable.

The variety of preparations containing sugar is so great that fixed rates of duty have been adopted for those regularly imported or exported, but there are many articles which have to be examined on each importation. Owing to the heavy duty on saccharin, search has to be made for it in all preparations in which there is any probability of its occurrence.

All consignments of tea imported are examined for purity; owing to the high prices ruling and to the dislocation of foreign markets numerous small shipments of doubtful quality have been made and have necessitated very extensive sampling. The packages condemned numbered 5035.

Many samples of tobacco were examined to determine the rate of duty and the contents of water and olive oil. Denaturants for tobacco, such as sulphur, asafoetida, sago flour, tar oil, carbolic and cresylic acids, moss litter, soda ash, borax, hellebore, cayenne, lampblack, and saltpetre, essential oils for flavouring purposes, and preservatives, were also examined.

The recovery of radium from one batch of luminous dials, gunsights, etc. was completed for the Disposal Board, over 300 mg. of radium bromide of 90 per cent. purity being obtained. In addition, 100 mg. of concentrated material suitable for immediate use was recovered.

The quantity of lead contained in the fumes evolved during the cutting of ships' plates by oxy-acetylene burners has been investigated (*cf.* Report on Factories and Workshops, J., 1922, 334 R). Specimens of dust from a plant used in bleaching flour were found to contain basic tin nitrate, the violent decomposition of which had been responsible for an explosion.

REPORT OF THE COMMITTEE OF THE PRIVY COUNCIL FOR SCIENTIFIC AND INDUSTRIAL RESEARCH, 1921—22. *Pp.* 123. *H.M. Stationery Office*, 1922. [*Cmd.* 1735.] *Price* 3*s.*

The economies effected recently in the Department of Scientific and Industrial Research have not interrupted good work already in hand, but have merely slowed down the programme of research. The total expenditure of the Department in 1921—22 was £525,584, and the net expenditure from public funds, exclusive of grants to research associations, was £333,552 (against £427,432 in 1920—21). Among the separate items were £190,024 (less receipts) for the National Physical Laboratory; £43,266 for the Fuel Research Station (less £1,883 from sales of by-products); £57,423 on the Geological Survey and Museum; £10,323 for the work of the Building Research Board; and £17,750 on the station for low-temperature research at Cambridge. Expenditure on grants in aid of scientific investigations conducted by other bodies amounted to £8287, and £47,005 was given in allowances to University research students (205), independent research workers (55), and to scientific workers (20) for the employ of laboratory assistants or the purchase of equipment.

Twenty-two of the 24 associations that have received licences are in active work and 3 new associations are likely to be formed shortly. Research associations, it is stated, cannot look for further grants from Parliament after the original fund of £1,000,000 has been exhausted. Reports are quoted from firms in the Portland cement industry as to the value of the work done by its association, and among other useful work accomplished is recorded the preparation by the British Scientific Instrument Association of a new polishing powder and a new abrasive for optical elements, the use of which saves much time and material. The association for the cotton industry has produced an instrument for recording the regularity of yarns, and that for the linen industry means of readily distinguishing flax and hemp fibres. In several instances research associations are engaging in co-operative work, and individual associations are undertaking fundamental scientific investigations.

Through the co-ordinating research boards Government departments are conducting their research work in closer co-operation, and there is a growing tendency to publish results. Under the Chemistry Co-ordinating Research Board researches on the partial oxidation of hydrocarbons have been carried out at the Royal Naval Cordite Factory where a semi-technical plant is being erected to obtain data on the possibility of manufacturing formaldehyde by this method; and under Dr. D. L. Chapman, of Oxford, results of much scientific interest have been obtained on the indirect production of methyl alcohol from methane *via* methyl chloride. The British Scientific Instrument Association has elaborated a method of producing zinc sulphide with a luminosity, in presence of radium, much greater than that obtained hitherto. Applications to the Board to conduct in Germany an inquiry into the causes of the explosion at Oppau were refused, but certain theories relating thereto are being investigated in the Government Laboratory and at Woolwich. Other work undertaken, or considered, bore on the improvement of accumulators and dry cells, the manufacture in this country of celluloid film for photography, and the corrosion of aluminium and its alloys. In the Oxygen Laboratory of the Air Ministry the question has been considered of replacing charcoal by non-inflammable substitutes as an adsorbent in the vacuous space of liquid-air containers, with the result that silica appears to be a good material for this purpose.

Physical properties of gases that are commonly stored and transported as liquids are being determined at the National Physical Laboratory for the Gas Cylinders Research Committee, which is also considering the use of alloy steels for making gas cylinders. Although fewer tests have been made at the National Physical Laboratory, more special researches have been conducted for research associations and private firms. The metrolog department has been busy; the engineering department is making investigations for the Lubricatio Research and other committees; the metallurgica department has published the results of researche on aluminium light alloys, and, in conjunction wit the Iron and Steel Institute, has prepare chemically standardised samples of steel.

The Fuel Research Board has studied the steaming of coal in vertical gas retorts, the national co resources, pulverised coal, peat, and domestic heating, power alcohol is still being considered, an experiments are to be undertaken on the production of tetrahydronaphthalene ("Tetralin") for admixture with petrol as a motor fuel. Research has been initiated by the Building Research Board on cement, brick-burning, titanium dioxide as a substitute for white lead, and the use of "Dekalin," a naphthalene derivative, as a thinner for paint. The new low-temperature research station of the Food Investigation Board has been completed, and work is being continued on the production of lactic acid in muscle at low temperatures, on putrefaction, etc. Information on the present practice in kiln-drying timber has been collected by the Forest Products Research Board, of which Prof. J. B. Farmer has been appointed chairman and Sir David Prain director of research. Work for the Lubrication Research Committee is proceeding at Cambridge (theory of friction), and at the National Physical Laboratory (pressure distribution in plain cylindrical bearings—failure in lubrication in large high-speed journals). The research work at the British Museum continues to yield valuable results, and the provision of a more convenient laboratory will enable the work to be extended.

The Board is considering the possibility of issuing accounts of investigations performed under its auspices to the daily Press.

Report on the Industrial and Economic Situation in Greece, to April, 1922. *By* E. C. D. Rawlins, *H.M. Commercial Secretary, Athens. Department of Overseas Trade. Pp.* 73. *H.M. Stationery Office,* 1922. *Price* 2*s.*

During 1921 Greek trade and industry suffered severely from political and economic difficulties, and the cereal crops were poor. Production of olive oil declined to 45,180 metric tons, but efforts are being made to improve the industry by introducing modern appliances for extraction and by combating the olive fly which greatly reduces the crop. The valonea crop of 500 tons was nearly double that of 1920. Exports of emery rose by 2317 to 12,709 tons. The Anglo-Greek Magnesite Co., Ltd. (a British company), produced 33,100 t. of crude magnesite, but exported, mainly to Holland and Germany, only 9130 t. of crude, 7055 t. of caustic calcined, and 750 t. of dead-burnt magnesite; other companies shipped 10,000 t. of crude ore, chiefly to Holland. The demand for magnesite was poor. Most of the chrome ore mined was shipped to France. The smelting of lead and zinc ores at Laurium and the mining of manganese ore are still restricted; the average value of the annual output of lead and arsenious oxide is Dr. 4,000,000 (average value of drachma in 1921=3·15d.).

Greek industry is small compared with that of Western Europe, but Greek products, such as soap, fertilisers and cement, are exported to other countries of the Levant. Development of the rich beds of lignite and of the potentially available water-power (estimated at 365,000 h.p. in Central Macedonia and the Greek mainland) would do much to promote industrial life. The chemical and related industries are progressing. There are four up-to-date factories for the manufacture of glass and pottery, sulphuric acid (from local pyrites) and fertilisers are made in one large works, and there is one modern factory making coal-tar dyes. Soap, sulphur oil, turpentine oil and colophony are manufactured from local raw materials; the leather industry has been long established; and there are six paper factories and five breweries.

The value of imports during 1921 was Dr. 1,674,375,055 compared with Dr. 2,131,038,321 in 1920. British trade lost ground to countries with depreciated currencies. Pharmaceutical products are now mainly supplied by Germans, who are also doing much trade in heavy chemicals; soda products, formerly almost a British monopoly, are being imported from Antwerp at a much lower price than the British; and glassware is once again being derived from Czechoslovakia. Exports in 1921 increased in value by Dr. 167,057,623 to 831,170,270. Detailed statistics for the complete year are not available.

OFFICIAL TRADE INTELLIGENCE

(*From the Board of Trade Journal for September* 28 *and October* 5)

THE GAS-MANTLE INDUSTRY

The text of the report of the committee appointed under the Safeguarding of Industries Act, Part II., to inquire into the importation of German incandescent gas mantles into this country, is given in the *Board of Trade Journal* for October 5. The committee's conclusions are summarised as follows:—

We are in the main satisfied that the bulk of the German mantles which are imported into this country are sold to dealers at the prices fixed by the Convention of German Mantle Manufacturers.

This price is very much above German manufacturing costs, very considerably lower than the costs of manufacture of the principal British manufacturers, and distinctly lower even than the lowest prices of British mantles quoted by the opponents as an indication of the real minimum cost of manufacture in this country. We find that the difference between the costs put before us by the principal British manufacturers and the price of the German goods is so large as not to be substantially affected by any qualification we may make with regard to the former.

We are of opinion that this capacity to undersell is principally due to the advantage which the Germans derive from their low costs in respect of labour, salaries, and other overhead charges, when reckoned in sterling, for the reason that these charges have not increased in proportion to the decrease in the exchange value of the currency. This advantage is not offset to any appreciable extent by any necessity to purchase raw materials abroad.

We are of opinion that, in view of the progressive rise in German imports, coincident with a decline from other sources, and in view particularly of the wide margin between German domestic wholesale prices and the Convention selling price in Great Britain, these imports have, and are likely to have, a serious effect upon employment in the home gas-mantle trade.

We are not convinced that the imposition of a duty on gas mantles would have any appreciable effect on employment in the gas industry, which is the only industry which, we think, could possibly be considered as using mantles as *material.*

We are of opinion that the gas-mantle industry is over-capitalised, and that this fact must tell against full economy in cost control, but that, as regards processes of manufacture and use of materials, it is up to date and efficiently conducted.

OPENINGS FOR BRITISH TRADE

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence), 35, Old Queen Street, London, S.W. 1, from firms, agents or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number.

Locality of Firm or Agent	Materials	Reference Number
Australia ..	Industrial chemicals, spring steel	356
Brazil.. ..	Iron and steel	352
British West Indies ..	Cement	9529/E.D./M.C.
Canada ..	Chinaware	323
,, ..	Pig iron	9594/E.D./E.C.
Czechoslovakia	Pharmaceutical goods, drugs, patent medicines	333
Egypt.. ..	Glass, glassware, pottery ..	225/36/F.G./M.C.
,, ...	China, earthenware, soap, perfumery, leather	371
France ..	Boot and metal polishes.. ..	711/F.G./M.C.
,, ..	Yeast	363
Germany ..	Ores, metallic residues	334
Hungary ..	Leather	335
Italy	Tin, tinplate, blackplate, copper..	336
,, ...	Iron, steel, tinplate, copper and brass pipes, lubricating oils ..	365
Mexico ..	Coal-tar dyes	6829/F.L./C.C.
,, ...	Kola oil, extract of coca, caffein and hyssop	6747/F.L./C.C.
Netherlands ..	Chemicals, soap, perfumery ..	337
,, ..	Alum, formaldehyde, caustic soda, Epsom salts, sodium sulphate, ferrous sulphate, soda crystals, sodium bicarbonate, tartaric acid, sodium bisulphate, sodium sulphite, copper sulphate, ammonium chloride, glacial acetic acid (98–100%), etc., paper, earthenware	341
Norway ..	Leather, imitation leather ..	368
Switzerland ..	Boot and metal polishes.. ..	711/F.G./M.C.

TARIFF CUSTOMS EXCISE

Angola.—The duty on rubber exported from ports outside the Congo Basin has been reduced to 0·1 per cent. and 0·2 per cent. *ad valorem*, respectively, according as the destination is to a Portuguese or a foreign port.

Australia.—The duties on certain categories of iron and steel products have been amended. The complete text of the reciprocity agreement between Australia and New Zealand is published in the issue for October 5; British preferential rates of duty are accorded to all goods not specified in the schedule.

Belgian Congo.—An export duty of 10 per cent. *ad valorem* has been levied on hides and skins.

Canada. — Provisions for the valuation for customs purposes of goods imported from countries with depreciated currencies have been applied to goods made or produced in Austria, Czechoslovakia, Germany, Hungary, Yugoslavia, and Russia. The period during which oleomargarine may be manufactured in, or imported into, Canada has been extended until August 31, 1923.

East African Protectorate.—By the customs agreement entered into with Uganda all export duties have been abolished.

Egypt.—The import duties on alcoholic liquors have been revised.

France.—A "co-efficient of increase" of 3 has been applied to the import duties on cellulose pulp not destined for the manufacture of paper for newspapers, periodicals and other publications.

Germany.—Articles with a sugar basis and fruits preserved or prepared in spirits may not be imported. New rates of monopoly tax have been applied to imported spirits, and the tax on imported acetic acid and vinegar has been increased to 56,190 marks per hectolitre of anhydrous acid.

Greece.—Recent modifications of the import duties affect coconut and palm oils, groundnuts, petroleum, coal-tar dyes, Sulphur Black, ethers, certain wares of porcelain and glass. "Co-efficients of increase" have been applied to the duties on cocoa, metal polishes, petrol, alcohol, white metal, and the importation of "luxury articles" is prohibited.

Jamaica.—A list of new duties on exports of spirits, wines, or spirituous liquors has been issued.

Japan (Korea).—The duty on tinplate for use in canning cottonseed oil is reduced by 70 sen per 100 kin; for tinplate of United Kingdom origin this remission equals the amount of import duty leviable.

Mauritius.—Increased customs duties have been applied to denatured alcohol, methylated or plain spirits, etc.

Mexico.—New rates of export duty on petroleum and its products have come into force.

Morocco (French Zone).—The following consumption duties have come into force:—Saccharin and artificial sweetening substances, 500 fr. per kg.; glucose and unspecified sweet materials (excluding glucose used in brewing), 20 fr. per 100 kg.; sugared products, condensed milk containing sugar, from 20 to 60 fr. per 100 kg.

Netherlands.—Animal fats that bear proof of having passed an official inspection are exempted from the Dutch regulations for the inspection of imported meat.

Poland.—A surtax of 79,900 per cent. has been applied to the duties on imported spirits, cork stoppers, wares of porcelain and glass, scent and cosmetics, soap, washing blue, artists' colours, and manufactures of copper, tin and certain other metals and metallic alloys.

Portugal.—By a recent Decree, the surtax on colophony is fixed at 50 escudos per metric ton, on essence of turpentine at 500 esc. per m.t., and a special surtax of 10 per cent. is applied to goods not specially mentioned.

Portuguese East Africa.—*Ad valorem* rates of duty have been applied to exports of certain grades of sugar.

Rumania.—It is proposed to increase the duties on dextrin, starch, glue, sesamum oil, tartaric acid, and lampblack.

San Salvador.—Preparations for purifying water are dutiable at the rate of 2 centavos (gold) per kg. The import duty on perfumed and toilet soap has been reduced to 40 centavos (gold) per kg.

Solomon Islands.—The export duty on copra has been fixed at 12s. 6d. per ton, and on ivory nuts at 15s. per ton.

Yugoslavia.—The import duties on goose grease, lard, and raw pigs' fat have been withdrawn.

COMPANY NEWS

NITRATE COMPANIES IN 1920-21

Of the eight nitrate companies whose financial year ended in June, 1921, all except one made increased profits, but only one paid a larger dividend and in three cases the dividend was reduced. Reserves increased by £35,145 to £639,333, and the sums carried forward rose from £116,868 to £335,088. The total share capital increased by £8268 to £2,045,068, due to the absorption of the San Lorenzo and Buena Ventura companies by the Liverpool Nitrate Co. Three companies disclosed an average estimated trading profit of 65·3d. per quintal (of 101·44 lb.), as against 30·5d. in 1919–20, and the combined trading profits of the eight companies represented 38·1 per cent. on the capital employed, compared with 30·5 in 1919–20. Dividends distributed amounted to £207,132, or an average of 10·1 per cent. on the total share capital, compared with £318,765, or 12·5 per cent., in the previous year.

The thirteen companies whose financial year closed on December 31 did badly during 1921: profits declined and dividends were reduced substantially. Their total issued capital was £3,664,950, the decrease of £200,000 being due to a reduction in the capital of the Lautaro Co. Debentures were diminished by £55,200 to £203,600. Reserves, excluding sums allocated to depreciation etc., fell by £249,351 to £959,665, and although most of the companies increased their carry-forward, a heavy reduction by the Alianza Co. brought the total down by £128,772 to £1,016,764. The position, however, is still good, as the reserves and carry-forward combined represent over 50 per cent. of the total share and debenture capital. The total estimated output was 2,965,417 quintals, which compares with 9,354,432 quintals in 1920. Reliable figures for calculating the average profit per quintal are not available. A total of £512,122 was distributed in dividends, representing an average of 13·9 per cent. on the total share capital, as against 21·7 per cent. paid on £3,864,950 in 1920.

Combining the figures of the 21 companies, the total share capital amounts to £5,710,018, upon which £719,254, or 12·5 per cent., was distributed in dividends, compared with £1,158,606, or 19·7 per cent., paid on £5,901,750 in 1920. Statistics of production, profits, etc. are appended.

NOBEL INDUSTRIES, LTD.

The address of Sir Harry McGowan to the third annual general meeting, held in London on September 22, was devoted to a detailed explanation of the company's financial position and of its investments in associated companies. Nobel Industries, he said, had weathered the storm of industrial depression and the outlook was hopeful. One of the essentials at the present time was to reduce the cost of manufacture, and hence selling prices. Owing partly to a slight fall in the cost of raw materials, but mainly to the policy of concentration which had been pursued, the company had been able four times during the past twelve months to reduce the prices of explosives, etc. Although much trade had been lost owing to the coal stoppage and general depression, the gross profit for 1921 was over £1,200,000, and the net profit, after deduction of income-tax, was £809,241. Out of this sum it was proposed to allocate £350,000 to a reserve fund, to pay 5 per cent. on the ordinary shares, and to carry forward £463,349. [The issued capital is £15,818,654, of which £7,958,872 is in ordinary shares and £3,000,000 in 8 per cent. 7-year notes. Investments in associated and other companies stand at £21,043,040.] A consolidated balance-sheet had been made out for the year 1920, which showed that there was a surplus of £3,000,000 of assets over all liabilities, and that actual values existed in full, pound for pound, for the entire share capital, with a substantial margin. The position at December, 1921, would be found to be no less satisfactory, and at the present time neither the parent company nor any of its constituent companies were indebted to banks in any part of the world.

The company had a large interest (809,425 shares) in the General Motors Corporation, an American company whose business was now improving; the investment in the Dunlop Rubber Co., which had effected many economies, remained the same, as did also that in the British Cellulose Co., but, owing to financial reconstruction, Nobel Industries had been forced to accept 6 per cent. income bonds in lieu of first debentures. The directors of the Cellulose Co. were so satisfied with recent progress that they had decided to extend the plant. The chairman of the British Dyestuffs Corporation had assured him that its works were now much more

* Estimated. † Loss.

—(*So. Amer. J., Mar.* 18, *Aug.* 19, 1922.)

efficient than formerly, and that when the textile industry improved the company should be working on a profitable basis. All the shares of the British Pluviusin Co., which manufactured artificial leather, were owned by Nobel Industries, and good results were expected for 1922. Considerable economies in the manufacture of gas mantles had resulted from the formation of Lighting Trades, Ltd., but German competition was being felt severely. The Chilean Explosives Co., in which Nobel Industries held 50 per cent. of the capital and American interests the rest, was about to erect a factory for the manufacture of explosives, thus making Chile self-contained in that respect.

BRITISH GLUES AND CHEMICALS, LTD.

At the second annual general meeting, held in London on October 5, the address of the chairman, Mr. T. Walton, dealt mainly with the company's financial position. In 1921–22 there was a net trading loss of £64,177, against a profit in 1920–21 of £241,722, subject to taxation; the ordinary shares again receive no dividend (the preference dividend was paid up to October, 1921), and £64,177 is carried forward, against £149,873 brought in. The loss was due mainly to bad trade and to constantly falling values, which necessitated the writing down of stocks nearly to their pre-war values. Many improvements have been made in the factories and production costs have been sensibly reduced. There are no mortgages or charges on any of the company's assets and the balance-sheet shows a surplus of liquid assets over all liabilities, except taxation, of £298,440 (issued capital £1,399,984). The directors, who have waived their fees, are contesting the claims of the revenue authorities for a large sum in respect of excess profits duty.

AMERICAN CYANAMID COMPANY

The annual report of the board of directors states that in the financial year ended June 30, 1922, the company made a gross profit of $624,765, after deducting $699,081 for depreciation of plant, and that the net income was $197,992, after setting aside $288,975 for income-tax and depreciation of patents (issued capital $12,190,200). The surplus account decreased by $148,213 to $3,143,276 and $4,200,246 is held in reserve. Ordinary repairs and maintenance of plants during the year cost $232,100, and extraordinary repairs and maintenance $113,945. Results are considered gratifying in view of the prevailing abnormal conditions and the reduced activity in most of the company's departments. The company's interest in the Amalgamated Phosphate Co. is now valued at $4,982,186, and in the Air Nitrates Corporation at $1000 at par.

KAYE'S RUBBER LATEX PROCESS, LTD.

This company has recently issued a prospectus, for public information, which states that its object is to acquire and exploit Mr. F. Kaye's patents for the use of rubber latex in paper-making, and in new classes of goods such as substitutes for leather and linoleum, asbestos goods, etc. The authorised capital of the company is £12,000, of which £1000 is in £1 ordinary shares and £2000 in 1s. deferred shares. The purchase consideration is £2000 in cash and 18,000 deferred shares.

TRADE NOTES

BRITISH

The British Industries Fair, 1923

The Board of Trade announces that the British Industries Fair, 1923, will be held concurrently at the White City, Shepherd's Bush, London, and at Castle Bromwich Aerodrome, Birmingham, from Monday, February 19 to Friday, March 2. The trades to be represented in the London Section, the ninth of the series organised by the Department of Overseas Trade, include light and heavy chemicals, dyes, drugs and perfumery, glass and ceramic ware, scientific and optical instruments, paper, etc. In the Birmingham Section, organised by the local Municipality and Chamber of Commerce under the auspices of the Board of Trade, will be exhibited plant for brewing, distilling, mining, lighting and many other industrial purposes, metals and metal products (excluding precious metals), indiarubber goods, paint, colours and varnish, and weighing and measuring appliances. Approximately 90,000 illustrated booklets about the Fair are being distributed in all parts of the world as propaganda by the Department of Overseas Trade, which will also issue invitations to 50,000 overseas buyers. Prospects for securing overseas business are enhanced by the comparative failure of the Leipzig Autumn Fair, and as admittance is confined to *bona-fide* buyers, every visitor will be a potential customer. Further information can be obtained from the Department of Overseas Trade.

FOREIGN

German Trade in Chemicals in 1921-22

Although the depreciation of the German mark has led to increased exportation of many chemicals, the quantities exported are still far below those in 1913. The following figures of exportation make this clear:—

	1913	1920	July, 1921, to June, 1922
		Metric tons	
Potash salts	1,676,187	843,065	662,502
Ammonium sulphate	75,868	26,094	17,182
Sodium sulphate	83,239	15,487	46,734
Potassium sulphate	133,368	158,368	236,292
Potassium magnesium sulphate Potassium chloride	59,207		
Coal-tar and sulphur dyes ..	64,288	17,847	27,310
Alizarin and alizarin dyes ..	11,040	3,325	2,474
Indigo	33,353	6,671	12,710
Basic slag, ground	713,879	4,874	2,103
Superphosphate, etc.	282,653	1,040	13,494
Quinine and alkaloids ..	319	74·7	103·8
Drugs, prepared..	2,508	1,049	1,437
Chemicals, medicinal	1,291	285	578

Exports of potash began to improve in 1921, but fell off in 1922, although exports of other chemicals and pharmaceutical products increased. The next table shows the destinations of the exports of coal-tar and sulphur dyes in 1913 and during the first half of 1922.

		1913	Jan.–June 1922
Total export,	Metric tons	64,288	.. 15,541
United States,	Per cent. ..	21·5	.. 0·7
Great Britain	„ „	17·1	.. 1·2
China	„ „	13·2	.. 23·1
Austria-Hungary	„ „	9·0	.. —
Austria	„ „	—	.. 4·0
Italy	„ „	6·4	.. 3·5
British India	„ „	5·9	.. 6·6
Japan	„ „	5·5	.. 10·7
Belgium	„ „	3·9	.. 0·6
France	„ „	2·2	.. —
Netherlands	„ „	2·1	.. 3·5
Russia	„ „	1·3	.. —
Czechoslovakia	„ „	—	.. 12·0
Baltic States	„ „	—	.. 7·7

The chief market for German dyes is now China, followed by Czechoslovakia, Japan, the Baltic States, and British India. The United States has fallen in importance as a consumer from first to seventeenth place. The values of the chief groups of imports and exports during the years (ending March 31) 1914, 1921, and 1922 were as follows:—

	Imports			Exports		
	Millions of dollars					
	1913–14	1920–21	1921–22	1913–14	1920–21	1921–22
Plant products	98	261	173	201	483	318
Animal products	41	62	47	77	188	136
Fibres, textiles	109	244	140	22	19	5
Wood, wood products, paper	37	57	36	63	285	180
Iron and wares of ..	144	246	110	15	77	28
Non-ferrous metals and wares of	36	56	30	53	46	28
Minerals, non-metallic ..	85	206	138	9	40	23
Chemical and related products	17	36	24	5	20	9
Other products	52	73	24	6	32	14
Totals	619	1,240	748	432	1,189	740

Much ground has been lost in the export trade to Canada; Germany now holds only the fourteenth place, as compared with the fourth place in 1914.

Union of Bulgarian Producers of Otto of Roses

The producers of otto of roses in Bulgaria have amalgamated to form a combine bearing the above title. The Union has offices in Kazanlik and Sofia, with a branch office and store in Berlin, from which exportation is conducted by the Balkan Trading Company.—(*Chem. Ind., July* 3, 1922.)

GOVERNMENT ORDERS AND NOTICES

IMPORT DUTY ON GERMAN GAS MANTLES.—The Board of Trade has issued the Safeguarding of Industries (No. 2) Order, 1922, dated October 7, imposing an import duty of 33⅓ per cent. *ad valorem* on mantles for incandescent lighting and component parts thereof, whether finished or not, manufactured in Germany. Certificates of origin are required for goods covered by the Order and consigned from European countries. The Order came into force forthwith (*cf.* p. 425 R).

DISTRIBUTION OF "REPARATION" DYESTUFFS.—The Board of Trade has announced that the British Dyestuffs Corporation, Ltd. has been appointed its agent for the distribution of "Reparation" dyestuffs from Germany in place of the Central Importing Agency. In future, prices quoted will include delivery to purchasers' works or stores, and will not be subject to any commission. Prices will be quoted for packages of 60, 120, or 240 lb., and a reduction of 1d. per lb. will be made on purchases of 4 cwt. or more, and of 2d. per lb. on purchases of 1 ton or more; for less than 60 lb. the price will be increased by 1d. to 3d. per lb., to cover cost of extra packing. The Corporation may allow 30 days' credit on all accounts. The dyestuffs will be distributed under their original German denominations and, as far as possible, in their original packages. Notification of the arrival of additional quantities of dyestuffs (which will be reserved for actual consumers for 14 days) will be given through the Colour Users' Association, but the Corporation will issue a periodical list of stocks and of the current prices fixed by the Board of Trade. Inquiries should be addressed to the British Dyestuffs Corporation, Ltd., Reparation Department, 70, Spring Gardens, Manchester.

REVIEWS

MANUFACTURE OF NITRIC ACID FROM NITRE AND SULPHURIC ACID. TECHNICAL RECORDS OF EXPLOSIVES SUPPLY, 1915—1918. No. 7. *Ministry of Munitions and Department of Scientific and Industrial Research. H.M. Stationery Office,* 1922. *Pp. vi*+86. *Price* 11*s., post free.*

The production of nitric acid from sodium nitrate and sulphuric acid was carried out on a very large scale during the war. Two national factories alone, Queen's Ferry and Gretna, were able to turn out 1300 tons of nitric acid per week. Although the method used was well known before the war, it had not been worked on such a large scale, and the appearance of the atmosphere around Queen's Ferry in the initial stages of its operation was sufficient to show that the problem of condensing the oxides of nitrogen produced in the works was not solved in the design of the plant. The final arrangements are described with admirable clearness by Mr. W. Macnab in the present report, which maintains the high standard of its predecessors and is a valuable contribution to the literature of chemical engineering.

The materials for the process, Chile nitre, and the pyrites for sulphuric acid, were imported, and the great demands made on shipping for this purpose at one time became extremely serious. Great Britain is still the only great power in the world which depends almost wholly on Chile for the supply of fixed nitrogen, and the description of the antiquated method of producing nitric acid from Chile nitre may therefore still possess an intrinsic interest. The question of this dependence, however, is one which must sooner or later be faced in the interest of national defence, and it is hardly conceivable that such immense retort plants for the production of nitric acid as were in operation during the late war will ever again be employed.

J. R. PARTINGTON.

DOCUMENTS AND THEIR SCIENTIFIC EXAMINATION. *By* C. AINSWORTH MITCHELL. *Pp. xii* + 215. *London: Charles Griffin and Co., Ltd.,* 1922. *Price* 10*s.* 6*d. net.*

This is a welcome and valuable addition to the present scanty but growing literature of forensic chemistry and is written by an expert. The subject matter includes the examination of paper, pen markings, ink, pencils and their pigments in writing, handwriting, secret writing, typewriting, stamps, seals, envelopes and finger prints on documents. The apparatus and methods used are fully described and the book contains a large number of illustrations and an excellent bibliography.

The author explains that the book, which has especial reference to the chemistry involved in cases of suspected forgery, investigation of disputed documents and the comparison of handwriting, is based upon personal experience extending over many years, and that when called upon to present expert evidence in legal cases he frequently found that the available information was so inadequate or altogether lacking that he was compelled to make prolonged laboratory investigations in order to obtain trustworthy results. The present book contains the records of those experiments, some of which have already been published in scientific journals, but many of which are now given for the first time.

The chapters on pencils and their pigments in writing (one chapter being devoted to blacklead pencils and another to copying-ink pencils) are particularly valuable, and contain a wealth of new information. Until Mr. Mitchell investigated the subject it was thought to be impossible to distinguish between writing made with different pencils, but it is now shown that under certain conditions the writing done with different pencils may be differentiated both by microscopical examination and by chemical tests.

The book summarises the proved results of the latest knowledge on the subjects treated, and is confidently recommended to all who are interested, whether from the point of view of the expert, who will find much that is new and to whom it will be especially useful; the lawyer, who will learn from it the possibilities and limitations of a subject with which he is frequently called upon to deal; the business man, especially the banker, who daily handles documents that may be forged; or even the general reader, who is interested in the practical application of chemistry to everyday life and who finds a fascination in mysteries and their solution.

The problem of whether a suspected document, which may be a banknote, a will, a promissory note, a deed of sale, a register, a passport, or even a postage stamp, is genuine or not is a constantly recurring one, and the book under review shows in a very practical manner how the truth should be sought and how it may be discovered. There is only one way, and that is by the use of scientific methods scientifically applied. The value of the expert is nowhere more patent than in questions having reference to suspected documents, since many of the facts can be found only by an expert, and he alone can present them in a convincing manner to a judge and jury.

The book is well arranged, well and clearly printed on good paper, and is strongly recommended.

A. LUCAS.

DIE LÖSUNGSMITTEL DER FETTE, OELE, WACHSE UND HARZE. *By* DR. H. WOLFF. *Monographs on the Chemistry of Fats, edited by Prof. K. H. Bauer. Pp. vi+118. Stuttgart: Wissenschaftliche Verlagsgesellschaft*, 1922. *Price 9s.*

During the past year or more a noteworthy feature of the oil and fat industry of Germany has been an active propaganda among its chemists in the direction of organisation and co-operation, ostensibly for the purpose of the furtherance of research. A perusal of the German technical journals leaves one with the impression that the spirit of pre-war days is far from dead, and that apparently, in spite of the present economic condition of their country, the chemists still hope and yearn for ascendency in provinces not altogether restricted to the laboratory. As one result of this activity may be mentioned the projected publication of a series of monographs under the editorship of Dr. K. H. Bauer, dealing in a specialised manner more particularly from the technical standpoint with the various branches of the oil, fat and allied industries.

The first volume of these monographs, now before us, covering as it does a description of the properties and uses of most of the solvents employed in connexion with oils, fats, waxes and resins, undeniably fills a gap in this particular branch of technical literature. The information found in this work is for the most part either absent or only lightly touched upon in text-books on the chemical technology of oils, fats, waxes, resins, and the like.

This book, or, as it would be better designated, brochure, is divided into five main sections; the first deals in a somewhat general style with the determination of the physical constants common to most organic liquids. Density, refractive index, flash-point, boiling-point, methods of distillation for solvents of a wide boiling-range, and so forth, are each described, wisely without excessive detail. The methods given for fractional distillation, particularly those for paraffin oils, though perhaps not of great interest to the English reader—conforming as they do with German practice where the standardised apparatus used complies with the regulations issued by the German Government and other administrative institutions—are certainly instructive for comparison.

The second and main portion of the work discusses with reasonable detail individual solvents, their sources, methods of refinement and purification, and their relative merits and degrees of utility as media for effecting solution and extraction; the latter points being treated both from the laboratory and the industrial viewpoint. Amongst the hydrocarbons are described the newer synthetic products, the hydrogenated derivatives of naphthalene, "tetralin" and "dekalin"; substances not so well known in this country, but which have become notorious in Germany as a source of "copy" to the technical Press for controversial articles on their merits and demerits as articles of commerce. Following the hydrocarbons, including, of course, a full treatment of paraffin and coal-tar products as well as turpentine, are given the chlorinated compounds with their main redeeming feature, the minimised risk of fire. Alcohols, ester of formic and acetic acid, ether, and finally carbon disulphide, are all included. Where applicable, methods of quantitative estimation, chemical test for impurities, and physical data are to be found in these individual descriptions. References, however, to English and American publications are sadly meagre, and to cite only one instance, the extensive work of Dr. H. G. Colman on the estimation of benzene and toluene in coal-tar distillate would, one might think, deserve mention in a wor of this kind. A good deal of the data included i this chapter has been tabulated and incorporated in a copious appendix with other information o the nature usually found in chemical year-books.

An interesting discussion on the physiologica properties of the solvents forms the third part o the book, whilst the fourth goes into the questio of identification of the solvents either singly or i mixtures. In the final chapter is given a descrip tion of the methods of quantitatively determinin the saponification and acetyl values of those sol vents amenable to these tests.

On the whole, the book can be recommended one of great utility; the style is lucid, the printin good. The author expresses a hope that the boo will be of great practical use in the laboratory, bu is certain that this poorly bound brochure edition uld not stand for long the rigorous handling ually meted out to such books of reference. One her point which serves to emphasise the justification of the remarks made in a recent article in this *urnal* (1922, p. 111 R), is the fact that this book published in Germany at 75 marks and its price reaching this country is 9s., equal to about 700 marks. Whilst no doubt one could hardly pect to benefit to the extent of the uttermost mit of the difference in the exchange, the great isparity between the two prices gives much food r thought.

E. R. BOLTON.

1) LES COLLOÏDES. *By* J. DUCLAUX. *Second edition, revised and enlarged. Pp. x+305. Paris: Gauthiers-Villars et Cie.*, 1922. *Price* 10 *francs.* (2) KOLLOIDE LÖSUNGEN. *By* JOACHIM LEIMDÖRFER. *Pp.* 108. *Augsburg: H. Ziolkowsky G.m.b.H.*, 1921. *Price* 4*s.* 10*d. post free.*

(1) The general trend of Duclaux's work is ufficiently indicated by two—slightly contradictory —passages in the preface to the first edition, of hich the following is a careful translation: "One s entitled to assert to-day (*although the contrary pinion is widely held*) that the theory of the colloids is complete, and that it is possible to bring into it the same clearness as everywhere else. . . . The present theory of colloids, which will be found set forth below, and *which is now almost universally accepted*, is not the work of one day. . . ." (Reviewer's italics.)

The theory thus referred to is the author's well-known "Complex" theory of sols, or more particularly of the ferric hydroxide sol. This is held to consist of "micellæ" having the constitution: $nFe(OH)_3.FeCl_3$, which dissociate into the complex ion or "granule" $nFe(OH)_3.Fe^{\cdots}$ and the corresponding number of chlorine ions. The osmotic pressure of the sol varies with the number of ions formed, and therefore, assuming the concentration of $Fe(OH)_3$ to remain constant, with the number n in the formula. Appropriate treatment, *e.g.*, prolonged dialysis, may cause this number to vary from 5 to 800. Electrolyte coagulation is an ordinary precipitation reaction, governed by stoichiometric relations and the solubility product. Although, admittedly, the sol of ferric hydroxide is the only one completely investigated in this sense, the theory is put forward as perfectly general, and all difficulties are to to yield to its rigid application. The biologists in particular, whose ordinary methods the author criticises with some severity, are exhorted to lay it to heart.

It is rather surprising that the author makes no mention even of investigations tending in the same direction, such as the work of McBain and his school on soaps, or of Pauli's extension of the chemical theory to such systems as gold sols. No evidence on the other side is presented, nor is the re-examination of the ferric hydroxide sol by improved methods (Pauli and Matula, 1917) mentioned; indeed, the small number of names quoted throughout the book is remarkable, and practically no references are given.

In view of the dogmatic manner in which the "chemical" theory of coagulation is put forward, the reader will be naturally curious to learn how the crucial phenomenon of protection is explained. He will be disappointed to find that the old suggestion of a coating formed by the protective colloid is all the author has to offer, although it has been repeatedly pointed out that the quantitative relations make this quite untenable, and although it is impossible to see how such a coating, even if it existed, could prevent the exchange of, say, SO_4-ions with Cl-ions, which is said to bring about precipitation.

The descriptive parts of the book, as far as they do not suffer from the author's strong bias in favour of purely chemical theories, are written with great lucidity, and emphasis is rightly laid on the development of a specialised and perfected technique. Perhaps the least satisfactory chapter is that on adsorption, in which no reference is made to any of the theories of the phenomenon, nor to the large bulk of recent work which is gradually clearing up the anomalies found in experimental investigations, by examining the adsorption of the *solvent* as well as that of the solute.

Whilst the book cannot be said to give an adequate or comprehensive view of the present state of the subject, it should be of great interest to readers familiar with other text-books and prepared to exercise the chief privilege of thinking beings, that of making a choice.

(2) The merest tyro in epistemology would, on reading Leimdörfer's book, come to the conclusion that it could have been written only in German, with its extraordinary facilities for forming compound words, with which—presumably—an equal number of subtly differentiated concepts may be coordinated. This remark applies principally to the first part of the book, of which a little more will be said below; the second consists of a brief account of the properties of colloidal solutions and the methods used in their study, which does not differ materially, or favourably, from those to be found in the standard text-books.

The first part sets forth a theory of the constitution of matter which the reviewer cannot claim to have grasped. This failure will be viewed leniently, or even sympathetically, by anyone attempting to study the book and confronted with entirely unfamiliar concepts, such as a unit of matter called a "Schwebeteilchen" (the bald translation "suspended" or "floating" particle at once emphasises the unfitness of English as a medium for speculation); with chess boards of 49, 121 and more squares, in which these particles are arranged in ones, twos, threes and fours, symbolising the three states of aggregation, and a fourth, postulated by the author and called the "hyper-solid"; with a further element of matter called a "Kristallom," etc. All this somehow leads to a conclusion bearing more immediately on the subject of the book: that true solutions differ from sols in the source from which the energy required for dispersion is derived —this being the solvent in the former, and the disperse phase in the latter. Even if this distinction could be established by recognised methods, which seems improbable, it is not at all clear what diagnostic of systematic value it could possess.

It is difficult to conceive any class of readers who could derive from the perusal of this book any benefit at all commensurate with the time and effort required.

EMIL HATSCHEK.

OBITUARY

ALEXANDER SMITH

Prof. Alexander Smith, who died in Edinburgh, his native city, on September 8, three days before his 57th birthday, is known almost wherever chemistry is taught as the author of several text-books on chemistry of superlative worth. His "Introduction to General Inorganic Chemistry" and his "General Chemistry for Schools and Colleges" are particularly well known, but nearly all his works have been translated into German, Russian, Italian, and Portuguese. As these books attest, Alexander Smith was a great teacher: he had the gifts of personality, originality, and of lucid and stimulating exposition. Unfortunately he overburnt the candle of life—he was a most strenuous worker—and his early death leaves a gap that will be hard to fill; but his text-books are a legacy that will perpetuate his memory for many years to come.

Prof. Smith received his chemical education in the Universities of Edinburgh and Munich, where he graduated B.Sc. and Ph.D., respectively. His first important appointment was to the chair of chemistry and mineralogy in Wabash College, Indiana, which he resigned in 1894 to become professor in the University of Chicago, where, perhaps, his best work was done. In 1911 he became professor and director of the department of chemistry in Columbia University, City of New York, resigning this post about two years ago owing to ill-health. His scientific papers included original investigations on diketones, the benzoin reaction and on potassium cyanide as a condensing agent; and in inorganic and physical chemistry he did notable work on the liquid and amorphous forms of sulphur and the determination of vapour pressures. Among the honours bestowed upon him were election to the presidency of the American Chemical Society and conferment of the honorary degree of LL.D. of Edinburgh University.

WILLIAM KELLNER

Dr. William Kellner died in London on September 12, in his eighty-third year. Born at Frankfurt in 1839, he received his scientific training under Prof. Wöhler at Göttingen, where he eventually took his Ph.D. degree. In 1862 he came to England as assistant to Sir H. Roscoe at Owens College, Manchester, whence in 1864 he went to Woolwich and joined the staff of the War Department Chemist, then Sir Frederick Abel. In his early years at Woolwich Dr. Kellner was engaged in the varied general work of the Chemical Department. Later his main work became investigatory and experimental in connexion with explosives, and to meet the requirements of the various Commissions and Committees on which the War Department Chemist was a prominent member; of these the Royal Commission on Accidents in Mines and the Explosives Committee (appointed in 1889 to produce a smokeless powder for the Service) may be mentioned.

Dr. Kellner also devoted much work to the production of an apparatus for determining the flash-point of oils, and was largely responsible for the Abel flash-point apparatus, subsequently perfected; in collaboration with Sir Boverton Redwood he carried out an exhaustive series of tests with this apparatus.

As a scientific worker Dr. Kellner was painstaking and methodical, and he displayed much skill in devising experiments. His most important practical work was that undertaken at Woolwich in connexion with the evolution of cordite; in spite of the numerous smokeless powders which have been brought into use since, the fact that after a period of 30 years cordite still remains the British Service propellant for Army and Navy use, is perhaps the best testimonial to the thoroughness of his work in this direction.

In 1892 Dr. Kellner succeeded Sir Frederick Abel as Chemist to the War Department and, in addition to the duties of this office, served as an Associate Member of the Ordnance Board and as Consulting Chemist to the Royal Gunpowder Factory at Waltham Abbey. He retired from the Service in 1904. Kellner was one of the first Fellows of the Institute of Chemistry and served on its Council from 1895 to 1898.

Of an extremely modest and retiring disposition, the value of Dr. Kellner's work was little known outside his Department; he had a kindly and sympathetic nature, and his courtesy and cheerful optimism charmed those with whom he came into contact and won him a large circle of friends.

REVIEW

Vol. XLI] OCTOBER 31, 1922 [No. 20

INTERNATIONAL CONGRESS ON LIQUID FUELS PARIS, 1922

THE growing importance of liquid fuel renders necessary the standardisation of nomenclature and of methods of analysis. This was recognised some years prior to the war, and several International Congresses were held to deal with these important matters. It has remained for the Société de Chimie Industrielle to realise that the time was ripe for re-starting these annual meetings.

An International Congress on Liquid Fuels, and an Exhibition, were held in Paris, from October 9 to 15, in a building specially erected on the Esplanade des Invalides, under the direction of the Société de Chimie Industrielle and the presidency of M. Paul Sabatier. The success of this first Exhibition and Congress organised by the Society, is a proof of its activity and foresight. The chairman, M. Paul Kestner, and the secretary, M. Jean Gérard, are certainly entitled to the many congratulations they received upon the success of their arduous work.

The Exhibition was comparatively small but exceedingly interesting, and was remarkable for the comparatively large amount of space occupied by firms connected with the academic and scientific side of the petroleum industry. Many small Diesel and semi-Diesel engines were shown in action, and considerable business seems to have arisen from the Exhibition. Many types of burners and furnaces were shown, some in action, and great interest was taken in a small central-heating installation, in which very heavy oil was being burnt without the use of either compressed air or a positive pump for spraying the oil. On the scientific side there were exhibitions of refractory glasses of the Jena type, for one of which—the "Boromica" glass—it was claimed that the co-efficient of expansion was about 33 per cent. less than that of a Jena glass. Some new types of laboratory fractionating columns were shown, in which the column itself is protected by an outer jacket, which can be evacuated if liquids of high-boiling point are fractionated. Engines were shown that were running on fuels containing different proportions of ethyl alcohol.

The attendance, in spite of the counter attractions of the Motor Show, was on the whole very good, and towards evening the rooms were congested. The Exhibition was visited by several Ministers, and by the President himself. The keen interest taken by the heads of the political world in scientific and technical matters in France is in marked contrast to the apathy shown under similar circumstances in our own country.

The Congress was divided into six sections, and the principal matters dealt with in each section were as follows:—

1. *Petroleums.*—Distillation and distillation products of crude petroleum: motor spirit, kerosene, heavy oils, lubricating oils, paraffins, vaseline, etc., and their uses.
2. *Shales.*—Distillation and products of distillation: heavy and light oils.
3. *Lignites and Peat.*—Distillation and distillation products: benzols and tars.
4. *Coal-tars and Benzols.*
5. *Alcohol.*—Alcohol production, uses of industrial alcohol, and admixtures of alcohol with other combustible liquids for use as fuels.
6. *Vegetable Oils.*—Use of vegetable oils as fuels and as lubricants.

The Congress was formally opened on the morning of October 10 by M. Paul Sabatier, who briefly outlined its aims and gave a historical sketch of the problems requiring solution, showing both the necessity for fixed nomenclature and unified methods of analysis, and for the compilation of a systematic inventory of the world's resources in fuels. He pointed out that the reserves were not inexhaustible, and asked whether before they disappeared, and so upset the conditions of modern life, it would not be possible to produce combustibles synthetically, and on an industrial scale, utilising, as plants do, solar radiation for producing carbohydrates from water and carbonic acid. The results realised in chemistry, since the discovery of catalytic processes, gave great hope of the possibility of accomplishing this.

Prof. Daniel Berthelot dealt with the question of a national liquid fuel, which, as he pointed out, the war had proved to be a vital one for all nations. France being an essentially agricultural country, the national fuel was alcohol, and the only question was, whether it could compete in price with petrol. He described the work of the scientific committee appointed to consider this subject, and gave reasons for the final decision that for the present mixtures of petroleum fuels with a certain amount of ethyl alcohol should be used. He referred to the various proposals which had been made to render ordinary commercial alcohol (95 vol. per cent.) miscible with commercial motor spirit in comparatively small proportions, such as the addition of butyl alcohol, isopropyl alcohol, cyclo-hexanol, "tetralin," ether, and the like.

The following two problems of an international character were put down for special consideration, namely :—

1. Terminology and characteristics of liquid fuels. 2. Analytical methods for determining these characteristics.

An international commission, appointed at the inaugural meeting to consider these problems, recommended that each nation represented should draw up a classified list of all commercial liquid fuels, together with exact particulars of their physical and chemical constants, as well as of the methods and apparatus employed for determining these constants, in accordance with a scheme approved by the commission ; the lists to be presented for consideration to the Fourth International Conference of Applied Chemistry, to be held at Cambridge in 1923. A sub-committee was appointed to draw up a form to be used in furnishing the information for each individual fuel ; this form was approved at the final meeting of the Congress. References were made to the work of the American Government Departments on testing methods and to that of the Standardisation Committee of the British Institution of Petroleum Technologists.

It can hardly be said that the organisation for the reading of papers was entirely successful. In the first place, frequently three meetings were going on simultaneously, and in the second place, the meetings were held in rooms within the Fuel Exhibition, and the noise of moving machinery and the roaring of oil-burners did not make for clarity in the proceedings. Then, again, the number of papers presented was far too great for the time available ; at future meetings it would be advisable to have a selection or editorial committee to select the papers of outstanding interest for reading and discussion, the remainder merely to be printed. As it was, in Section 1, between 9 and 11.55 a.m., ten papers were announced for reading and discussion. Many were not read in entirety, and many were not read at all ; in consequence, one never knew at what time to be present to hear any given paper. All the papers will be published in a special number of *Chimie et Industrie*, which should appear in November. Many of the papers in all Sections were compilations dealing with generalities, rather than original work dealing with specific subjects, a few were of the advertisement type, and some were of outstanding interest. As the official *précis* of the papers presented to the six sections occupies 30 pages of close print, in this place it is only possible to indicate their nature very briefly.

In the Petroleum Section Dr. J. P. Wibaut, of Amsterdam University, read a most interesting paper on the relationship between single and double linkages of the carbon atoms in hydrocarbons, as measured by the heats of combustion. From a technical point of view, M. A. Mailhe's paper on industrial and laboratory processes for transforming solid into liquid hydrocarbons, either by cracking or catalysis, was important. A paper by MM. H. Gault and A. Merle on petroleum in Madagascar was of considerable economic interest ; experiments have shown the possibility of obtaining oils by distilling mixtures of local bitumens in special plant. Other papers dealt with petroleum from various sources, methods and apparatus for obtaining, testing, and using it. Two papers dealt specially with the production of petrol by the hydrogenation of heavy oils, according to the Bergius process.

In the Shales Section a paper by Admiral P. Dumas and Mr. Cunningham Craig urged the necessity for developing shales and bituminous peat, described the modes of their formation and the methods of mining them, and outlined distillation and refining processes. There were papers on the French shale measures, on those of the Lower Alps and of Esthonia, as well as on the various bituminous rocks of Syria, and also on the French shale industry and on new methods of distillation, etc.

The Lignite and Peat Section dealt with the lignites of Hérault, Aude, and of Serbia. Papers were also read on the low-temperature distillation of lignites and on the recovery of by-products. It was brought out in the papers, and in the discussion, that the French lignites can be as successfully worked as those of Germany ; those of Hérault, for example, give 15 per cent. of crude oil, from which 25 per cent. of light oils, similar to benzol and petrol, can be obtained. A description was given of the French peat fields, and of methods of winning, treating and using the peat.

In the Tars and Benzols Section, papers were read on the production of benzol in the principal countries, on the treatment of tars and benzols as sources of liquid fuels, and on the subject of liquid fuels in relation to the low-temperature distillation of coal. The question of de-benzolising in small establishments was discussed by M. Baril, who explained that the technique was not well understood, because the law fixing a limit to the calorific value of gas was still before the Chamber, and, therefore, no one in France was troubling to work out de-benzolisation on economic lines. Two other papers were read on the same subject. Modern methods of extracting benzol from coal gas were described as well as the manufacture of cyclo-hexanol, the hydrogenation of phenol by the platinum-black method, and the hydrogenation of naphthalene. The use of benzol and of naphthalene in connexion with the production of a national liquid fuel was considered.

The principal papers read before the Alcohol Section discussed the production of alcohol from vegetable materials and from ethylene ; its use, either alone or in admixture with hydrocarbons in internal-combustion engines, and as a national liquid fuel. Other papers which proved of great interest related to the hygroscopicity of absolute alcohol, the preparation and use of alcohol in combustible liquid mixtures, the findings of the scientific committee on a national liquid fuel, and the trials in connexion with the use of alcohol in admixture with benzol, petrol and ether in the London General Omnibus Company's 'buses. A paper in this section which attracted great attention, was that by M. W. Vernet describing a new process (*Procédé* Prodor) for the production of alcohol by the acid hydrolysis of sawdust and cellulosic materials. Strong hydrochloric acid, both liquid and gaseous, is used, and the operation takes place at ordinary temperatures in a vessel which is constructed of an acid-resisting concrete, made of fine quartz and pitch. A yield of 250 litres of 100 per cent. alcohol per metric ton (56 gallons to the long ton) is stated to have been obtained in a semi-technical plant.

A series of papers was read before the Vegetable Oil Section on the production of these oils, and another series on their utilisation in internal-combustion engines, particularly in the colonies, where petrol is not available. Palm oil, groundnut oil and even castor oil can be used, but objections were raised in regard to their acidity and consequent action on the cylinders and valves.

The proceedings terminated with a most interesting lecture by Professor Mailhe on the production of petroleum bodies by the hydrogenation of vegetable oils. The possible bearing of this on the theory of the origin of petroleum was briefly referred to.

The social side was by no means neglected. The delegates were received by the Committee of Organisation at the Palais d'Orsay on the evening of Monday, October 9, and on Tuesday evening at the Hôtel de Ville there was a reception by the President of the Municipal Council. On Saturday evening the delegates were invited to a banquet at the Palais d'Orsay, where the chair was taken by the Minister for Public Works, who referred to the interest taken by the French Government in the subject which had been discussed by the Congress, and whose importance was not only national but world-wide.

THE COLLOID MILL

A. FORSTER and J. REILLY

According to Svedberg, the preparation of colloidal solutions can be grouped under two general headings : (a) the condensation method, depending on the building up of disperse particles from molecules ; (b) the dispersion method, in which the solid material is scattered throughout the liquid by various means. There is a large literature on the technical preparation of these solutions by (i) chemical reactions, which can be classified under either (a) or (b), and (ii) electrical methods which come under grouping (b). It is curious, however, that mechanical means to disperse materials have not been employed technically, except on a limited class of substances until a comparatively recent date. In the present review attention will be confined to a recent development of this method of producing colloids.

For many chemical and technical purposes it is often necessary to reduce materials to a certain degree of division, and recently much attention has been given to the evolution of disintegrators and so-called " colloid " mills—machines for greater efficiency and new effects in fine grinding. The method employed is the application to the material of a high-power blow, either direct as in ball- and hammer-mills, or by throwing the material at a high speed against a resistant wall, as in throw-mills. The limitations of dry grinding, however, even with these machines, have long been realised, owing to the resistance of the air, the development of frictional heat, and the necessity for ventilation. Consequently, in mills aiming at maximum division the material is suspended in a liquid—usually water. In the disc-mill—perhaps the best known of these—the material in an aqueous suspension is fed into the centre of two discs in rapid revolution, either in the same or in opposite direction, and becomes disintegrated by its friction against the discs while being forced centrifugally to their edges. Another general form is the " dismembrator," in which the material in aqueous suspension is fed on to the axis of a high-speed revolving arm-wheel, surrounded by a number of close-fitting baffles.

Recently Dr. Plauson and his co-workers have published papers and patents* claiming the attainment of new effects in mechanical milling, whereby ultra-microscopic suspensions of particles less than 0·001 mm. diameter, which show the characteristic Brownian movement, are readily obtained with a wide range of substances. Two types of mill have been employed. One is a disc-mill in which is applied (a) an adjustable pressure to the suspension passing through the discs, (b) a continuous circulation of the milled suspension, and (c) a rapid counter-revolution of the discs at 2000 r.p.m. The other mill consists in principle of a "dismembrator," in which Plauson's innovations are (1) the rotating arm-wheel is placed eccentrically towards the base of the containing case so that the material continually falls into the field of action instead of circulating centrifugally outside the arm-wheel range, (2) the reduction of the baffles to the minimum number—two for balance—in order to obtain a maximum force at each; in the ordinary dismembrator the force is divided over a number of baffles; (3) the application of extremely high speeds of revolution.

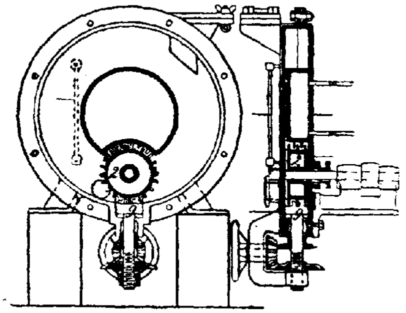
Plauson has embodied his modifications of the dismembrator mill in a standard design, generally known as Plauson's Colloid Mill, as shown in the diagrams. The standard size of this mill is 15 litres capacity, but larger sizes have been built. The containing case is a circular body of cast iron (or other suitable metal), the front being detachable on horizontal arms for inspection and repairs. The body is double-cased in the casting, the cavity being arranged for heating or cooling. The beater-wheel is mounted on a horizontal shaft (ball bearings) eccentrically placed. It consists of several armed discs of special quality steel bolted together. The arms pass closely with 1 to 3 mm. clearance through gaps in the stationary baffles (or anvils) above and below the axis of the revolving shaft carrying the beaters. The number, width, arrangement and clearance of the teeth may be varied. The beater-wheel and the two baffles almost fill the lower part of the mill case; in the upper part are feed-holes, level-gauge, sight-glass, cooling coils and steam-inlet. As an additional effect perforated baffle-plates are arranged co-axially with the beater-shaft in order better to retain the material within the area of the beater-wheel. The arm-wheel is rotated by a belt-drive up to 3000 r.p.m. The material in suspension is added through an inlet into the case, and, becoming engaged by the revolving wheel, is subjected to the forces between the wheel-arms and the baffles.

The arm-wheel at its high speed of revolution (3000 r.p.m.) may be considered to be running in a highly cavitated fluid offering small resistance, thus avoiding much of the loss of power experienced in some other mills by undue friction. The surrounding liquid suspension is said to be continually thrown towards the arms of the rapidly rotating wheel. The particles in suspension in this liquid receive a powerful blow either directly, or through the liquid between the travelling arm and the water behind it, at such a velocity as to shatter them before any of the force can be dissipated, thus utilising the short-duration high-energy impulse transmitted through the water. The disintegrating action of this mill is probabl in the main, mechanical. The use of t enclosing baffles is to impart an increase pressure to the liquid being forced through it b the travelling arm. Stress also is laid upon t function of the force of each individual blow the disintegration of particles, and distinctio is made between the positive results in th direction effected by a powerful force of sho duration, and the negative results of a small force over long periods. Thus, for each substance there is a minimum impulse, that is, i the colloid mill, a minimum rate of revolution the arm-wheel, below which disintegration cannot be achieved. This critical or specific ra of revolution depends upon the hardness, ela ticity, and strength of the material, and range roughly from 3000 r.p.m. upwards. In preparing some emulsions, it is stated that excessiv speeds have a coagulating effect. In certai cases temperature, too, it is stated, must b kept within certain limits for the best results.

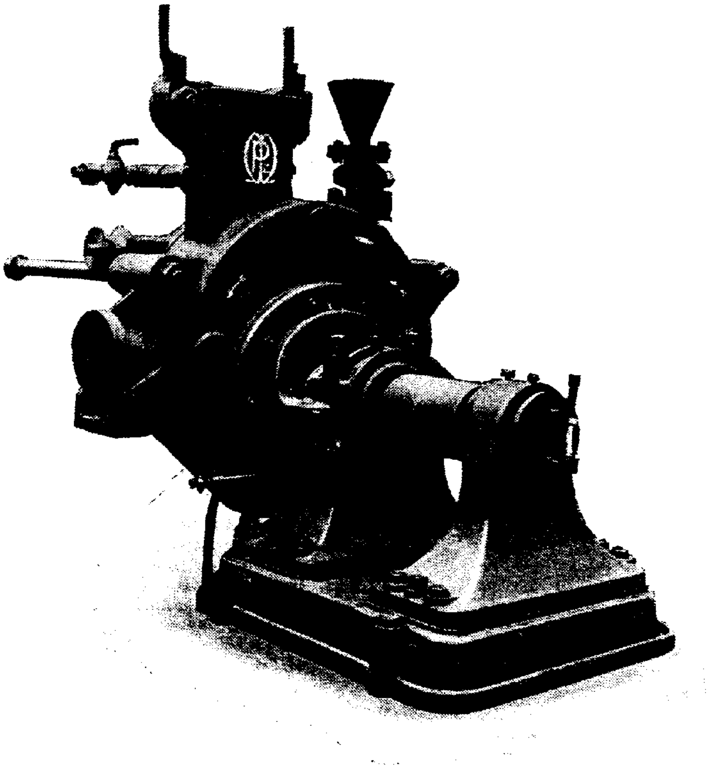


Sectional View of Mill: Front and Side Elevation.

In almost every colloidal preparation, however, the mechanical action of this mill i assisted by the addition of "dispersators" o "accelerators," which are claimed to be necessary for the preparation and permanency o many colloids. Their purpose is, by physical o chemical means, to allow or accelerate the disintegration of the particles and reduce th power consumed by the mill. Theoretically their function is to absorb or to precipitat soluble electrolytes always present, althoug sometimes only in traces, in the material bein reduced to the colloidal state. Actually, they appear to act as protective colloids. These accelerators cover a wide range of substances, as may be seen in the patent literature quoted. Another use claimed for the mill is the fractional disintegration of mixtures of substances of different hardness, enabling a ready separation of the less disintegrated ingredient by settling.

During a recent visit to Plauson's Research Institute, at Hamburg, a 15-litre mill, running at 3000 r.p.m., was inspected, and some experiments were carried out with this mill. A great variety of products made in the mill was seen. The specimens approximate to the list attached.

For the manufacture of colloidal solutions, it is proposed to run the mill as a continuous operation. Many substances are said to be sufficiently quickly dispersed in the mill as to be capable of being run continuously through at a comparatively rapid rate. With more resistant material a continuous process is aimed at by the use of a number of mills in series.



Complete Mill, showing Setting of Shaft.

The material to be milled must first be ground in ordinary mills, ball-mills, etc., since the colloid mill cannot deal with particles too large to be caught in the small clearance between the wheel-arms and the baffle-sides. After preliminary grinding, it is then made into a suspension with water (or other liquid), in suitable proportions not exceeding the specific saturation. The accelerator, the nature and amount of which depend on the colloid to be prepared, may be added at this stage, or simultaneously run into the mill. The suspension is then run continuously into the top of the mill, the beater-wheel of which must exceed the critical number of r.p.m. for the material being milled. During the milling the sight-box provides a view, and samples may be run off from the gauge-glass. The product, after passing through the mill, runs off continuously from the base outlet.

In some cases it is not considered economic to aim at a complete disintegration of the material in one set of millings, but to allow the non-colloidal material to settle out for milling in a succeeding batch.

If the milling continues over several minutes, a rise in temperature takes place. In the majority of cases this heat is stated to assist disintegration, but sometimes it is a disadvantage which must be obviated by a flow of water through cooling coils in the upper part of the machine. In some cases the injection of steam into the machine facilitates the disintegration.

Thus, a Plauson-mill installation would usually include preliminary crushers or breakers, pre-grinding mills, sieves, storage and mixing tanks for water, accelerator and suspension, and settling tanks for the milled product together with elevators, conveyors and dust catchers. When the colloid has to be separated special filters and driers might also be required (E.P. 155,834).

The output and power consumption of the mill depend on the ease of disintegration of the material, the extent of disintegration, and the rate of revolution of the mill. It is stated that three 15-litre machines in series, running at 9000 r.p.m., can grind 1000 kg. ground "raw phosphate," or 200 kg. cellulose in an hour to such a state of division that 85 per cent. of the particles is estimated to be of the order of 0·001 mm. diameter. Exact figures of power consumption have not been obtained. It is understood that with the older type of 15-litre apparatus for tar oil the power consumption was of the order of 1 h.-p. per 33 kg. of material disintegrated, and with calcium phosphate of the order of 1 h.-p. per 5 kg. of material treated. These figures are only very approximate and with the new machines, fitted with baffles, etc., and possibly run at higher speeds, a much greater output per h.-p. is claimed.

For convenience the industrial uses claimed for the colloid mill have been divided into four groups. The following is a brief outline, under these headings, of the industrial uses claimed :—

I. The Preparation of Plastic Masses

Raw material	*Use*
Sawdust-waste, wood-meal, mica waste (with resin, etc.)	.. Insulators, buttons, etc.
China clay	.. Filling, etc.
Slag	.. Road bricks, porous bricks
Shale residues	.. Bricks
Rubber waste	.. Regeneration and moulding
Gelatin, casein, starch	.. Masses (buttons, etc.)

II. The Preparation of Colloidal Solutions for Direct Use

Raw material	*Use*	*Remarks*
Sulphur	.. Disinfectant, spraying on plants	.. Rapidly absorbed
Creosote	.. Do., general	.. Avoids precipitation by dilution
Metals Cu Mn Ag	—	.. Form of disinfectant
Phosphate Felspar	Fertilisers	Rapidly absorbed without sulphuric-acid treatment
Milk (condensed)	.. Formation of milk (substitute)	.. —
Tar	.. Road spraying, etc.	.. Saves heating
Asphalt	.. —	.. —
Scents Essential oils	Scents	Saves solvent for exporting abroad. Increased efficiency
Mineral and organic pigments	.. Inks	.. New pigments can be used
Graphite Oil (grease) Water emulsion	Lubricants	Enhanced lubrication, avoids overheating of lubricant and charring
Resin (in water)	.. Polishes	.. Saves solvent
Vaselines	.. —	.. —
Shellac	.. Lacs	.. Saves solvent
Resin, size, cellulose esters, copal, Bakelite, rubber	Enamels, etc.	.. —
Ultramarine	.. Paints, etc.	.. —
Metals and alloys (bronze)	.. Paints, etc.	.. —

III. The Division of Materials for Chemical Action

Raw materials	*Use*	*Remarks*
Fats	.. Soap	.. Cold saponification
Nitro-compounds	.. Dyes, etc.	.. Cold reduction to amino-compounds
Nickel	.. For hardening oils	.. —
Peat	.. Fermentation	.. Rapidly assimilated
Cellulose	„ Viscose	.. „ „ Reduces amount of reagents
Cellulose	Glucose Fermentation	.. Dilute acids, higher yield,, avoids decomposition by acids

IV. The Separation of Mixtures by Fractional Disintegration

By suitably adjusting the speed of the mill and the type and amount of accelerator, intimate mixtures are fractionally disintegrated; and if the milling be suitably timed, a separation of one ingredient in colloidal solution from another in coarse suspension by simple screening through fine mesh sieves can be made, as for example :—

Application	*Remarks*
Dyes	.. Brown pigment removed from Royal Blue, etc.
Metallic ores	.. Metal from rock
Clay	.. Kaolin from silica
Shales	.. Oil from mineral
Bituminous coal	.. Montan wax

For the formation of emulsions, and the rapid, continuous, fine disintegration of soft colloidal solids, such as china clay, graphite, dyes etc., the mill offers possibilities.

In conclusion it may be said this colloid mill is sufficiently suggestive to justify a recommendation to manufacturers to put it to the test in every possible direction.

ATMOSPHERIC DUST*

The results referred to in this paper have been obtained by the aid of a new instrument for measuring atmospheric dust. This instrument has already been fully described elsewhere,† and therefore a very short description of the method will be sufficient for the present purpose.

The instrument is based upon the facts that atmospheric moisture can be condensed by a reduction of pressure and that such condensation occurs around the dust particles as nuclei. The principle is utilised by J. Aitken,‡ but in Aitken's dust-counter the actual particles counted are the drops of water, and as it is now known that condensation can occur round nuclei other than dust, the counting of such drops does not give the information required.

In the instrument referred to here the reduction of pressure and temperature is brought about by impressing a very high velocity on the air in a small jet. The jet travelling at its maximum velocity, *i.e.*, that of sound in air, has its pressure reduced by the loss of "velocity head," and condensation takes place; as the jet is caused to strike a microscope cover-glass placed 1 mm. away from the opening, the dust particles striking the glass adhere to it by virtue of the condensed water, which is then evaporated as the air flows away, leaving the dust behind.

In the actual instrument a ribbon-shaped jet is used, 1 cm. long and 0·1 mm. thick, and the efficiency of this, when used under suitable conditions, has been found to be extremely high. The air before entering the jet is caused to pass through a damping chamber to provide sufficient water.

The nature of the record obtained is a linear deposit of dust which can be examined microscopically or micro-chemically, and the number of dust particles counted. If sufficient air is drawn through the instrument a thick deposit of dust will be obtained, and if during the process the damping chamber is slightly warmed, excess water will be condensed and this dust deposit will be washed by the condensed water, with the result that on the record itself dried-up stream beds will be found flowing out laterally. In these streams crystals of the soluble salts contained by the dust are to be found. The dust particles are counted by means of a net-ruled micrometer eye-piece with millimetre squares, and by the use of this a few strips across the linear record may be counted and an average obtained which, multiplied by a factor depending upon the length of the record and the volume of air taken, will give the number of particles per c.c.

---

* Paper read by Dr. J. S. Owens, before Section B (Chemistry) of the British Association, Hull, 1922.

NATURE OF DUST OBTAINED FROM THE AIR

Size.—Most of the records taken to date have been in London, but a fair number have also been obtained in country districts and at sea. It has been found that the particles composing a smoke fog in London are curiously uniform in size and rarely exceed 1 micron in diameter, the average size being about half a micron.

Shape.—The particles vary in shape, and are usually irregular but with somewhat rounded outlines.

Composition.—It is somewhat difficult to ascertain the true composition of this suspended dust, but certain means are available such as crystallographic and micro-chemical methods. The suspended matter in London air can be definitely stated to consist mainly of soot. It has been possible, for examples, to volatilise from a record quite a recognisable quantity of tar. From the presence of sulphur in coal and coke smoke one would expect to find crystals of sulphates in the air of cities, and this has been found to be the case.

In country districts the dust obtained by means of this instrument is quite unexpectedly large in quantity under certain conditions; notably during the bluish haze which is often found over practically the whole of England with certain types of weather. This impurity is doubtless derived from cities. It is black in colour, contains some soluble salts, and is very finely divided, the size of the particles averaging about half a micron in diameter. The existence of a haze overlying a country is not, however, a proof of the presence of smoke, as I have found a similar haze at sea when nothing could be obtained from the air but crystals, presumably of sulphates. Again, a record taken in Algarve, in the south of Portugal, last March showed that a haze which existed at the time was composed practically entirely of common salt.

The nature of the dust suspended in the air is of considerable importance from many points of view:—In a haze consisting of salt crystals it is obvious that there would be a marked tendency to fog with a smaller increase of humidity of the air than would otherwise be required; due, for example, to fall of temperature. Doubtless in many cases the presence of such crystals suspended in the air is a fruitful cause of fogs. The dust, however, which is found over the country in England is quite different. It is mainly insoluble in water and the amount of crystalline salts contained is very small. This dust interferes with visibility, and one cannot help feeling that it is not conducive to health to breathe air containing several thousand insoluble particles per c.c., as is often the case during a comparatively light haze.

Microchemical Examination.—The attempt to produce crystals from the records, as already indicated, is one of the means available for examination; the crystals can then be examined microscopically for shape, and under polarised light; they can also be examined chemically by using minute quantities of reagents, but the excessively small size of the crystals, even when obtained, makes their recognition somewhat difficult, for the crystals rarely exceed a few microns in length and there is also the tendency to form imperfect and skeletal crystals. Records taken on cover-glasses treated with dilute solutions of an indicator, such as methyl orange, show that the dust is sometimes acid and sometimes alkaline.

Practical Bearings.—The importance of dust in the air from the standpoint of public health is well recognised, and to fix permissible standards of dust pollution it is essential to have a means of measuring it and of obtaining samples for examination. Again, in the study of visibility and factors affecting it, there appears to be little doubt that the presence of suspended impurity, other than water in the air, has a profound effect, and is, indeed, the governing factor. The whole question of visibility and its measurement is one requiring careful investigation since the present methods of measurement are very crude. There is little doubt that parallel measurements of visibility and dust pollution would show a definite relation between them, as, indeed, I have demonstrated.*

Another practical use for this instrument is in the testing of air-purifying plant. There are many forms of so-called air-purifying plants but few of them produce anything like the effect intended or claimed, and the methods adopted for examining their efficiency have been so unreliable as to be of little use. It is now possible, however, by the aid of this instrument, to state what is the percentage efficiency of an air-purifying plant; to say, for example, out of every 100 particles of dust in the air entering the plant how many penetrate through.

There is, again, a bearing upon the question of condensation of water from the air. It has long been held by some authorities that the initial stages of condensation take place round hygroscopic nuclei composed of soluble salts or even of sulphuric anhydride, and that the haze which we often see in the mornings, and which has already been referred to, consists of minute drops of water condensed round such nuclei. This is a question of fact rather than one of theory, and given a sufficient number of hygroscopic nuclei in the air there is no doubt condensation would initially occur upon them. The question is, however, are there a sufficient number present, and does the haze referred to consist of liquid? I think this question can now be answered fairly definitely: in some cases there are quite sufficient hygroscopic nuclei present and few or no solid dust particles, in others the reverse holds good, and the suspended matter consists mainly of insoluble dust. By the use of the instrument referred to, I have demonstrated that the haze over the country in England during a fine summer's day consists of insoluble dust and not liquid.

*Proc. Roy. Soc., A. Vol. 101, 1922.

Electrical State.—There is a method of examining the electrical condition of dust suspended in the air which has been adopted by Millikan and others by which the suspended particles are examined microscopically while in the field between two charged electrodes, one positive and the other negative. In such a field the dust particles sort themselves out, the positively charged moving towards the negative, and the negatively charged towards the positive electrode, neutral particles being unaffected. Tobacco smoke examined in this way shows a mixture of positively and negatively charged particles with some which are neutral.

In order to examine this effect a simple apparatus has been devised which consists of a vulcanite cell, 2 or 3 mm. deep and about 1 cm. in diameter, which contains two insulated electrodes connected to terminals on the outside. The cell can be placed upon a microscope slide and closed above by a cover-glass. Such a cell illuminated by the dark-ground method, and examined under a comparatively low power, say a ⅔ in. objective and ×10 eye-piece, shows the particles of tobacco smoke suspended in the air between the electrodes, each particle in rapid Brownian movement. By charging the electrodes the movements of the particles can be examined. The cell is illustrated in Fig. I, and it is hoped that by its use it may be possible to ascertain the electrical condition of London fog particles.

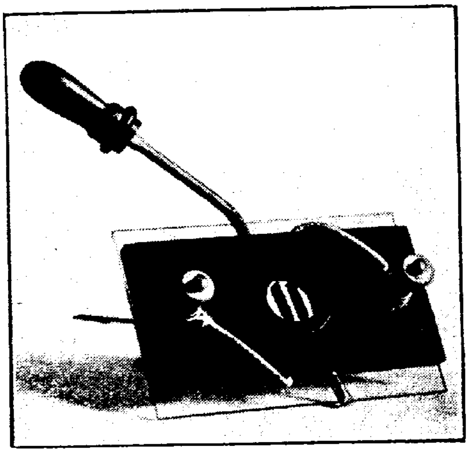

FIG. 1

SOURCES OF DUST

The common sources of dust are the smoke from imperfect combustion and dust blown up from the ground. There are other sources whose importance has not yet been ascertained; the most probable seem to be volcanic, cosmic, and solar. It is well known that the finer particles of dust ejected during volcanic eruptions may remain in suspension in the air for many months; again, the arrival of dust from outside the earth's atmosphere, either of cosmic or solar origin, would tend to bring about a concentration in the lower strata of the air, since the rate of settlement of such particles through the air would be continually reduced owing to the increasing density of the air near the earth. An extract from the *Barbados Advocate* of May 23, 1922, was referred to in the *Meteorological Magazine* of July last. This is of great importance in the present connexion and reads as follows:—"A peculiar phenomenon which has spread over the whole Carribbean from Barbados to St. Kitts, and extending south almost to Demerara, has been the prevalence of a low-hanging mist which has shut off the horizon. For some time the idea prevailed that it was dust due to volcanic eruption, but this was removed by the reports from vessels arriving, and from advices, from the neighbouring islands. Captains trading in these waters for years state that they have never before experienced such continued low visibility at this time of the year. No scientific explanation of the phenomenon has yet been offered."

Dust from space outside our atmosphere would naturally be drawn towards the earth when it came within the sphere of the earth's attraction, and there is little doubt that some, at least, of our dust comes from this source. There is again the projection of dust particles from the sun under the action of light which may also account for some of the dust in our atmosphere. The latter source has been dealt with by Fleming[*] and others.

In this connexion the presence of spherical particles mixed with the ordinary irregular dust particles is suggestive, and although a small proportion of such particles is nearly always found in the dust records, sometimes the proportion rises considerably, so that a very large percentage of the dust particles found consists of apparently perfect spheres, usually transparent and varying in diameter from 1·5 μ downwards. For example, early in March last the proportion of such spheres commenced to increase and towards the end of the month reached something like 50 per cent. of the dust particles in London air. The number of these and their distribution were investigated by Mr. G. M. Watson, the Advisory Committee's research chemist, and the result of this investigation is given below:—

The presence of an unusually large proportion of spherical particles in the dust of the atmosphere was first noticed on March 16, 1922, when, from a record taken with the jet instrument in Westminster, it was found that quite 50 per cent. of the particles was spherical. Many were apparently colourless and transparent, similar in appearance to air bubbles in a liquid, and as much as 1·5 μ in diameter, *i.e.*, three times as large as normal fog particles.

The presence of large spheres is not unusual since they are produced during combustion in certain types of industrial furnaces, but never before had such numbers been found. In an investigation carried out in the neighbourhood of such a furnace, 90 black spheres per c.c., together with 7700 smaller particles, were detected, the diameters of the spheres ranging from 0·75 to 1·8 μ.

On another occasion 64 spheres, of diameters from 0·75 to 1·5, with 3800 particles of an average diameter of 0·5 μ were found per c.c. These results, however, were obtained near a chimney from which spheres were constantly emitted, and all the particles were opaque and black.

A local source of the spheres was suspected in Westminster, but records taken on March 18 and 19 in Surrey, 12 miles from London, showed a similar abnormality. Records taken on March 26, 20 miles

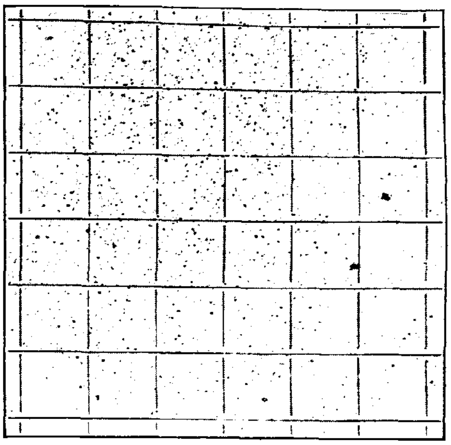
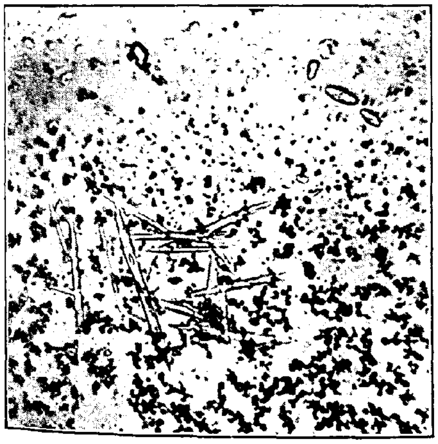
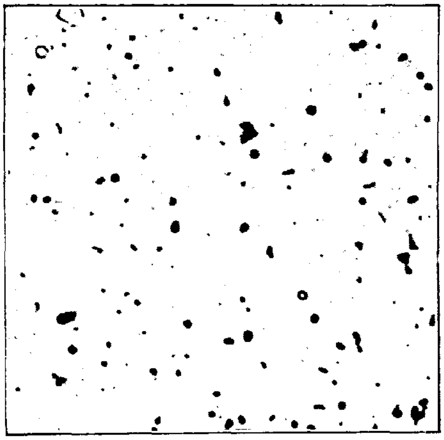
Haze of Salt Crystals,
Algarve, Portugal.
Magnification—1000 diameters.



Record of London fog, taken on Sunday, November 27, 1921, showing the squares in eye-piece used for counting particles. Magnification—approximately 250 diameters.



Suspended matter brought across the North Sea from the Continent, showing crystals and smoke particles. Record taken on East Coast of Norfolk, August 19, 1921. Each millimetre of linear record contains dust from 1000 c.c. of air. Magnification--1000 diameters.



Dust from London air showing spherical particles—Sunday, March 26, 1922. Wind from N. Each millimetre of linear record contains dust from 5 c.c. of air. Magnification—2000 diameters.

north of London showed the same phenomenon, when the wind was from the North. The investigation was therefore continued, records were taken under conditions as varied as possible, and many back records were re-examined with a view to ascertaining:—(1) Nature of the spheres; (2) first occurrence in abnormal quantities; and (3) subsequent distribution.

Appearance of Particles.—Every examination was carried out under a 1/12 in. oil-immersion objective, a magnification of at least 1200 diameters being essential. Whereas the majority of the particles seem solid and opaque, the larger ones appeared as black circles, each with a bright spot in the centre. The width of the bounding rim could be altered and the bright centre moved slightly from side to side by varying the illumination. The smaller the particles, the smaller were the bright centres, and at a diameter of 0·75 μ the spots disappeared and the particles appeared entirely black. Occasionally reddish brown spheres were found.

The term "transparent sphere" will be here reserved for the particles large enough to show a bright spot in the centre, although the small black spheres may be made of the same material.

When an object, such as a pencil, was interposed between the source of illumination and the microscope-condenser, each transparent particle behaved as a lens, producing a sharp, recognisable image of the object. For instance, it was easy to distinguish between the square and pointed end of a pencil by examining the images produced in spheres of 1·5 μ diameter. Images of the thin supports of a stop in the carrier of the condenser were perfectly definite, about half a micron above the spheres, showing that they were composed of a transparent glassy material and their appearance was not a spurious effect due to diffraction. The dust was mounted dry; thus bubbles were impossible.

When mounted in xylol, Canada balsam, cedarwood oil, or water, the transparent spheres altered in appearance but did not dissolve. This was established by focussing upon a particle and allowing the liquid to flow under the cover-slip until the sphere was immersed. The spheres then appeared less conspicuous and the bright centres became smaller. From the movements of the boundary, when focussing on a sphere mounted in balsam, it was concluded that the refractive index of the material was slightly less than that of Canada balsam—1·54. The particles were not hygroscopic. After being kept for some weeks several records became covered with drops of moisture, but there was no tendency for them to form round the spheres more than on other parts of the cover slip. Occasionally spheres were enveloped in the drops, but they remained undissolved. The spheres had no effect whatever on polarised light, and mounted in blue glycerin jelly showed no tendency to take up the stain. The effect of heat was never attempted, as this was impossible under the microscope.

Quantitatively the problem was much more difficult and the results can be taken only as a rough guide, for the following reason:—No distinction is possible between transparent spheres and black spheres, the one passing into the other at a diameter depending somewhat upon the illumination, thus introducing a personal element. Moreover, there is a limit to the resolution of the microscope, and below a diameter of 0·3 μ, every particle appears spherical—a spurious effect due to diffraction. Thus, if true spheres and irregular particles were present together, distinction would depend entirely upon the size of the irregular particles. In general, spheres classed as transparent were of a diameter of 0·9 μ or over. In estimating the number of black spheres, all particles above the limit of resolution which were obviously spherical and not large enough to appear transparent were counted.

The type of result will be best illustrated by a particular case. On April 5 last, at 4.30 p.m.:—

Total number of particles per c.c. ..	2,400
Number of transparent spheres definitely greater than 0·9 μ.	26 per c.c.
Number of spheres greater than 0·75 μ. but not all transparent	50 per c.c.
Very many spheres	1·2 μ. diams.
Few small particles, estimated as 10% below limit of resolution. All above limit appeared spherical. Therefore 90% called spheres.	

Results.—Table I shows some typical results selected after examination of a large number of records.

TABLE I

Date (1922)	Time (summer time)	Total No. of particles per c.c.	No. of transparent particles per c.c.	Percentage of transparent spheres	Estimated % of all spheres	Place of observation
Mar. 18	Afternoon	1200	66	5·5	100	Cheam, Surr'y

„ 25	4 p.m.	3,480	0	0	10	„

The only definite conclusion which can be formed is that about March 4 there appeared in the air some abnormal particles, reaching a maximum about March 18, followed by a slow return to the normal. The spheres were not confined to one district and therefore, presumably, the source was not local, yet there was apparently a distinct variation with the smoke content of the air. If the source were extra-terrestrial the number of spheres might be expected to be independent of other particles, which is clearly not the case.

On consecutive days, at corresponding hours, there are great variations in the smoke content of the air of cities. This does not imply that on one day more smoke is produced than on the other, but that on some days meteorological conditions do not permit of its removal. If the conditions which prevent smoke from rising would also tend to bring down any impurity from the upper air due to a distant source, this might account for the relationship between the spheres and smoke particles above indicated.

Attempts to correlate the number of spheres with other particles were made on May 8, 9, and 11, when series of records were taken at the same place throughout the day. The results were not conclusive, since the spheres were not sufficiently numerous to give a reliable indication, but there was no evidence of any definite relation to the number of other particles. In 10 cases out of 11 the number of transparent particles per cubic centimetre was 13, whereas the total number of particles per c.c. varied from 1850 to 5750.

Fig. 2 shows the daily percentage of transparent spheres, and if the spheres and smoke particles had the same origin we should expect the percentage to remain fairly constant, whereas it varies considerably.

Variation of Transparent Spherical Dust Particles in Air

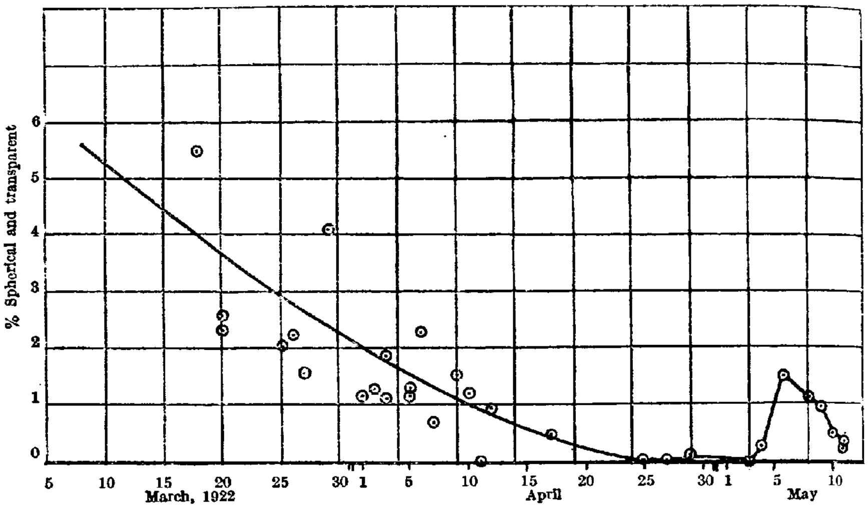

Fig. 2

Origin.—Some of the possible explanations of spherical particles in the air are as follows:—(1) Micrococci; (2) spores of fungi, or pollen grains; (3) drops of oil or of solutions; (4) furnace ash; (5) bits of crystal too small to show definite shape; (6) organic matter synthesised from CO_2 and H_2O by radio-activity; (7) cosmic or solar dust; and (8) volcanic dust.

Considering each of the above separately, we may dismiss most of them as unlikely in the present case.

(1) Micrococci should show more uniformity of size than the spheres noted. They should presumably be independent of, or vary inversely with, the smoke content of the air, and should be capable of staining. The presence of micrococci could not explain the sudden increase of numbers in March and subsequent decrease. Micrococci are also of large diameter.

(2) Spores are rarely less than 12 μ and pollen grains than 25 μ in diameter. The particles noted never exceeded 2 μ. Spores are capable of being stained and would not account for the increase in March.

(3) Drops of oil or solutions would be soluble in xylol or water.

(4) Industrial furnace smoke would not produce large variations in the percentage of spheres on different days and gives no explanation of their comparative absence before March 4.

(5) Crystals below a critical size are spherical in shape and these spheres may be minute crystals of insoluble matter. But they have no effect upon polarised light and show no tendency to grow together. Further, this will not explain the increase in March.

(6) Formation of globules of carbohydrates by radio-activity has been described.* This would not explain the increase in March and the variation with smoke content of the air.

(7) Cosmic dust. This is a likely explanation but does not account for variation with smoke content. If the whole of the upper air were full of spheres they should be detected all over the world. This was not noted. Records taken in Portugal in April contained no spheres.

(8) Volcanic dust is the most probable source. This is known to travel great distances (compare Krakatoa, 1883), and for some time before March there was great volcanic activity in Europe. Particles of material thrown molten into the air would assume a spherical shape and cooling quickly would remain structureless.

In verification of the volcanic dust theory, a sample of the finest dust collected at Krakatoa after the eruption of 1883 was examined.

Only the larger particles which had settled near the volcano were available and so a comparison with the minute spheres obtained in the jet-apparatus records was hardly correct, though information which may throw light upon the nature of the material of the spheres was obtained. Nearly all the particles consisted of thin flakes of colourless, glassy material with a finely pitted surface, broken into irregular angular pieces. The appearance suggested fragments of thin-walled bubbles blown in molten glass. The size of the pieces ranged up to 18 microns, the average being about 12. Very few were smaller than 3 μ, but there were some spheres of diameter 1·2 μ, identical in appearance with the unknown atmospheric dust. There were also a few perfect spheres with smooth surface of about 5 μ diameter, some appearing reddish-brown in colour.

When mounted in Canada balsam the large irregular particles disappeared, the refractive index being the same as that of balsam. Their positions could then be distinguished by the fact that many of the marks on the surfaces were really adhering particles, which in balsam stood out as black spheres up to 1·2 μ diameter. These were not air bubbles in the balsam, as they were quite different in appearance. Occasionally black spheres up to 3·5 μ diameter, made more obvious by the disappearance of the irregular pieces, were also seen, affording support to the theory that the particles described above were of volcanic origin.

---

* Harrison Glew, *Nature*, June 3, 1922, 714.

The photographs given illustrate some of the records obtained by the instrument referred to.

The following are typical counts of recent records which afford comparison of the state of the air in different localities:—

TABLE II

Date, 1922	Place	Time (summer time)	No. of smoke particles per c.c.	Remarks
Sat, Sept. 2	Holme, Norfolk	12 noon	152	Country air, no chimneys near
Tues. „ 5	Brighton	12.10 p.m.	1,380	Wind NE'N.

SOCIETY OF CHEMICAL INDUSTRY

ANNUAL DINNER IN LONDON

This year's annual autumn dinner of the Society was held in the Connaught Rooms, London, on October 13, Dr. E. F. Armstrong, F.R.S., President, in the chair. Among the guests were Mr. Roscoe Brunner, the Rev. E. C. Pearce, D.D. (Vice-Chancellor, Cambridge University); Mr. Robert Hicks (Master of the Salters' Company); Mr. Chas. T. Heycock (Prime Warden of the Goldsmiths' Company); the Hon. W. Hulme Lever; Sir R. Waley Cohen; Mr. Max Muspratt (Chairman of the Association of British Chemical Manufacturers); Dr. H. S. Hele-Shaw (President of the Institution of Mechanical Engineers); Mr. A. Chaston Chapman (President of the Institute of Chemistry); Mr. P. A. Ellis Richards (President of the Society of Public Analysts); Mr. A. Gordon Craig (Chairman of the Chemical Industry Club); Dr. T. M. Legge (Chief Medical Inspector to the Home Office); and Mr. E. G. Gillick, the designer of the Messel Memorial Medal.

Proposing the toast of "The Society of Chemical Industry," Mr. Roscoe Brunner said that although they could have selected a more distinguished person than himself to propose this toast, they could not have chosen a more appropriate one because his family and business connexions with the Society dated from its very commencement. Mr. Ludwig Mond, his father's partner, was chairman of the first meeting which started the Society, and his patron saint, Henry Roscoe, was the Society's first president. Incidentally, Henry Roscoe had had something to say about the tonnage of salt which had been decomposed during his first year of office by the Leblanc process, and it was noteworthy that the tonnage of soda produced in that year was equalled in ten days during the palmiest days of the ammonia-soda process. That showed how the world had progressed. He ventured to say that the Society of Chemical Industry since its foundation had done more to raise the status of the chemist than any other agency. He could claim to have been connected with the chemical industry since 1874, and in those days the elder members of the Society would remember that a chemist who had not been educated somewhere on the Continent was not considered worth his salt; but we had progressed very far since then. The scientific education in this country was certainly better than the scientific education in any other country in the world. Even Oxford now had a very brilliant scientific school, and speaking in the presence of so distinguished a member of the University of Cambridge as its Vice-Chancellor, he even ventured to say that Oxford had a reputation as a school of chemistry second to none in the whole world. He hoped that the Society would continue to press for the better standing of the chemist. In his opinion it was improper that the scientific man who had studied chemistry should be classed with the pharmacist, and he hoped that the Society would take such steps as were possible to give the chemist that standing in the world to which, in the opinion of those qualified to judge, he was entitled. What steps the Society could take to that end he confessed he did not know. He wished long life and prosperity to the Society of Chemical Industry.

Dr. H. S. Hele-Shaw supported the toast and said that he felt quite at home in a gathering of chemists because of the close relationship between the work of the chemist and the engineer. He was, moreover, happy to be in the company of the sons of two men who had done so much for chemistry and engineering. The late Sir John Brunner was one of the greatest friends of all professors and a generous host. When they wanted advice, assistance, and sometimes pecuniary assistance, they knew where to go and never came away empty. Mr. Max Muspratt, who was present, was also the son of a man who had always assisted the universities. The objects of the Society of Chemical Industry and the Institution of Mechanical Engineers were identical in their respective industries, and everyone knew how the chemists and engineers had come together and were jointly responsible in aiding, backing up and making a success of the noble efforts of the fighting line during the war. It was admitted that the engineers and the chemists did not fail when the crisis came. All these things made him, as an engineer, feel at home in a gathering such as this. The chemist of to-day was not the chemist of the old days. Times had changed. The picture of the old chemist was that of a venerable man with a long beard reaching to the ground, a man who worked in a very dark and mysterious place, with, perhaps, a long tall hat, something like a fool's cap, on his head, with various retorts and furnaces all around him. That old idea of a chemist, like the old idea of an engineer, had passed away. The chemical works of to-day had its furnaces and retorts, but there was a great development of engineering appliances in the chemical works of to-day, and it was this which constituted a great bond of union between the chemist and the engineer. Engineers and chemists must co-operate, for it was co-operation which formed the strongest bond of union between men. In another respect the Society of Chemical Industry and the Institution of Mechanical Engineers had an interest in common, and that was they both issued Journals. The ably-edited *Journal of the Society of Chemical Industry* gave the latest information of what was going on all over the world, just as the *Journal of the Institution of Mechanical Engineers* tried to do. The Institution of Mechanical Engineers had just celebrated its 75th anniversary and had a membership of 10,000. The Society of Chemical Industry was in its 40th year and had a membership of about 6000, a figure which the Institution of Mechanical Engineers reached ten years ago. He hoped that in another ten years the Society would have a membership equal to that of the Institution of Mechanical Engineers and that it would continue to progress and flourish.

The President (Dr. E. F. Armstrong), replying to the toast, said that in the old days chemistry was a very formal science; chemists were very formal people and they used to have very formal dinners and sit at long tables. Everything now had changed. Formality had gone by the board and ladies now appeared at their functions. It was, indeed, the desire of the Society that the proceedings should be as informal as possible and that enjoyment should be general. If we endeavoured to take a broad view of the present as compared with the past, it was instructive to cast our eyes right back to ancient Egypt, to ancient Greece, and to the wonderful Roman Empire, and to reflect in what way we differed from the men and women of those times. Had we progressed in Art? He thought the answer was No. Had we progressed in Literature? The answer was No. Had we progressed in Government, whether State or Imperial? Had we progressed or were our methods not founded on those of the ancient Empires? Why was this age different? Was it not because of mechanics and mechanical inventions? This was a mechanical age and all the changes which had taken place were due to the brains of man evolving mechanical aids for his well-being. The theme which he wished to elaborate for a moment was that whilst we used the term "mechanical" and thought of the mechanical inventions, was it not the chemist who had made these discoveries and the engineer had taken the credit? Ought not it to be asserted at meetings such as this that engineering was but the handmaid of chemistry, and that the engineer was but the kindly gentleman who carried out in the world the ideas which the chemist had conceived in the laboratory? What they wanted to drive home was that the engineer—who he believed originally was a Scotsman—was a very canny man. They had just been told that 35 years before the chemists, the engineers got together and formed a society, and the moral they had to learn was that the engineers got together and as a consequence of that they had got the ear of the public and the credit, and well they deserved it, because surely the prize was to the swift. Chemists did not seem to have been swift enough. Take the social services which were so essential to the public. In the case of the water supply of the great City of London, which was the outstanding name? He believed it was the name of Sir Edward Frankland. But who really got the credit for the water supply of the City of London? It was one or other of their friends the engineers. The same thing applied to sewage; it was the chemist who had made the discoveries which had rendered it possible to live in our great cities, but it was the engineer who had reaped the reward both materially and in the shape of knighthoods and the like. There was something about the chemist which was hard to define. Chemists seemed to suffer from an excess of modesty, and if they were to reach that standard of excellence and to have that weight in the counsels of the nation they deserved, something must be done to put this state of things right, and the only advice he could give them that evening was advice based on the words of the President of the Institution of Mechanical Engineers, viz., to keep on getting together. The chemists in the Society o Chemical Industry numbered only some 5000; le them get together and become 10,000 in a very shor time.

Passing to another theme, the President said tha the Society was unique in that its activities wer world-wide. It had Sections not only throughou the British Empire, but even firmly planted in th very heart of the United States. Two President had been citizens of the United States, and h wished to emphasise the importance both to th welfare of Anglo-Saxon chemistry and also to th welfare of civilisation, that British and American should stand together firmly at the present juncture If any of them had sufficient leisure to reflect upo the future of civilisation they could not help havin a fear for its future at the present time. Th world was upset. The East was in a fermen and in the Bolshevik Great Britain had th greatest enemy she ever had in her history. A the present time we alone stood in the brea between Bolshevism and the wreck of all that we hold dear. It was a great pity that America did not understand that fact and had not yet come to our assistance. If any of them had the advantage of going to America they would realise that what was called America was not America. America was controlled politically by the inhabitants of what was known as the Middle West, and those people lived so far from the sea that they did not understand the problems of Europe. Some of the enlightened men in America, and particularly enlightened chemists, realised the danger, but as chemists we must make our brother chemists in America alive to the fact that the situation menacing civilisation is a grave one. We must co-operate as chemists and develop an Anglo-Saxon chemistry. The first steps in that direction had already been taken, for the Society of Chemical Industry was almost a pioneer and unique in having an American Section; he felt that a message should go forth across the seas on the occasion of a meeting like this to tell our American friends that there were duties bigger than national duties, namely, a duty to civilisation. The time had come when chemists must hang together if they were to go forward, and they must put the interests of their profession before themselves. He wished to thank Mr. Roscoe Brunner and Dr. Hele-Shaw for the kind words they had said about the Society, and to express the hope that the chemists could rely upon the support of the great and successful manufacturers and their friends the engineers.

Mr. Edwin Thompson proposed "The Visitors," and in mentioning their names said the Society looked forward with very great pleasure to being the guests of Cambridge at the next annual meeting.

The Rev. E. C. Pearce (Vice-Chancellor, Cambridge University), who replied, said that although, as Mr. Roscoe Brunner had said, Oxford University might have a school of chemistry second to none, he noticed that the Society was not going to Oxford for its next annual meeting. Speaking of the applied chemist and the pure chemist, he said that in Cambridge they had a very great respect for the applied chemist, because he had done a great deal for the University and was going to do much more for it. Some of them might know that the oil firms a little time ago gave the University 200,000 guineas because they realised what pure chemistry in Cambridge was doing for them. The University very much appreciated the action of the oil firms, and wished that other firms would do the same because they were all very poor in Cambridge. That was really no laughing matter because the salaries for which people who were worth very much more were working in Cambridge would surprise those present if he were to mention them. That, however, was rather a domestic matter; on behalf of the visitors, he wished to say that if the Society enjoyed itself in Cambridge at its next annual meeting as much as he had enjoyed himself—and he was sure the other visitors, too—at that dinner, the University would be more than repaid.

NEWS FROM THE SECTIONS

BRISTOL

On October 13 the first session of the Bristol Section—which does not now include South Wales—was inaugurated by an address from the President, Dr. E. F. Armstrong. Mr. C. J. Waterfall, the chairman of the Section, presided over an audience of 111 members and guests, the latter including a large number of students of the Chemical Department of Bristol University. Dr. J. P. Longstaff was also present. At the close of the address votes of thanks to Dr. Armstrong were moved by Prof. F. Francis, on behalf of the students, and by Dr. T. H. Butler, seconded by Dr. F. W. Rixon, on behalf of the members of the Section.

Dr. Armstrong, who chose as his subject "The Importance of the Chemist to the Nation," first spoke of the great services rendered by chemists during the war, and said that it was the duty of the Society and possibly of the Institute of Chemistry to see that such a shortage of chemical munitions which was then experienced would never occur again. The man-in-the-street did not fully realise the value of those services, and he was sure that the daily Press did not, for from time to time it made announcements of great discoveries which either were erroneous or had been made many years before. The ignorance of the public was due mainly to the ignorance of the Press, and the chemist was responsible for the latter. The chemist was far too modest and had allowed others, *e.g.*, the engineer, to take the credit that was due to him. Prof. Hinchley had said that the success of our chemical industry depended upon our progress in engineering, but he (the speaker) would say the success of our engineering industry depended upon our progress in chemistry. That was well illustrated by the history of the development of high-speed steel; the credit of the achievement had gone to the engineer. Most applied sciences were really applied chemistry; and the chemist's work had laid many of the foundations of human progress. As illustrations might be cited the solution of problems connected with sewage disposal and other public utility services, therapeutics, the discovery and manufacture of antiseptics, food-supply, and so on. How came it that the chemist's work was unknown or imperfectly understood? In the first place, the youth of the country was brought up largely on obsolete educational methods. Almost everyone posed as an expert on education, and hence that subject had been a great battlefield for would-be reformers; and the more would-be reformers the smaller the progress. There had been some advance in the teaching of science, but the urgent need was to stimulate the pupil's interests and activities in such a way that he learnt without conscious effort things really worth knowing, and not merely such things as the names and deeds of professional cricketers and football-players! By teaching science in that way, the public would learn to appreciate it and there would be an end to the murders of elementary scientific facts committed by the Press. At present chemists were almost incomprehensible to one another; how much more so must they be to the man-in-the-street. They must learn to express themselves in clear and simple language. They had many advantages over the average man; in their first year's training in the University, experience in analytical work should inculcate the habit of inquiry and develop to some extent the critical faculty; in the second year they should acquire the synthetic, the constructive, habit of thought; and in the third year, when they passed on to theoretical studies, they had a good opportunity of developing their reasoning faculty. Chemists had something to learn from the medical profession, especially in the matter of standing together. No profession exercised so much authority with so little knowledge. How did they do it? The explanation was that every medical man praised every other medical man. On the other hand, the characteristic of the chemist was to condemn every other chemist. Chemists must learn to speak with one voice. On several occasions when he had taken part in a deputation to a Cabinet Minister on some question of importance to chemical industry, he had learned that a day or so before an equally eminent deputation of chemists had waited upon the Minister to express diametrically opposite views. Unless chemists pulled together they would never speak with one voice and never exercise any real power in national affairs. He regarded the formation of any new society as a potential disaster to the community of chemists. There should be one, and only one Society, with sectional groupings, if necessary, but all under the umbrella of a Federal Council, to which the affiliated sections would send representatives. With the exception of organised labour, the most powerful community in the country was the brewing industry, and this was because it spoke with one voice. The organisation of chemists in this country compared badly with that in America and Germany. Lately the Institute of Chemistry had opened wide its doors and was now really representative of the chemical profession; and he would ask all those who could to support what he might term the latest form of collective chemical activity, viz., the Chemical Industry Club, which had the great advantage of being one of the few places where chemists could meet and converse informally.

Speaking to the younger chemists present, Dr. Armstrong pointed out the need for greater self-assertiveness on their part, particularly in regard to joining in discussions at meetings like the present one. In the past the work of leading and supporting the Sections had been left to a small minority. It would be a healthy sign if at an election for a local committee there were twice as many candidates as there were vacancies to be filled. Then, again, the elder men complained sometimes of narrowness of outlook on the part of the juniors. Personally, he thought that an attempt was made to teach far too much in the University course. This was not the fault of the teacher, but of the syllabuses on which examinations were based. The result was that far too much time was spent in preparing for examinations. The ultimate test of a "first-class" man was his ability to acquire knowledge of any subject in which he was interested. Broadness of outlook should be cultivated to the fullest extent possible in private life; and the future chemist would benefit if he would almost drop his chemistry as chemistry and regard it as a training in scientific method, which was to be applied to the broadening of his interests. When the University graduate entered the works he would find that his knowledge was more up-to-date than that of many with whom he had to work, and this advantage, among others, would give him driving power; the ability to speed up a process or any part of it was worth more than all the first-class honours in the world. The chemical profession was terribly overcrowded at the present time, and the men who entered the Universities during the post-war boom were now leaving them at a time of great industrial depression; to find employment was very difficult. These men should remember that they had lost nothing by their scientific training; if they had profited by it they would be in a position to take any job provided it was an honest one, *i.e.*, one that required hard work and "push." Better progress could be made in commercial posts, for which there was much less competition, than in the position of junior chemist, which too often led to nowhere.

SOUTH WALES

The first meeting of this new Section was held on October 20, in the Technical College, Cardiff, Prof. C. M. Thompson presiding. A paper was read by Prof. W. J. Jones on "The Congealing Temperatures of Essential Oils," describing an investigation carried out in the University College, Cardiff, on essential oils, and in which special attention was given to their purification and to the thermometry. It was shown that European oil of rue consists of a solution of methylheptylcarbinol in methylnonyl ketone; the congealing temperatures of the purest product, after repeated fractional crystallisation followed by distillation *in vacuo*, was found to be 12·6° C. Aniseed oil showed a maximum congealing temperature of 21·3° C., which is also the freezing-point of pure anethole. When the oils are at least of 93 per cent. purity, it is found that the percentage of impurity is directly proportional to the difference between the observed freezing-point and that of the pure oil; so that a simple determination of the congealing temperature affords an accurate method for the analysis of essential oils when the required data on the pure oils have been obtained. Many of the required data are given in the paper.

CHEMICAL ENGINEERING GROUP

On October 20, in the Hotel Cecil, London, members of the Group gave a complimentary dinner and made a presentation to Mr. H. Talbot on the occasion of his forthcoming marriage, as an expression of appreciation and gratitude for the good work he has done as hon. secretary of the Group. Mr. J. Arthur Reavell, chairman of the group, presided and proposed Mr. Talbot's health; other speeches were made by Prof. J. W. Hinchley and Messrs. C. S. Garland, F. A. Greene, W. J. Gee, F. H. Rogers and E. A. Alliott. A programme of music, as well as a "syncopated" orchestra, contributed to the general enjoyment.

MEETINGS OF OTHER SOCIETIES

THE CERAMIC SOCIETY

The eleventh meeting of the Refractory Materials Section of the Ceramic Society, held in Birmingham on October 3 and 4, was characterised by a full and varied programme. Lt.-Col. C. W. Thomas presided, and after a few introductory remarks from him the regular business commenced with a discussion on "Bricks for Coke Ovens." This was opened by Mr. A. H. Middleton's paper, in which he strongly advocated the adoption of silica bricks in preference to the clay silica bricks now mostly used in this country. There seemed to be fairly general agreement that silica bricks would give better results in cases where salty coals were coked, but in other cases, whilst some speakers favoured the use of silica bricks, others considered that, having regard to the different conditions here and in America, a satisfactory quality of the type of brick now used would be more suitable.

Sir Arthur Duckham described "Some New Forms of Kilns" which have been successfully used during the last few years. One of these consists of 16 chambers placed in two rows side by side. Each chamber has four fireholes and bags, and the firing is semi-gaseous with down-draught. The products are firebricks, burned to cone 13, and artificial draught is recommended. A second type of kiln consists of a single chamber with a central bag, heated by an outside producer burning coal. This gives even heating and other satisfactory results. In an open tunnel-kiln, cross walls on each truck, registering with offsets on the kiln walls, force the gases to travel zigzag, and in this way the length of the tunnel-kiln can be reduced from, say, 300 ft. to 130 ft. The heating is even, and cooling is greatly facilitated. An annular tunnel-kiln was designed for burning large glazed goods. Continuity of the tunnel is broken at the unloading and loading point, but the annular firebrick tray carrying the material is continuous all round the kiln. The kiln is heated by producer gas burned in six separate horizontal flues placed one above another in the side walls of the tunnel. Mechanical draught is provided by fan and motor. The chief advantages of this kiln are convenience of working, elimination of trucks, even heating, and economy of fuel.

"The Grading of Silica Bricks" was the subject of a paper by Messrs. P. B. Robinson and W. J. Rees. The results obtained led to the conclusions that for a mechanically strong brick (*a*) a hard rock crushing into fragments of high angularity is ecessary; (*b*) the best size for the largest pieces the brick is 6—7 mm., these large angular pieces mparting strength to the brick both at high and w temperature; (*c*) at least 40 per cent. of fine round material passing 100-mesh should be used, nd for a dense brick addition of fine ground aterial from a ball-mill must be made; and (*d*) the ricks must be well-burned.

In a paper on "The Behaviour of Fireclays, auxites, etc. on Heating," by Mr. H. S. Houldsworth and Prof. J. W. Cobb, the materials nvestigated included several forms of silica and lumina, red and white bauxites, kaolin, fireclays, nd other hydrated compounds of silica and lumina, and the three minerals of the composition $Al_2O_3.SiO_2$. The outstanding points are:—(*a*) Kaolin and all the clays and shales examined show distinct heat absorption at 500°—530° C. and heat evolution at a higher temperature; (*b*) this heat evolution occurs at 1060°—1130° C. with pure alumina made by calcining aluminium nitrate at 700° C., but about 100° C. lower with the bauxites and clays; (*c*) most of the materials show heat absorptions below 500° C., presumably due to the loss of water from colloid substances; (*d*) the phenomena observed with the clays are not primarily dependent on the presence of silica, being noticeable with alumina and with a red bauxite practically free from silica; (*e*) although alumina calcined at 700° C. and the bauxites and clays showed marked heat evolution at about 1000° C., precipitated alumina gave no sign of it.

"Some Changes Taking Place in the (Low-Temperature) Burning of Stourbridge Fireclays" was the title of a paper by Mr. C. E. Moore. Four different clays were examined, two Old Mine and two New Mine, of which analyses are given, as well as very numerous data concerning contraction, porosity, specific gravity, hygroscopicity, solubility in HCl, heating curves, and dehydration. The chief conclusions are:—(1) Three definite critical ranges are to be found in Stourbridge fireclay at temperatures approximating to 700° C., 920° C., and 1030° C.; (2) the changes take place in all the clays of the series and at similar temperatures in each; (3) the magnitude of the changes decreases slightly with the alumina content, particularly of the changes at 700° C. and 900° C. The change at 1030° C. is probably of a purely mechanical nature.

A paper entitled "X-Radiogram of Kaolinite, and the Thermal Decomposition of Clay" was communicated by Prof. W. H. Bragg and Dr. J. W. Mellor. Prof. Bragg has recently been working on the structure of crystalline powders with the aid of X-rays. He has found definite crystalline structure in kaolinite before heating. After heating at 600° C. it becomes practically non-crystalline, showing the merest trace of crystalline material. Radiograms of china clay were found to agree with those of kaolinite.

"An Examination of Refractories by the Oxy-Hydrogen Blowpipe," by Mr. A. L. Curtis, relates to a method for rapidly examining the properties of refractories, especially in small amounts. Coal gas or acetylene may be used instead of hydrogen, but acetylene is difficult to control for a small test-piece. The refractory in powder is mixed with water or with a solution of dextrin in water. For check tests Seger-cone mixtures are similarly prepared, and the number of seconds required to produce the desired effect is noted. A camera is used to record appearances, microscope- and telescope-objectives being employed. The effect is watched on a screen all the time.

The final paper was by Dr. C. H. Lees, "On the Stresses in Cylindrical and Spherical Bodies due to Differences of Temperature Inside and Out."

THE CHEMICAL SOCIETY

The first ordinary scientific meeting of the session 1922—1923 was held on October 5. The President, Sir James Walker, alluded to the appointment of Dr. M. O. Forster to the post of Director of the Indian Institute of Science, Bangalore, and said that his wise guidance of the Society's finances during the critical period of high expenditure had obviated further increase in the subscription. Prof. J. F. Thorpe had been appointed by the Council to fill the office of treasurer, and Prof. J. T. Hewitt to that of vice-president, each to hold office until the next annual meeting.

Sir J. Walker made a further appeal on behalf of Russian men of science, and read a letter from the president of the Russian Physical Chemical Society acknowledging assistance already given. As an example of the difficulties with which scientific men in Russia had to contend, he said that it had been ascertained that whereas the salary of a Russian professor averaged an equivalent of about £3 10s. a month, the cost of commodities which he had to purchase was approximately double their cost in this country.

The following papers were read:—(1) "Cupric tetrammine nitrite and the corrosion of copper by aqueous solutions of ammonia and of ammonium nitrate": H. Bassett and R. G. Durrant. (2) "The additive formation of four-membered rings. Part I. The synthesis and resolution of some derivatives of 1:3-diazidine": C. K. Ingold and H. A. Piggott. (3) "A determination of the relative proportions of the isomerides in nitrotoluene or toluidine": W. H. Patterson. (4) "Rates of reduction of nitro-groups by hydrogen in the presence of colloidal palladium, especially of nitrotoluene isomerides": W. H. Patterson.

(1) Prof. Bassett has examined the action of ammonium nitrate on copper in presence of air, and found a blue product, the tetrammine nitrate $Cu(NH_3)_4(NO_3)_2$, and a green one consisting mainly of the insoluble basic nitrate $Cu(NO_3)_2 3Cu(OH)_2$. The small amount of nitrite which was found in the corrosion products results from the catalytic oxidation of ammonia and not from the reduction of nitrate, for some nitrite is always formed when air and aqueous ammonia act upon copper. Pure cupric tetrammine nitrite $Cu(NH_3)_4(NO_2)_2$ is best prepared by extraction of the basic nitrite $Cu(NO_2)_2$, $3Cu(OH)_2$ with ammonia (0·880). It has not the formula $Cu(NH_3)_2(H_2O)_2(NO_2)_2$ given to it by Pélagot (Comptes. rend., 1861, **53**, 209), nor does it deflagrate. At 100° C. it forms the diammine nitrite, and at a higher temperature it decomposes leaving a residue of copper oxide. Pure cupric tetrammine nitrite and nitrate are a little more sensitive to shock than picric acid; a mixture of the two is much more sensitive.

A meeting was also held on October 19, when Prof. H. E. Armstrong presided, and papers on valency and polarity in organic compounds were presented by Prof. T. M. Lowry, Dr. J. Kenner, and Mr. W. E. Garner.

SOCIETY OF LEATHER TRADES CHEMISTS

A meeting of the British Section of the Society of Leather Trades Chemists was held in the Leathersellers' Technical College, London, on October 6. Mr. J. R. Blockey presided over a good attendance.

Reports were presented from some of the Analysis Committees, and a long discussion arose on the question of the determination of Insolubles in Tannin Analysis. Mr. D. Woodroffe sent a report from the Crome Leather Analysis Committee.

The following papers were read:—(1) "The estimation of sulphides by means of standard zinc sulphate solution": W. R. Atkin. (2) "The estimation of ammonia in lime-liquors without distillation, and incidentally the simultaneous estimation of caustic alkalinity": W. R. Atkin. (3) "Proposed provisional method for the analysis of lactic acid": F. C. Thompson. (4) "Water-soluble matter in leather; its estimation and significance": J. R. Blockey. (5) "The sampling and preparation of leather for analysis": J. R. Blockey.

Discussion followed the reading of the papers, the first three of which came as contributions from the Limeyard Control Committee, and the other two from the Sole-Leather Analysis Committee.

THE PROPOSED INSTITUTE OF PAINT AND VARNISH TECHNOLOGISTS

Members of the Paint and Varnish Society and of the Oil and Colour Chemists' Association met at dinner in London on October 10, and resolved unanimously to take steps to form an Institute of Paint and Varnish Technologists. Sir Ernest Benn presided, and among others present were Prof. H. E. Armstrong, Prof. T. M. Lowry, Dr. F. Mollwo Perkin, Dr. R. S. Morrell, Dr. J. N. Friend, Dr. M. B. Blackler, Messrs. T. H. Barry, G. H. Howse, Noel Heaton, A. S. Jennings, J. Cruikshank Smith, H. D. Bradford, H. A. Carwood, W. F. Reid, W. J. Palmer, C. Harrison, and C. A. Klein.

The opinion was expressed that the formation of an Institute of Paint and Varnish Technologists would bring together two bodies which had worked independently since 1918. It was felt by those members of the Oil and Colour Chemists' Association who were present that the best interests of the industry would be served by co-operation in such an undertaking. The most important function of the Institute must be to issue a live Journal, which would help the members to keep abreast of modern developments in the industry. Since the failure of the National Federation of Paint and Varnish Manufacturers to devise a scheme of organised investigation, it was hoped that the proposed institute would be able to encourage research work throughout the country and, if possible, to form a centre for providing a better knowledge of the properties of the raw materials in the industry, whereby goods could be produced more economically and of a uniform standard of excellence. The Institute would also influence the education of its future members and endeavour to establish some kind of professional status for the paint and varnish industry. It would afford members an opportunity of reading papers and would help to maintain a high standard of qualification among its technical members. One of the speakers at the dinner considered that if each of the 250 paint manufacturers in this country subscribed £10 a year, a good start would be made towards carrying out the proposals which were approved by those present at the dinner; as an insurance against ignorance it would be well worth the money.

A provisional council of nine members of the Oil and Colour Chemists' Association and nine members of the Paint and Varnish Society was elected to examine the proposed articles and memoranda of association as well as to consider the financial requirements. The report of this council will be submitted to the two societies, and if approved by them the Institute will be inaugurated. The members of the provisional council are:—Dr. J. N. Friend, Dr. R. S. Morrell, Dr. H. H. Morgan, Messrs. S. G. Clifford, E. S. Hanes, S. K. Thornley, A. de Waele, W. J. Palmer, H. A. Carwood (all of the Oil and Colour Chemists' Association); Dr. F. M. Perkin, Dr. M. B. Blackler, Messrs. Cruikshank Smith, W. F. Reid, A. S. Jennings, C. Harrison, Noel Heaton, C. A. Klein, and H. D. B. Bradford (of the Paint and Varnish Society).

INSTITUTION OF PETROLEUM TECHNOLOGISTS

The opening meeting of the current session was held on October 10 at Burlington House, W., Prof. J. S. S. Brame presiding. A paper on "Standardisation of Petroleum Tests" was read by Dr. A. E. Dunstan.

The lecturer recalled the speech of Mr. Alexande Duckham in 1917 in which he suggested that th Institution should appoint a Standardisatio Committee whose function should be to investigat methods of testing and to recommend standards fo adoption in this country. That suggestion receive strong support from many quarters, and early thi year a Standardisation Committee, with Mr. Duckham as chairman, was appointed. The range of investigation and deliberation was divided among six sub-committees, and the tentative recommendations of these sub-committees up to the present date were set forth in the paper with the object of stimulating discussion and inviting helpful criticism before the conclusions were revised and summarised by the main committee. The Standardisation Committee had worked in close accord with the British Engineering Standards Association and the American Society for Testing Materials, and in many cases the valuable recommendations of the latter society had been adopted without modification. It was intended to arrange meetings between the Committee and the various firms of instrument-makers in order to assist in the attainment of uniformity in apparatus used for petroleum-testing. Prof. Brame had consented to edit a special brochure containing the recommended tests, which would be tentative tests and subject to periodical revision, if necessary, and it was anticipated that this brochure would be published early next year.

Messrs. Alexander Duckham, Arnold Philip, Le Maistre, and Anfilogoff took part in the resulting discussion, and comments and criticism i writing were invited for consideration by the Committee and for publication in the correspondence columns of the Institution's *Journal.*

AMERICAN ELECTROCHEMICAL SOCIETY

The annual meeting of the Society was held in Montreal on September 21 and 22. Dr. C. G. Schluederberg, of Pittsburgh, Pa., president of the Society, gave an address upon "Electrochemistry and the Electrochemist," in the course of which he said: "An electrochemist is a cosmopolite in the truest sense of the term. He must be an engineer, chemist, metallurgist, manufacturer, and an all-round scientist. In order that he may keep abreast of developments he must be broadminded, progressive and aggressive." Papers were read "On Electric Heat; its generation, propagation and application to industrial processes," by E. F. Collins; "On the Principles of High Temperature Furnace Design," by E. L. Smalley; "Some Electrical Properties of Alloys at High Temperature," by M. A. Hunter and A. Jones; and on "Resistivities of some Granular Resistor Carbons," by C. E. Williams.

Of the technical papers presented on the 22nd, that by P. S. Gregory, of the Shawinigan Water and Power Co., upon "Electric Generators and their Application," was of greatest local interest. It was followed by a very good discussion, fruitful of much general information upon the subject, which is considered one of the most important in electrochemistry. The type of generator seen by the members of the Society of Chemical Industry during their visit to Shawinigan in 1921, has been further developed and improved and made more applicable to conditions in Canada by F. T. Kaelin, (*cf.* J., 1922, 94 R, 412 R). By the adoption of these electric generators, and utilisation of the "off peak" hours, the two large industrial factories of the Laurentide Pulp and Paper Co. and the Belgo-Canadian Pulp and Paper Co. are saving 400 tons of coal daily. In the ensuing discussion, Prof. W. D. Bancroft declared that some day the electric firing of porcelain would bring artistic and decorative porcelain to a very much higher state of perfection than was formerly thought possible.

SAFEGUARDING OF INDUSTRIES ACT

GALLIC ACID

On September 26 Mr. Cyril Atkinson, the Official Referee, heard the complaint made by Mr. J. L. Rose, chemical manufacturer, of Barking, that the Board of Trade had improperly removed gallic acid from the list of chemicals subject to import duty under Part I of the Act. The parties were not represented by counsel, and the hearing was terminated within three hours. Mr. W. J. U. Woolcock, M.P., General Manager of the Association of British Chemical Manufacturers ("A.B.C.M."), appeared for Mr. Rose, who is a member of the Association, but the Referee stated that in future he would enforce the rule that a complainant must either conduct his own case or be represented by a barrister or solicitor.

Mr. Rose, after giving evidence in camera concerning his process of manufacturing gallic acid (3.4.5-trihydroxybenzoic acid), said that he had been making it since the beginning of the war; for 30 to 40 years prior to that time all the gallic acid used in this country had been imported from Germany. The imported acid was sold by merchants; he had supplied the acid to R. W. Greef and Co., and had dealt only with that firm's fine-chemical department; but he was unable to bring into court such trade witnesses because merchants as a class were opposed to the Act. Gallic acid was regarded by the trade as a fine chemical. In his process of manufacture samples had to be taken and tested at every stage; he employed a staff of fifteen of whom two were qualified chemists. The gallic acid he manufactured was of about 98 per cent. purity.

Mr. Woolcock said that gallic acid was made only from gall-nuts in plant similar to that used in making azo-dyes and other fine chemicals; the nature and amount of supervision required justified the classification of the substance as a fine chemical. In previous inquiries the heading to Group VI in the classification of the A.B.C.M. had been wrongly interpreted. The first term—"fine chemicals"—alone was definitive, the remaining terms ("analytical," "pharmaceutical," etc.) were illustrative: a chemical might well be a fine chemical even if it did not come under one of these descriptive sub-headings. Gallic acid was not covered by any one of the sub-headings, but the same was true of many other fine chemicals. On the other hand, he suggested that the group to which the Council of the Association allocated a member was a criterion; a member could not join any group he liked. Mr. Rose was a member of Group VI. Gallic acid was used in the manufacture of pyrogallic acid, an admittedly fine chemical, and of certain dyes, which were but fine chemicals coloured. When the Schedule to the Dyestuffs Act was being drawn up, the Board of Trade had omitted gallic acid from it on the ground that it was not a dye-intermediate; it was undoubtedly the intention of the legislature to include gallic acid within one Act or the other.

Mr. J. Ronca, for the Board of Trade, accepted substantially all that had been said. In compiling the list of dutiable articles, the Board had considered the trade classification of "heavy" and "fine," and it had not applied to each article what might be called the secondary tests of its correct classification. In doubtful cases, however, it was useless to refer to the trade, different sections of which would invariably hold divergent opinions, and certain secondary tests had to be applied. Originally the Board had never thought of applying the secondary tests to gallic acid, having no doubt that it was a fine chemical, but after its inclusion in the Schedule had been challenged, thus proving that in fact there was doubt as to its correct classification, the Board gave consideration to certain criteria or secondary tests as laid down or described by the Referee in the Tartaric Acid case (*cf.* J., 1922, 116—118 R). For example, in his judgment in that case the Referee stated that, the search for a definition of fine chemical having failed, he would adopt trade usage as the test and "the trade regarded heavy chemicals as commercial products mainly used for industrial purposes." By that test gallic acid was not a fine chemical, and it was consequently deleted from the original list.

Mr. Woolcock said that if the Board's interpretation of the judgment were correct, very many admittedly fine chemicals, including all those used in making other fine chemicals, would have to be removed from the list. The Referee said that he had not intended his remarks in the judgment mentioned to constitute a definition; he still believed that, in the main, the trade regarded a big industrial use as a criterion of a heavy chemical. Mr. Ronca said that the Board did not accept the view that industrial chemicals were invariably used in large quantities; some were used in very small quantities. The Referee pointed out that Mr. C. A. Hill's paper on the manufacture of fine chemicals, read before the Society of Chemical Industry in 1916, was definite and important evidence for complainant's view, but he required direct evidence, dating from before the passing of the Act, that the trade regarded gallic acid as a fine chemical. After the adjournment for lunch, Mr. Woolcock produced the new trade catalogue "Where to Buy" in which gallic acid was listed as a fine chemical. Mr. C. A. Hill stated that for 25 years at least he had known gallic acid as a fine chemical and had never heard it referred to as a heavy chemical; and copies of the *Journal of the Society of Chemical Industry*, dating from 1895, were produced to show that up to 1909 gallic acid had been classified in the *Abstracts* among fine chemicals. The Referee stated that he was satisfied with the evidence produced, and no evidence had been given to the contrary. Mr. Ronca's view was that his original classification was right. In future he would regard trade usage as determinative if it can be found, and evidence must always be given on that point.

Judgment was issued on October 18, as follows:—

The complaint in this case is that gallic acid has been improperly excluded by the Board of Trade from the lists of articles dutiable under the Act. Gallic acid was originally included in the list. Complaint was made of this inclusion, and the Board of Trade took it out of the list in the belief that it was covered by something I said in the Tartaric Acid case. There was not any real contest at the hearing before me. None of those persons who might be interested in maintaining the exclusion of the substance from the list attended to take part in it. I am satisfied that the usual notices have been given and that persons interested have had the usual opportunities of giving evidence and of taking part in the argument. I regret that no one of them has availed himself of these.

On the evidence of Mr. Hill and Mr. Rose, and of the chemical journals and catalogues that were put in, I find that gallic acid has been and is regarded by the trade as a fine chemical. I think, therefore, that the original inclusion of the substance in the list was right and that its present exclusion is wrong. The reason for this exclusion is the supposition that in the Tartaric Acid case I defined a heavy chemical as a commercial product mainly used for industrial purposes. It is said that as gallic acid is a commercial product almost entirely used for industrial purposes therefore it is a heavy chemical. So far from laying down any definition in the Tartaric Acid case of the terms "heavy" and "fine," I expressly decided that there was no scientific or trade definition of the terms and that therefore the test was the trade classification in each particular case. The view that I intended to express in the Tartaric Acid case was this; there was no definition of "heavy" or "fine," but that in ascertaining how any particular substance had been regarded by the trade one would probably find that the purpose to which the substance had been put had had a good deal to do with its classification, and that for the most part chemicals mainly used, and used to a substantial extent, in industry had been classified as "heavy." I do not think that this applies to photographic chemicals. As to gallic acid, the total quantity used in a year is comparatively small, and I find on the evidence that the trade has regarded it as a fine chemical. Applying, therefore, the same test as that applied in the Tartaric Acid case I come to the conclusion that gallic acid should be included in the list and I so award. No costs.

CHEMICAL INDUSTRY CLUB

The report of the Executive Committee for the year ended August 31, 1922, shows that the Club has well maintained its position: the membership has increased from 690 to 707 and the financial position is excellent. A feature of the past year has been the strengthening of the *liaison* between the Club and the Federal Council for Pure and Applied Chemistry. For some time past three members of the Federal Council have been co-opted on the Executive Committee of the Club, and the hon. secretary of the latter has served on the Federal Council. Sir William Pope, Dr. C. A. Keane, and Mr. E. V. Evans were the original representatives of the Federal Council, but Dr. Keane, to everyone's regret, has been obliged to retire from this and other similar positions owing to illness. Dr. S. Miall has been appointed in his place. During the past year co-operation has been extended by the institution of informal, periodical meetings of an advisory body consisting of seven members of the Council and seven members of the Club. The ordinary monthly meetings were continued as usual and were much appreciated by those who attended them. The report also refers to the re-decoration of the Club premises, the provision of additional papers and magazines in the reading room, the foreign guests who were offered temporary membership, joint meetings with the Institution of Mechanical Engineers and the London Section of the Society of Chemical Industry, and to the annual dinner. This year's annual dinner will be held in the Connaught Rooms on Friday, November 24, and the speakers will include Lord Riddell and Mr. Roscoe Brunner (tickets, 15s. each, exclusive of wines). The report of the hon. treasurer is equally satisfactory. In spite of increased expenditure, there is a balance in hand of £86, in addition to a reserve fund of £100, a portion of which is being utilised to defray the cost of re-decoration.

The above reports were presented to and adopted by the annual general meeting, which was held in the Club on October 15, Mr. A. G. Craig, chairman of the Executive Committee, presiding over a good attendance. Except for some discussion upon a few points concerning organisation the business was formal. The hon. secretary, Mr. H. Edwin Coley, and the hon. treasurer, Capt. C. J. Goodwin, were re-elected, and the ballot for candidates to fill the five vacancies on the Executive Committee resulted in the election of Dr. E. F. Armstrong, Mr. A. J. Chapman, Mr. W. Cullen, Mr. C. S. Garland and Mr. T. Miller-Jones.

NEWS AND NOTES

FRANCE

Industrial Notes

Chemical Industry.—The continued instability of the international situation has affected the chemical market, which is very sensitive to such political disturbances; buyers have not been inclined to purchase forward, and business has been generally dull. German competition is not serious at present owing to the wide fluctuations in the value of the mark, but Belgium, benefiting from an appreciable decrease in costs, is undercutting French producers and gradually obtaining a hold on French markets. Manufacturers are again complaining of the State monopoly of the sale of alcohol. Whereas the State pays only 70 fr. and 90 fr. per hectolitre for alcohol of 95° and 99·5°, respectively, produced from beet molasses, the sale price to manufacturers of organic chemicals is so high that they find difficulty in reducing their costs so as to meet foreign competition. Fertilisers are not much in demand, and ammonium sulphate is being replaced by sodium nitrate, which is cheaper. The sugar-beet crop is very promising; the fine, rather cold weather has helped to ripen the beet, and extraction will probably be easy, as the quality is reported to be high. The estimated yield is 500,000 metric tons of refined sugar, to which must be added about 90,000 t. of raw sugar from the colonies.

An account of the International Congress on Liquid Fuels appears elsewhere in this issue. At the close of the Congress the delegates visited the petroleum field at Pechelbronn, where one well is producing at the rate of 1100 gallons per 24 hrs., and another, with an intermittent production, is yielding 45 metric tons per day. A new well is being sunk at the rate of 2 metres per day of 16 hrs. The annual output of crude petroleum in this locality is now about 70,000 t., which represents 8 per cent. of the entire consumption in France.

Metallurgy.—The general outlook is good, and the exportation of metallurgical products to Germany is increasing steadily. On September 1 the number of blast-furnaces alight was 98, compared with 94 on August 1, three having been blown-in in Alsace-Lorraine and one in the eastern metallurgical area. During the first eight months of 1922 the total output of pig iron was 3,136,482 t. and of steel 2,809,703 t. Rumours of an agreement between French and German metallurgical interests still persist, and in certain well-informed quarters are considered likely to prove true.

GERMANY

Chemical Industry in September, 1922

According to information transmitted by H.M. Commercial Secretary in Berlin, the inland demand for dyestuffs during September was satisfactory, despite a crisis in the textile industry. In many cases the orders in hand would suffice to ensure employment for some time to come, but the disparity between the amount of working capital available and the high prices of the necessary foreign raw materials compels restriction of work. The practice of investing in foreign currency may offer a security against fluctuations in exchange, but it also results in the raising of inland prices to prohibitive levels. Foreign sales were also satisfactory. A reaction in the unusual business activity is feared owing to the increasing difficulty of purchasing raw materials from abroad. Soda and benzol have, in particular, had to be imported in large quantities. The supply of rocksalt and lime was frequently insufficient owing to the scarcity of railway trucks, and that of fuel was quite inadequate. Large quantities of foreign coal and coke had to be imported for the nitrogen and dyestuffs industries, and the use of different kinds of fuel greatly hindered operations. The paper industry has suffered severely from difficulties in procuring raw material and a crisis is anticipated owing to the scarcity of capital. Dependence upon foreign coal and raw material is also handicapping the fine ceramic industry whose output is now about 75 per cent. of the pre-war total and whose exports are but 30 per cent. of the production, or less than one-half of the pre-war figure. —(*Official.*)

The Potash Industry

Preliminary returns from the German potash mines show that the production during the first six months of 1922 was 5,893,711 metric tons of potassium salts, equivalent to 682,787·5 t. of pure potash (K_2O). Export deliveries were below expectation but inland sales of potash products were fairly brisk and 58 per cent. higher than during the corresponding period of 1921. The number of workers employed increased from 39,594 to 42,139, and full-time was worked until towards the end of June when 76 of the 206 works ceased production. Later advices state that export sales have improved and for the year will probably amount to 23 per cent. of the total sales (5 per cent. in 1921), and these will probably create a record, even over pre-war totals.

The Cause of the Oppau Explosion

Before the Parliamentary Committee appointed to investigate the cause of the explosion at Oppau (*cf.* J., 1921, 381 R, 453 R), Prof. Wöhler reported on the evidence of the experts who were charged with the task of finding answers to the following questions:—

(1) Is there any evidence of a criminal act? (2) Was an exceptionally powerful explosive used, and could it have been the cause of the explosion? (3) Could the use of a large amount of the explosive normally employed have caused the explosion? (4) Can a normal fertiliser-salt be exploded with the explosive used? (5) Can a salt of abnormal composition be exploded? (6) Could such an abnormal salt have been present? (7) Can a positive answer be given as to the origin of the explosion? (8) Does the fact that two successive explosions occurred indicate the possibility of another cause, and can that fact be harmonised with the suggested explanation?

The replies of the experts to these questions were negative in nearly every case, including that to question (7). A charge of negligence against the Badische Anilin- und Soda-Fabrik could not be sustained, and even when every possibility was taken into consideration, such an explosion as occurred could not have been foreseen. The experts recommend that blasting of fertiliser salts containing nitrate be forbidden (as it has been since), but do not see any necessity for discontinuing the manufacture. As the printed evidence of the experts was not in the hands of the members of the Committee, it was decided to postpone the final decision.—(*Chem.-Z., Oct.* 5, 1922.)

Technical Utilisation of German Lignites

Prior to the war difficulties of sale restricted the output of German lignites (brown coals), and the maximum possible output was not attained despite a rapid increase in demand, which extended into the period of the war, and except for a temporary set back in 1919, has continued since. Supplies in 1921 amounted to 141 per cent. of those in 1918. In 1921-22, according to returns of the Deutsche Braunkohlen-Industrie Verein, more than 80 per cent. of the output of lignites was obtained by open-working, a factor influencing the output of this commodity, as all the coal in the country has to be mined. Owing to increased production and reduction of working hours, the number of workers engaged was about 125 per cent. greater in 1921 than in 1918.

The calorific value of lignite is only about one-third of that of coal, but the calorific value of brown-coal briquettes is about double that of the original lignite. Even then, freight charges for transport over any considerable distance, operate against the use of lignite in place of coal. The unsuitability of lignite as a fuel in certain branches of industry is also an adverse factor, and thus it comes about that lignites are exclusively employed in the districts where they are produced. In 1921, 57 per cent. of the output of lignites was briquetted, and the output of briquettes amounted to 28,243,000 tons, an increase of 116·4 per cent. compared with 1920, and of 128·5 per cent. compared with 1913. Although, owing to the lack of coal, lignites have of recent years found extended application in certain directions by the introduction of new devices, coal has not been displaced to any great extent for technical purposes. Thus the attempt to use lignites for the firing of locomotive boilers proved unsuccessful. Aided by the increased charges for transport, the "migration of industry towards coal," which set in before the war, has made considerable progress.

The following table shows the distribution of the consumption of lignite during the period January—April, 1922:—

	Lignite (crude)	Lignite Briquettes
Domestic and small industrial uses	5·1	52·7
Marine and military	—	0·2
Rail and water transport	0·3	1·0
Water- and gas-works	0·5	0·5
Electricity works	22·7	4·2
Chemical industry	22·4	5·8
Stone, earth, glass and porcelain	6·6	7·6
Textile and paper industries	13·3	6·5
Iron and metal industries	11·5	11·6
Foodstuffs	5·7	3·6
Potash and salt works	6·4	1·4
Other industries	5·5	4·9

The power station at Zschornewitz uses 7200 tons of lignite per day. It supplies Berlin with current and is also connected with the large nitrogen factories of middle Germany, and other chemical works. These works themselves are large users of lignites, and those situated in the vicinity of lignite deposits are in many cases part-owners of the mines. In this manner is explained the fact that in 1921—1922, over 15 per cent. of the output of lignite in the Mid-German district was credited to "associated factories."

In former years a considerable amount of lignite was imported from Bohemia. This was of higher calorific value and readily accessible. Gradually this trade has been abandoned in favour of the home product, and more especially of briquettes manufactured in Germany, and the imports, which amounted to 7,960,000 tons in 1900, fell to 1,910,000 tons in 1919, rising again to 2,662,000 tons in 1921. The principal buyers are the glass, porcelain and textile manufacturers of Saxony and Bavaria.

About 1·74 per cent of the output of lignites is used, not as fuel, but as raw material in chemical industry. Certain varieties are suitable for treatment by the Schwel process of producing paraffin and lubricating oils, and more recently for making soap. The residue, known as "Grudekoks," is a popular fuel. The production of ozokerite and liquid fuels from lignites has recently been extending.

"Rhenania" Phosphate

By the production of this material it is claimed that the problem of making a high-grade fertiliser from low-grade phosphate, without the use of sulphuric acid, has been solved. The process consists in heating to 1200°—1300° C. an intimate mixture of crude phosphate, limestone, and alkali silicate, such as felspar, phonolith or leucite, and the product is a brown mass, which is finely ground before marketing. The composition of the fertiliser may be represented approximately by the formula  $[\mathrm{CaO}]_2\begin{matrix}\mathrm{K}\\ \mathrm{Na}\end{matrix}\!\!>\mathrm{O.P_2O_5}$, and its percentage composition varies as follows:—P_2O 15—25, K_2O+Na_2O 8—15 (of which $K_2O=8$), SiO_2 10—20, CaO 35—40. The phosphoric-acid content is but slightly soluble in water, but from 80 to over 90 per cent. dissolves in citric acid or alkaline ammonium citrate, and 75 per cent. is soluble in an aqueous solution of carbon dioxide.

Rhenania phosphate can be used on any type of soil, and, being strongly basic, obviates the use of lime. Over superphosphate it has the great advantages that sulphuric acid is not required in its manufacture and that the poorest grades of mineral phosphate can be utilised. Factories at Wolfersberg a. d. Lahn and Amberg (Bavaria) are producing it, and nearly one million tons has already been sold. The evidence of pot experiments and field trials is favourable.—(*Z. angew. Chem., Oct.* 3, 1922.)

The German Commission on Atomic Weights

A second detailed report on the determinations of atomic weights published during the period 1916 to 1920 has been issued by the German Commission on Atomic Weights, consisting of Professors Hönigschmid, Bodenstein, Hahn, and R. J. Meyer. The general principles followed in drawing up the tables are described, and then the atomic-weight determinations carried out (a) by physico-chemical methods, *e.g.*, vapour density, and (b) by gravimetric methods. Regret is expressed at the multiplication of national tables of atomic weights, as there are now Spanish, Swiss and German tables in addition to the International Table.—(*Chem.-Z., Sept.* 7, 1922.)

The Porcelain Industry

The Union of German Porcelain Factories (Verband Deutscher Porzellangeschirrfabriken) reports that the 97 plants comprised in the Union produced 62,925 tons of porcelainware in 1921 as compared with 48,151 tons from 92 plants in 1920. Shortage of coal kept the production below capacity and wood fuel had to be used because the industry only received 49 per cent. of the pit coal, 42 per cent. of the lignite and 80 per cent. of the briquettes required. In 1921, 13,929 men and 13,329 women workers were employed by the industry, in addition to 2090 men and 279 women employed in the offices. Production costs increased by over 200 per cent. between April, 1920, and January, 1922. Before the war the United States was the principal market for German porcelain goods. The percentage of the total exports taken by the United States was 41·9 in 1912, 4 in 1919, 12·77 in 1920, and 44·48 in 1921. In normal times about 60 per cent. of the German production is exported; in 1920 it was only 28 per cent. Japan is now Germany's chief competitor in this industry.—(*U.S. Com. Rep.*, *July* 10, 1922.)

UNITED STATES

The Camphor Industry

According to Dr. Stockberger, physiologist to the U.S. Department of Agriculture, the cultivation of the camphor tree and the extraction of camphor in the United States have ceased. Apparently the industry has been abandoned because of the ravages of the camphor "thrips," a pest for which no effective means of control has been discovered, and of inability to compete with synthetic camphor. The prospects were deemed not sufficiently hopeful to justify the costs incurred in waiting seven or eight years for the first harvest. Although large areas were planted to camphor in Florida (*cf.* J., 1921, 236 R, 388 R), and the various stages from planting to distillation were studied, no reliable data concerning yields or costs were obtained.—(*Oil, Paint and Drug Rep.*, *Oct.* 2, 1922.)

Mica in 1920

During 1920 the sales of mica in the United States amounted to 6565 short tons (842 t. of sheet and 5723 t. of scrap), valued at $713,898 at or near the mine, representing an increase of 76 per cent. in quantity and 188 per cent. in value compared with 1919. In order of importance the chief producing States were North Carolina, New Hampshire, Virginia, Alabama, Georgia, Texas, South Dakota, New Mexico, Idaho, and Colorado. Prices were high during the first half of the year, but declined afterwards, owing to foreign competition; the average price per ton of scrap mica increased by $11 to the record value of $29, but the average price per lb. of sheet mica only rose from $0·31 to $0·32. Exports of mica were valued at $316,169 ($109,348 in 1919), over 75 per cent. going to England, Canada, Belgium, Japan, Cuba, Newfoundland and Labrador, in the order named. Imports of sheet mica were valued at $3,189,377, the highest value recorded, and included 649 t. of unmanufactured mica valued at $1,177,943. —(*U.S. Geol. Surv.*, *Apr.* 12, 1922.)

JAPAN

The Artificial-Silk Industry

Owing to lack of technical experience and supervision and high costs of production, the Japanese artificial-silk manufacturers cannot compete with America and Europe, and they have suspended production pending the conclusion of an agreement for co-operation with German manufacturers. In contrast with the rapid extension of the manufacture of artificial silk in England and the United States, the Japanese industry, although it is twenty years old, has been on the verge of collapse for some time. The chief companies (Nippon Jinzokinuito Seizokaisha, Toyo Jinzokinuito Seizokaisha, Asahi Jinzokinuito Seizokaisha, Teikoku Jinzokinuito Seizokaisha and Tokyo Jinzokinuito Seizokaisha) were almost unanimous in taking the above decision, but they have not yet completely closed down. Methods of improving the industry are being considered; the Asahi Co. has bought a German factory and will begin to produce in the autumn; and other companies have engaged German experts and will buy directly from Germany.—(*Chem. Ind.*, *Sept.* 25, 1922.)

CANADA

Industrial Notes

Two British brewing firms have recently inspected sites in the Province of Quebec with a view to establishing plants, because of their inability to meet the demand for their products on account of the import tax.

This season the sugar-beet crop of Ontario has been light, owing to the shortage of rain, and as a result only the Wallaceburg and Chatham refineries of the Dominion Sugar Co. will be operated, the plant at Kitchener being closed.

The Dominion Glass Company, which operates two plants in Montreal, proposes to erect one large plant in the vicinity of Montreal, at a cost approximating $1,000,000, which will take over the business handled by the two present plants, and at the same time provide for expansion.

The firm of F. X. Baumert and Co., Inc., of Antwerp, has concluded negotiations for the erection of a large milk plant at Huntington, Que. This town is the centre of a large dairy industry, which is capable of delivering 2 million lb. of milk within a radius of six miles. Much of the milk went to the United States, but the new U.S. tariff has practically closed this market.

The United Kingdom was a better customer of Canada than the United States during the twelve months ending with July, according to a statement of the Dominion Bureau of Statistics. The total exports of Canadian products to the United States for that period were valued at $304,000,000, and to Great Britain and Ireland nearly $307,000,000. Under the new U.S. tariff, which came into force on September 23, it is expected that the export trade to that country will further decline. On the other hand, it is anticipated that there will be an appreciable development of Canadian trade with Europe and other continents.

The American Nitrogen Products Co., at Lake Buntzen, B.C., which is manufacturing nitrates from atmospheric nitrogen by the electric method, has approached the provincial government for a loan, under the Industries Act, to assist in the development of new products. The plant at Lake Buntzen has been producing nitrate of soda, which was largely exported to the United States, but the new tariff has placed such a prohibitory duty on the product that the company now proposes to manufacture nitric acid. The plant is stated to have cost $500,000, and was operating at a good profit. C. F. Graf, of Seattle, Wash., is head of the organisation.

It is claimed that the money spent to-day in Canada on rubber products is greater, *per capita*, than in any other country in the world. In 1910 the number of rubber companies did not exceed a half-dozen, with an invested capital of $8,000,000 and 5000 workers. The crude rubber imported was 1070 long tons and the value of the products $5,000,000. A decade later the rubber companies exceeded a score, operating 32 factories with an invested capital of $50,000,000 and a personnel of 15,000. The import of crude rubber is almost ninefold; the value of the products is approximately $56,000,000; and the export trade amounts to $15,500,000, which is more than treble the value of the whole output of 1910.

Petroleum

In boring a deep well for water near Vauxhall, about 28 miles north-east of Taber, Alberta, gas was struck at a depth of 840 feet. The gas flow exceeds two million cb. ft.

The Imperial Oil Co., Ltd., is to construct an oil refinery in south-east Calgary, Alberta, at a cost of $2,500,000. The company has secured 108 acres of land and will employ between 300 and 500 men.

The report that the "Discovery" well of the Imperial Oil Co., at Fort Norman, was flowing at the rate of 70 barrels per diem has been confirmed. The flow comes from a depth of about 1000—1100 feet.

GENERAL

Proposed Honour to Prof. H. B. Dixon

A committee of past and present students of the Chemical Department of Manchester University has been formed to honour Prof. H. B. Dixon on his retirement from 35 years' service as Director of that Department. It is proposed to hold a dinner in the Midland Hotel, Manchester, on Friday, December 8, at which Prof. Dixon will be the guest of the evening, and to invite subscriptions (*a*) to raise a fund, to be handed over to the University authorities, from which the income will be given as grants-in-aid to necessitous students of chemistry; and (*b*) to purchase a medallion portraying the head of Prof. Dixon, to be placed in the Chemical Theatre adjacent to the medallions of Frankland and Roscoe. Dr. J. E. Myers is hon. secretary, and Dr. Norman Smith hon. treasurer to the committee. Applications for dinner tickets (12s. 6d), and donations to the Harold Baily Dixon Fund, should be sent to Dr. Smith at The University, Manchester.

Vanadium

A small but valuable brochure on "Vanadium, 1913—1919" (pp. 19, price 6d.) has been issued by the Imperial Mineral Resources Bureau which contains considerably more recent information than is indicated by the title. As a source of supply of vanadium, Peru has recently ousted the United States from the first place, as the following table shows:—

Output of Vanadium (in terms of Metal) contained in the Ores produced

	Peru	U.S.A. Long tons	Total
1913	—	386	386
1914	4	404	408
1915	790	560	1,850
1916	760	411	1,171
1917	805	432	1,237
1918	229	246	475
1919	491	254	748
1920	1,095	455	1,550

The large deposits of patronite, a black carbonaceous mineral containing vanadium sulphide, which occur at Minasraga, near Cerro de Pasco, Peru, and are owned by the Vanadium Corporation of America, are estimated to contain ore in sight equivalent to 16,500 tons of metallic vanadium. The grade of ore now worked has recently fallen from 40—45 per cent. V_2O_5 in the calcined product to 30·4 per cent. (1919), and on this account the company has decided to erect an electric smelting plant to produce a concentrate containing 85—90 per cent. of the oxide. In addition to these deposits, there are extensive occurrences of vanadiferous asphalt to the south of Cerro de Pasco, in Yauli and other districts, but it is improbable that these will prove of commercial significance, except under abnormal conditions.

The chief deposits of vanadium ores, mainly carnotite, in the United States are found in south-eastern Utah and north-western Colorado. Production has declined, and in 1921 the only vanadium produced from native ores was that obtained as a by-product from carnotite worked for its radium-content. Exports of ferro-vanadium from domestic ores, of which a large proportion is shipped to the United Kingdom, amounted to 280 long tons in 1914, 1167 t. in 1917, 28 t. in 1918, 173 t. in 1919, and 100 t. in 1920 (the last three years are calendar years).

Mr. J. L. F. Vogel contributes some interesting notes on the metallurgy and uses of vanadium. The manufacture of steel claims practically the entire consumption. For steel subject to vibration, a content of 0·2 to 1·5 per cent. vanadium imparts greater resistance to fatigue or failure through recrystallisation, and the presence of 0·5 to 2 per cent., together with tungsten and chromium, greatly improves the efficiency and cutting-power of high-speed steel. Its addition to molten steel also removes nitrogen and reduces dissolved oxides.

British Chemical Plant Manufacturers' Association

The second annual report of this Association states that notwithstanding the recent critical state of trade, the Association has increased in strength and has established itself as representative of the industry it was designed to foster. The membership has increased from 28 to 33 firms. Mr. J. H. Rawson (The Widnes Foundry Co., Ltd.) has acted as chairman of committee and Mr. L. M. G. Fraser (W. J. Fraser and Co., Ltd.) as vice-chairman. Of the work undertaken during the year, mention is made of the standardisation of jacketed pans and cast-iron filter presses (*cf.* J., 1922, 52 R, 210 R). Investigations into the use of nickel for chemical plant have led to the conclusion that this metal is satisfactory for use in the construction of small vessels. A Directory of members has been issued, and the question of transport has been considered.

The Polish Iron Industry, 1922

The ore supply for the Polish and Upper Silesian iron industry has recently been the subject of a conference in Warsaw. The Poles wish to induce the ironmasters, especially those in that part of Upper Silesia which now belongs to Poland, to develop the exploitation of ores found in the country, in order not only to further the mining industry, but also to save losses on exchange. But the Upper Silesian smelters have estimated their needs at 400,00 tons per annum, whereas at present the Polish mines cannot supply more than 200,000 tons. The supply of Russian high-grade ores is practically cut off, and the Russian railways are incapable of handling large quantities of material. The coke supply is another difficulty. Supplies are obtainable from England, Czechoslovakia, and the Waldenburg district in Germany; those from the first two countries are plentiful, but prices are very high.

Mica Deposits in Austria

According to information published in the *Berliner Tageblatt*, the mica present in extensive deposits in Styria and Carinthia is well suited for electrotechnical use. Mica from Styria has already been used industrially, and a company has been extracting Carinthian mica for some time. The Kölflach fields are to be exploited by a new company, the Oesterreichische Glimmerwerk G.m.b.H., of Gratz, which will also work part of the Carinthian deposits. As there are no deposits of mica in Germany, the Austrian product should find a ready sale there.—(*Ch. of Comm. J., Aug.* 4, 1921.)

The Fertiliser Industry in the Ukraine

The reports for June announced that all except one of the Ukrainian factories constituting the ring called "Phosphatuk" were at work, but only 1920 long tons of superphosphate was produced, as against 480 t. in May. The output of sulphuric acid was about 450 t.; of hydrochloric acid, about 32 t.; English red (colcothar) 50 t.; Glauber's salt 2·5 t.; "hypo" 2·8 t. Adequate supplies of pyrites, phosphates and fuels, particularly peat, are on hand, but none of the factories has adequate working capital.

The Russian Platinum Industry in 1922

The dredging operations in the Russian platinum regions have had to be restricted owing to the difficulty found by Russian factories in executing repairs; the number of plants now at work is only about sixteen, *i.e.*, half the usual number. At the end of 1921 a trust—the Ural Platjina—was formed which included the six important gold and platinum mining districts, and also the platinum refineries at Ekaterinburg and Moscow. Production in the first six months of 1922 was 64·4 per cent. of that intended; the actual weight is not given, but it is stated that 46 pounds of platinum changed hands during the period from the end of April to the middle of July. It is probable that the production of the trust is small, and that considerable quantities of platinum are in the hands of the population.

Mineral Production in Russia

According to reports abstracted from the Bolshevist Press by the U.S. Department of Commerce, 97 mining plants are registered in Russia as being in working order. During the first half of 1921, 89 plants employing 15,000 men were operated, the number falling to 42 plants and 5682 men at January 1, 1922. The output of the chief ores during 1921 and the first quarter of 1922 was as follows:—

	1921	Jan.-Mar. 1922
Ores:—	Long tons	
Iron	133,831	43,013
Manganese	11,054	13,703
Copper	4,369	—
Chrome	3,512	97
Lead and zinc	4,063	2,099
Magnesite	9,037	4,323
Asbestos	6,083	1,032
Pyrites	2,593	—

The quantity of manganese ore dispatched from the mines during 1921 was 18,992 tons and during the first quarter of 1922, 5417 tons.—(*U.S. Com. Rep., June* 26, 1922.)

PERSONALIA

Prof. Arthur Smithells will shortly retire from the chair of chemistry in the University of Leeds, after 37 years' service.

Dr. Percy Longmuir, of Sheffield, has been appointed Director of Research to the British Cast-Iron Research Association.

Prof. G. Errera, professor of general chemistry in the University of Padua, has been elected director of the School of Pharmacy in the same University.

Dr. W. Rosenhain, Head of the Metallurgy Department of the National Physical Laboratory, will deliver the next May Lecture of the Institute of Metals.

Dr. George Senter, Principal of the Birkbeck College, London, has been elected by the science graduates of London University to fill a vacancy on the Senate.

Col. F. M. Gaudet, C.M.G., who during the past year has been Technical Executive Officer of the Research Council of Canada, has resigned and joined a large industrial firm in Montreal.

Mr. C. S. Garland, managing director of Lighting Trades, Ltd., a vice-president of this Society, has been adopted as the Conservative and Unionist candidate for South Islington (London), in place of Sir Charles Higham.

The following appointments have been made in the Massachusetts Institute of Technology:—Dr. G. B. Waterhouse to be professor of metallurgy; Mr. W. S. Hutchinson to the chair of mining; and Dr. F. G. Keyes, formerly chief engineer to the Cooper-Hewitt Co., to be acting head of the department of chemistry.

Following the resignations of Sir H. V. Kilvert, Mr. G. W. Currie, and Dr. M. O. Forster from the Advisory Licensing Committee appointed under the Dyestuffs (Import Regulation) Act of 1920, Sir Thomas Robinson, M.P., has been appointed chairman, and Mr. R. Waddington, M.P., and Prof. G. T. Morgan members of the Committee.

The Council of the Institution of Mining and Metallurgy has awarded the Gold Medal of the Institution to Sir Alfred Keogh on the occasion of his retirement from the Rectorship of the Imperial College of Science and Technology, and the Medal of the Institution to Sir George Beilby in recognition of his contributions to science, with special reference to his researches on fuel.

Dr. Max Bodenstein, professor of chemistry in the Technical *Hochschule* at Hannover, has been called to the chair of physical chemistry in the University of Berlin, in succession to Prof. W. Nernst. Professors B. Helferich and A. Sieverts have been appointed to professorships in the University of Frankfurt, the latter succeeding Prof. E. Ebler in the chair of physical chemistry. Dr. F. Straus has been appointed professor of chemistry in the Technical *Hochschule* at Breslau.

* * *

E. Stassono, the inventor of the electric steel furnace named after him, died in poverty on May 1, aged 63 years.

Mr. Frank Washburn, who was president of the American Cyanamid Company from its inception until a short time ago, died on October 9.

Prof. F. D. Brown, emeritus professor of chemistry and physics in Auckland University College, died at Remuera, New Zealand, on August 2, aged 71.

Mr. James Lund, Vice-President of the Merrimac Chemical Co., Boston, U.S.A., and for 30 years a member of this Society, died on September 29, aged 64 years.

From Germany are announced the following deaths:—Prof. Lassar-Cohn, of Königsberg, aged 64 years, who, besides contributing to the development of organic chemistry, achieved a well-earned reputation as the author of several books on chemistry written in a popular style. W. P. L. Beth, the author of the Halberg-Beth system of purifying blast-furnace gases, died in Lübeck on August 27; and Dr. H. Schelenz, the historian of pharmacy, died on September 28 in his 75th year.

OFFICIAL TRADE INTELLIGENCE

(From the Board of Trade Journal for October 12 and 19)

OPENINGS FOR BRITISH TRADE

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence), 35, Old Queen Street, London, S.W. 1, from firms, agents or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number.

Locality of Firm or Agent	Materials	Reference Number
Australia ..	Castor oil	402
,, ..	Pottery, glassware, fibre-board ..	411
,, ..	Dry colours	412
,, ..	Glassware	*
Brazil ..	Paint, glazed bricks	442
Burma, Ceylon, Far East ..	Perfumery, pharmaceutical preparations, linseed and paint oils	439
Canada ..	Copper, galvanised and insulated wire, lighting glassware, tungsten-lamps, glass- and porcelain-insulators	9640/E.D./ E.C.
,, ..	Tinplate	†
,, ..	Galvanised sheets	9785/E.D./ E.C.2.
Denmark ..	Crude rubber	421
France ..	Tin-coated paper, fancy, kraft and printing paper	16925/F.W./ M.C.
Guatemala ..	Earthenware	443 *
Mexico ..	Drugs	398
,, ..	China, earthenware	399
Panama ..	Glass, glassware, pottery	225/68/F.O./ M.C.
Poland ..	Tin, copper, antimony, bearing metals, solder, steel, lead, coloured glass, cylinder oil, zinc white, white lead	429
South Africa ..	Tar or tar substitute (tender for) ..	9720/E.D./ M.P.
Switzerland ..	Chemicals for the paper, textile and tanning industries	388
Syria	Glass, glassware, pottery	225/51/F.G./ M.C.
United States	Pottery	225/4/F.G./ M.C./C.

TARIFF CUSTOMS EXCISE

Australia.—" Anti-dumping duties " have been applied to dairy thermometers and 4711 eau-de-cologne. An Act amending the Customs Act provides that *ad valorem* duties are to be based on the value of the goods in the exporting country or on the price f.o.b. paid by the Australian importer, whichever is higher. If the currency of the country of origin has depreciated to less than one-twelfth of its normal value, the *ad valorem* duty is replaced by a duty representing the difference of the cost plus duty plus profit in Australia and the wholesale price of similar goods made in Australia.

Ceylon.—Details of the proposed new customs tariff are given in the issue for October 19. Goods affected include acetic acid, cement, certain wares of glass, many metals, lubricating oil, perfumery, salt, soap, and sugar, but research chemicals and apparatus, copra, coconut oil, fertilisers, non-ferrous metals, unwrought metals, petroleum, quinine, crude rubber are not affected. The export duties on areca nuts, coconut products, plumbago, and rubber are also to be revised.

Esthonia.—The export duties on gold, silver, platinum and wares thereof have been revised.

France.—Goods bearing any mark suggesting that they are of French origin may not be imported unless bearing the name of the country of origin.

Gold Coast.—The differential export duty on palm kernels has been abolished.

Italy.—An export licence is no longer required for potassium permanganate or for small quantities of sugar.

Mexico.—The import duty on lard has been modified.

New Zealand.—Regulations have been issued controlling the importation, sale, etc., of opium, morphine, heroin, cocaine, codeine, or ecgonine.

Northern Rhodesia.—Revised rates of duty have been applied to crown corks and stoppers, bioscope films, medicinal preparations, essences, syrups, tinctures containing over 3 per cent. of proof spirit, and starch.

South Africa.—Rebates are allowed on the duties payable on oils, gums, turpentine, solvent naphtha, " Sealtite " and similar fluxes, when imported for industrial use.

Spain.—Under the commercial convention made with Norway, reduced import duties are applied to cod-liver and other animal oils, synthetic nitrogenous compounds, oxalic acid, commercial oxalates, and nitrate of soda.

United States.—A partial reprint of the new customs tariff is given as a supplement to the issue for October 12.

Vladivostock.—The following rates of export duty, based on the local market value, have been fixed:— 2·5 *per cent.*: Beeswax, calamine, zinc blende, copper ore, scrap metals, glassware; 10 *per cent.*: wolframite, nickel, cobalt, manganese ores; 5 *per cent.*: other goods, except linseed, pottery, and bricks, which are duty-free.

Mandated Territories.—By an Order in Council, dated October 13, from November 1 the Tanganyika Territory, the British Sphere of the Cameroons, and the British Sphere of Togoland, will be included within the definition of the British Empire for the purposes of Section 8 of the Finance Act, 1919, which confers preferential rates of duty on goods grown, produced or made within the British Empire.

REPORTS

RST ANNUAL REPORT OF THE SECRETARY OF MINES FOR THE YEAR ENDING DECEMBER 31, 1921, AND THE ANNUAL REPORT OF H.M. CHIEF INSPECTOR OF MINES FOR THE SAME PERIOD. *Mines Department. Pp.* 181. *H.M. Stationery Office*, 1922. *Price* 6*s.* 6*d.*

This report, which marks the completion of the st year of the existence of the Mines Department, ntains, in addition to the report of H.M. Chief spector of Mines, a review of matters outside his ovince. Part I is devoted to a review of the coal-ining industry during 1921, of the effect of the al stoppage, and of the scheme of organisation hich brought the dispute to an end. The number mines working under the Coal Mines Acts ineasd from 2851 to 3045; the number worked under e Metalliferous Mines Acts fell from 498 to 383, d the number of quarries decreased from 5479 to 66. Workers employed at the mines under the al Mines Act numbered 1,156,938 (including 4,649 workers underground) and at the quarries ,979. The numbers of persons killed and injured accidents were 768 and 86,888, respectively, inuding 756 fatal and 86,352 non-fatal accidents coal mines.

The output of minerals in the United Kingdom is own in the appended table:—

	1921	1920
	Long tons	
Coal	163,251,181	220,532,081
Iron ore, ironstone	3,477,955	12,706,895
Bauxite	2,269	11,020
Copper ore, dressed	36	81
Copper precipitate	100	194
Gold ore	—	1
Lead ore, dressed	6,787	15,399
Manganese ore	514	12,875
Tin ore, dressed	1,078	4,858
Tungsten ore, dressed	*	94
Uranium ore	76	60
Zinc ore, dressed	814	5,064
Alum shale	2,840	5,539
Arsenic, white and soot	1,032	1,997
Arsenical pyrites	—	1,178
Barium compounds	24,669	64,150
Bog ore	817	2,179
China clay	435,844	777,511
China stone	34,886	73,102
Chromite of iron	—	1,100
Fluorspar	23,137	54,683
Fuller's earth	20,242	28,906
Gypsum	264,840	286,978
Iron pyrites	3,943	6,659
Lignite	—	150
Natural gas (cb. ft.)	100,000	95,000
Ochre, umber, etc.	10,310	15.537
Oil shale	1,866,896	2,842,582
Petroleum	342	375
Salt	1,382,629	2,158,370
Soapstone	—	361
Sulphate of strontia	6,622	4,183
Chalk	3,434,357	3,747,165
Chert, flint, etc.	45,641	84,303
Clay and shale	8,351,450	8,021,484
Fireclay	1,352,587	1,966,040
Gravel and sand	2,489,817	2,757,052
Igneous rock	5,740,014	5,620,691
Limestone	7,335,862	11,227,817
Ganister	150,562	310,019
Sandstone	1,884,550	1,873,797
Slate	237,350	215,269
Total (excluding natural gas)	201,999,903	284,601,174

* Cannot be stated.

The decline in the total value of the mineral prouction from £427,444,884 in 1920 to £231,681,358 n 1921 reflects the reduced output due to low prices nd high working costs.

Coal.—The average net selling-value fell from 4s. 6·97d. in 1920 to 26s. 2·23d. in 1921. At the lose of the year, both the output per man-shift and he export improved. The total electric power used in coal mines was 1,148,103 h.-p., an increase of 67,281 h.-p., and the number of coal-cutting machines rose by 188 to 5259, but the output of coal by machine-cutting fell from 30,194,306 t. to 23,039,705 t. The total quantity of coal shipped abroad was 37·7 million t., leaving 129·1 mill. t., including 3·5 mill. t. of imported coal or its equivalent in coke, for home consumption (185·8 mill. t. in 1920), or 55 cwt. per head of population. Coal carbonised at coke ovens amounted to 6,885,940 t., and at gas works to 16,651,757 t., the output of coke being 4,575,618 t. and 6,798,492 t. (excluding coke used in the gas works), respectively. The number of coke ovens in use fell from 15,400 to 13,026, of which 4044 were beehive and 8146 by-product ovens.

Iron.—Owing to the collapse in prices and the coal stoppage, the production of iron ore, and of iron and steel was very greatly reduced. Retained imports of iron ore totalled only 1,887,642 t. Returns for the pig-iron industry in 1920 and 1921 are appended:—

		1921	1920
Works in operation		117	116
Furnaces built		486	481
Furnaces in blast	(average)	95¼	$284\frac{7}{12}$
Pig iron made	(tons)	2,616,300	8,034,717
Iron ore used	,,	5,604,093	19,137,460
Coal used	,,	651,077	2,062,370
Coke used	,,	3,075,947	10,036,219

Tin Ore.—Tin mining practically ceased early in 1921, but as the cost of fuel, materials, and wages has gradually fallen. it appears probable that work in mines that have kept their pumps going will be resumed when the price of metal improves slightly.

Zinc Ore.—There was no market for zinc concentrates during the year, and the zinc-smelting plants were at a standstill. Consequently the mines which produce chiefly zinc blende remained closed.

Manganese Ore.—The mining of manganiferous ore has almost ceased owing to its low grade.

Oil-shale.—There are 31 oil-shale mines in Scotland with a normal annual output of 3 mill. t. of shale, yielding about 60 mill. gallons of crude oil and 55,000 t. of ammonium sulphate. Many of the mines had to be closed during the coal stoppage and have not yet been reopened owing to the fall in price. The value of the products from one ton of shale was 29s. in January and 16s. in December.

Petroleum.—The petroleum well at Hardstoft is the only one now producing in England, all the others having been plugged and abandoned. Oil has been struck at the D'Arcy boring in Scotland and the West-Calder well is being plugged. Oilfields of England, Ltd. is prospecting for petroleum near Kelham, Notts.

Metals.—Figures showing the production of metals from home-produced ores and the mean monthly prices during 1921 are given below:—

		Production		Average monthly price during 1921		
		1921	1920	£	s.	d.
Copper	(tons)	72	127	—		
Standard		—	—	69	8	8
Electrolytic		—	—	75	1	1
Best selected		—	—	71	11	7
Iron, pig	(tons)	1,071,120	3,952,692	—		
Cleveland No. 3		—	—	7	1	11
Lead	(tons)	5,158	10,961	22	14	6
Tin	,,	679	3,065	165	8	2
Zinc	,,	292	1,655	26	4	1
Gold	(fine oz.)	—	34·5	—		
Silver	,,	12,229	76,344	—		

An important event of the year was the appointment of the Safety in Mines Research Board, to advise the Secretary for Mines on research work and to supervise its execution. The chief subjects investigated at the Eskmeals Experiment Station included the propagation of flame; the ignition of gaseous mixtures; the spontaneous combustion of coal; tests of mining apparatus and miners' lamps. No large-scale work was carried on, owing to lack of funds. A joint committee of the Department of Scientific and Industrial Research, the Chemistry Co-ordinating Board, and the Safety in Mines Research Board has undertaken an inquiry into the adequacy of the tests for permitted explosives. Research on miners' lamps was continued.

The retained imports and the exports of British minerals and their products in 1921 were as follows:—

	Imports retained		Exports
		Tons	
Iron ore (except chrome iron ore and pyrites)	1,887,642	..	1,566
Copper ore	24,338	..	242
Copper manufactures	80,792	..	29,330
Copper sulphate	11	..	27,997
Lead ore	819	..	3,857
Lead manufactures	122,451	..	15,998
Lead, red	1,059	..	2,588
Lead, white	3,463	..	6,182
Tin ores and concentrates ..	20,277	..	199
Tin manufactures	6,314	..	10,877
Zinc ore	5,945	..	1,416
Zinc, crude and manufactured ..	72,265	..	7,343

* Figures not available.

REPORT ON THE ECONOMIC SITUATION IN THE NETHERLANDS EAST INDIES, TO MARCH, 1922. *By* H. A. N. BLUETT, *British Commercial Agent, Batavia. Department of Overseas Trade. Pp. 92. H.M. Stationery Office*, 1922. *Price 2s. 6d.*

Agriculture in the Netherlands East Indies progressed continuously until 1920, but since then trade depression has made necessary a reduction in the area under estate cultivation, particularly on rubber, tea and coffee estates. Agricultural research has been continued, however, and progress has been made in cultivating oil-palms and cotton; large areas of jungle in Sumatra have been cleared for planting cinchona, and other developments are proceeding. Sugar is the principal export of Java, and the sale of the output of 148 of the 183 sugar factories is controlled by the United Java Sugar Producers (*cf.* J., 1922, 402 R). Some 800,000 acres are now planted with Hevea rubber. Cinchona production is controlled by the Kina Bureau and the British Combine of Cinchona Planters in Java; the former controls, roughly, 45,594 acres planted to cinchona, and sells the output to the Bandoengsche Kininefabriek, which produces over 80 per cent. of the world's consumption. The British combine controls 3407 acres and sells its produce to a manufacturer in the United Kingdom. Production of bark from uncontrolled plantations is small, but several plantations will in time have a large output. The export of cinchona bark from Java and Madura in 1921 was 4601 metric tons (*cf.* J., 1921, 356 R) and of quinine 281·6 t. (310·3 t. in 1920). So far plantations of the oil-palm have been made only in Sumatra, where 22,230 acres have been planted; in 1921 the output was 2314 t., and the industry is gradually being established. The important copra industry is mainly in native hands; the factories established for extracting coconut oil during the war are finding difficulty in competing with European factories, as it pays better to export copra than oil. In 1921 exports of copra from Java and Madura amounted to 93,009 t., and from the other islands to 66,807 t., compared with a total of 182,000 t. in 1920.

Petroleum, coal, tin, gold, silver and iodine are produced in important quantities, and manganese, iron, nickel and copper ores, magnesite, phosphate rock, trass, sulphur and diamonds are either produced in small quantities or offer prospects of development. The petroleum resources are not so great as those of America, but the production is steady and will probably remain constant for many years. Development of petroleum and minerals is discouraged by the new mining law, which reserves a large share of any profit to the Government. The output of coal is increasing steadily and reached 1,117,432 t. in 1921; if the output continues to increase, external markets will have to be sought. Two gold and silver deposits in the Residency of Benkoelen (Sumatra) are being developed by the State, and a rich deposit of copper has been found at Tanim (Dutch Timor), but a body of ore sufficient to warrant exploitation has yet to be discovered. A deposit of iron ore, estimated to contain 5 million t. of surface ore and 155 million t. of clay ore, has been discovered in the island of Celebes near abundant water-power; the dry ore contains 48 per cent. of iron, 6·5 per cent. of aluminium and 10 per cent. of moisture. In 1920 there were produced: gold 8,864,771·3 fine oz.; silver 102,027,820·7 fine oz.; manganese ore 4179 t.; tin 2072 t.

The Government has fostered the establishment of new industries. Progress has been made in the manufacture of edible oils and of soap, factories for making firebricks, bricks and tiles, paint, etc. have been established, chemical industry is developing, and oxygen, carbon dioxide, iodine, sodium bisulphate, carbon bisulphide, calcium carbide, and pyrotechnical compounds are being made on a limited scale. An iron and steel works is being built at Cheribon by German interests, a paper mill with an (annual) capacity of 3000 t. is under construction, as are also a blast furnace in Sumatra and a lead factory at Gedangan. A British-Dutch-Norwegian combine is considering the erection of a factory for making synthetic fertilisers.

In 1920, the latest year for which statistics are available, exports from the Dutch E. Indies reached the record value of 2,254,000,000 guilders (guilder= 1s. 8d. at par, now about 1s. 9d.), of which 47·1 per cent. was for sugar and molasses, 8·9% for rubber and gutta-percha, 11·7% for tobacco, coffee and tea, 4·1% for quinine, 0·4% for cinchona bark and 25 per cent for minor agricultural, mineral and forest products. Since the war new markets have been found in the United States, Australia, and the Far East, and the future is regarded with optimism. Imports in 192 were valued at 1,116,200,000 guilders, derived, i order of importance, chiefly from the United Kingdom, the United States, Japan, and Singapore. Import statistics for 1921 will probably show a heav reduction both in quantity and value. At presen there is a growing demand for textiles, chemicals glass an paints, leather, earthenware, porcelain, lassware, but the market for iron and steel is dull. reat Britain, Germany, the United States and apan are competing keenly in the chemical trade, nports from Japan are decreasing, and Germany as almost recovered her pre-war position. British rade in the Dutch East Indies could be coniderably increased, the market offering very great ossibilities.

EPORT ON THE INDUSTRIAL AND ECONOMIC SITUATION IN CZECHOSLOVAKIA, DATED MAY, 1922. *By* R. H. B. LOCKHART, *H.M. Commercial Secretary, Prague. Department of Overseas Trade. Pp.* 44. *H.M. Stationery Office*, 1922. *Price* 1*s*. 6*d*.

Since the publication of the previous report on echoslovakia (*cf.* J., 1921, 372 R) this State has rogressed further in construction problems. The ood support accorded to a State loan floated in ondon and the establishment of an Anglo-Czech ank in Prague are indications of the interest and onfidence of English business men in the country. he continued decrease in purchasing power of eighbouring States has led to a crisis in the ndustry of the country, which relies on exports for ts prosperity. This was, however, foreseen by most anufacturers, and no serious failures have ccurred, nor are any anticipated. As a remedy trong efforts are being made to reduce wages and he cost of living. Glass holds third place in zechoslovak exports for 1921. To extend their arkets window-glass manufacturers have formed wo sales organisations under the names of "Vitrea" and "Fenestra." In the spring of 1921 ontrol of the sugar industry was taken over by a yndicate. The estimated output for 1921–22 is 50,000 metric tons. (For further details of the 921–22 sugar trade *cf.* J., 1922, 177 R, 315 R, 334 R.) he coal industry has suffered badly in the period nder review, though the output in 1921 was lightly greater than in 1920. In 1921 the output f hard coal was 11·65 million tons, and of lignite 1 million tons. The position of the metal industry as also declined owing to high costs. Of the total 921 imports, 3,961,716 metric tons, Great Britain upplied 2·5 per cent., and of the exports, ,645,765 t., took 1·6 per cent. (*cf.* J., 1922, 225 R). he quantities and distribution of certain groups of mports and exports in 1921 were as follows:—

	Metric tons	Percentage distribution
Imports:—		
olours, dyes, tanning materials	17,882	Austr. 19, Yugoslav. 18, Ger. 11
ums, resins	13,248	Ger. 37, Fr. 27, U.S. 12
ineral oils, tar, coal tar	104,256	Pol. 72, Rum. 18
lass, glassware	1,487	Ger. 85, Austr. 10
hemicals, chemical products	168,065	Ger. 36, Belg. 11, Austr. 6
Exports:—		
ugar	447,225	U.K. 21, Fr. 20, Austr. 14
ood, coal, peat	7,632,092	Ger. 41, Austr. 38, Hung. 14
olours, dyes, tanning materials	10,414	Hung. 48, Ger. 16
ums, resins	17,765	Pol. 42, Ger. 27
lass, glassware	132,741	Austr. 15, Italy 14, U.K. 11, Ger. 8
hemicals, chemical products	62,485	Ger. 22, Austr. 21, Pol. 16

Official statistics give the value of the total imorts and exports in 1921 as 22,435 million kronen nd 27,312 mill. kr., respectively, leaving a favourble trade balance of 4877 mill. kr., as against 85 mill. kr. in 1920 (present value of krone = bout 1·7d.).

TRADE NOTES

BRITISH

Gold Coast in 1920

This colony enjoyed great prosperity during the first half of 1920, but the fall in price of cocoa—the chief article of export—from £122 to £39 per ton caused much financial distress and the export decreased by 51,403 tons to 124,773 t. Less attention was paid to the palm-oil industry and only 629,612 galls. of pericarp oil and 7664 t. of kernels were exported, compared with 938,595 galls. and 9892 t., respectively, in 1919. Special steps were taken to foster the copra industry along the sea coast, but the export of coconuts declined by one-half to 427 t. Exports of rubber fell by 58 per cent. to 134 t. and those of kola nuts declined slightly, the demand remaining good. The experiments on the cultivation of sisal and groundnuts and the production of shea-butter (*cf.* J., 1921, 440 R) were continued.

Small diamonds of good quality were found in the lower Birrim valley and a company has been formed to exploit the diamondiferous area of the colony. An occurrence of gold recorded near Kwamang, in Eastern Akim, is not considered of economic importance. Deposits of low grade manganese ore were observed in the area north of Seccondee.

Exports of domestic produce and manufactures were valued at £11,336,046, an increase of 22 per cent. and imports increased in value by over 90 per cent. to £15,152,145. The United Kingdom still holds the largest share of the external trade of the colony, but has not yet regained the pre-war position. Ground was gained by the United States, which supplied most of the imports of sugar, kerosene, iron and steel, perfumery, etc. and took a large share of the exports of lumber, manganese ore, and cocoa.—(*Col. Rep.-Ann., No.* 1119, 1922.)

Chemicals, etc., used by S. African Mines

According to the Union Department of Mines and Industries the values of the chemicals, etc. purchased for South African mines in 1921 were as follows:—Cyanide, £414,801; disinfectants, £21,692; explosives, £2,035,958; iron, and products of, £339,294; lead, £4,727; lubricants, £347,149; oils, non-lubricating, £15,268; paint, tar, etc., £39,004; steel, £617,079; zinc, zinc discs, £166,568. —(*U.S. Com. Rep., Sept.* 11, 1922.)

FOREIGN

The Indigo Market in China

The chief dyestuff imported into China is synthetic indigotin, of which 90 per cent. is distributed in the form of 20 per cent. paste. It is estimated that 60 per cent. of the world's production of synthetic indigotin is consumed in China, and that the trade is worth nearly £2,000,000 per annum. Sales depend upon the price, as the Chinese use natural indigo if the price of the artificial product rises much above 40 taels per picul (equivalent to about 1s. per lb. in Aug., 1922). Stocks of indigotin-paste in China, excluding Hongkong, are being offered at 1s. 4d. per lb., and amount to about 6500 long tons, derived as follows (per cent.):—Germany 50, Switzerland 10, France 15, the United States 10, Germany ("reparation" deliveries) 15. Competition in the indigo trade depends upon the possession of an efficient sales organisation, and those Swiss, French and American firms which are able to compete with the Germans have their own organisations on the spot. Stocks of British-made indigotin have been shipped back to England, probably because they were unsuitable for the Chinese market, but it is anticipated that the British indigotin will be a factor in this trade in the future.—(*U.S. Com. Rep., Sept.* 18, 1922.)

The Chilean Nitrate Industry

H.M. Consul at Antofagasta reports that 447,197 tons of nitrate was produced in Chile during the six months ended June 30, 1922, as against 851,239 t. during the same period of 1921. Exports declined from 785,362 t. to 279,034 t., of which about 36 per cent. was shipped to Europe and Egypt, and 50 per cent. to the United States. Consumption during the first half of 1922 is estimated at between 900,000 and one million tons, the Nitrate Pool alone having sold 590,000 t. out of 800,000 t. it held in stock at the end of December, 1921. At the end of June, stocks in Chile were estimated at 1,609,000 t., and in Europe and Egypt at 217,500 t. Many factories which reduced output during the recent crisis have completed their stocks and closed down. Only 33 factories were working at the end of June, but it is anticipated that trade will improve early in 1923.—(*Official.*)

Exports of Carnauba Wax from Brazil

Carnauba wax, used in making phonograph records, physical apparatus, etc. is obtained from a palm tree which flourishes in the hot, dry zones of north-eastern Brazil (*cf.* J., 1921, 319 R). The quantity and value of the exports during recent years have been as follows:—1918, 4215 metric tons, 20,432,956 milreis; 1919, 6224 t., 20,539,680 milreis; 1920, 3516 t., 10,873,046 milreis; 1921, 3906 t., 10,394,627 milreis (milreis = 2s. 3d. at par, now about 6·5d.). The chief ports of shipment are Fortaleza in the State of Ceara, and Ilha do Cajueiro, in the State of Maranhao.—(*U.S. Com. Rep., July* 17, 1922.)

Proposed Capital Increases in the German Dye Industry

The capital of the Farbwerke vorm. Meister Lucius u. Brüning, Höchst, is to be increased from 470 to 940 million marks. Of the new shares to be created, there will be 400 million ordinary shares, participating in this year's dividends, which will be taken over by a bank at 150 per cent. and offered to existing shareholders on a share for share basis; and 30 million preference shares with dividend rights as from January 1, 1923, to be taken up by the other firms constituting the "I. G" (who also contemplate doubling their capital). The directors of the company are of the opinion that the company will be able to pay dividends commensurate with the increased capital.

The following table gives a survey of the capital increases during the last few years of the various companies belonging to the combine:—

The Italian Market for Paint and Varnish

Most of the paint and varnish made in Italy is second-grade material. About 10 per cent. of the requirements in high-grade paints and varnishes is made in Italy, Great Britain supplying 70 and the United States 20 per cent. Germany practically controls the market for dry artificial colours, linseed oil and red lead are imported from Great Britain, rosins and turpentine from the United States, France and Greece, size from Great Britain and China, and wood oil from China. Most of the mineral colours needed are produced in the country. In 1913 Italy imported about 8500 m.t. of paints and colours and 3000 t. of varnish, but owing to trade depression the imports in 1920 fell to 6350 t. and 2250 t., and in 1921 to 4400 t. and 1158 t., respectively.

The World's Trade in Dyestuffs

The following statistics concerning the world's trade in colours and dyestuffs is based upon the classification adopted by the United States. This classification includes coal-tar dyes, turpentine, linseed oil, chalk and crayons.

Exports in 1920:—	Value $	Destination Per cent.
United States ..	.. 28,600,608 ..	America 56, Europe 26, Asia 8·7 Austral. 7·1, Afr. 1·6
England ..	.. 25,693,000 ..	Brit. Col. 35, Europe 35
Germany ..	.. 9,679,000 ..	Chiefly Europe
France ..	.. 5,271,000 ..	Europe, Egypt
Holland ..	.. 6,776,000 ..	Belgium, U.K., France, Dutch E Indies
Japan ..	.. 3,815,000 ..	China 60, Rest of Asia 40
Canada ..	.. 1,756,000 ..	U.K. 70, U.S.A. 30

Imports in 1920:—	Value $	Origin Per cent.
England ..	.. 9,791,000 ..	U.S.A., Can., France, Holl. Germ.
Holland ..	.. 3,999,000 ..	Germ. 74
France ..	.. 2,324,000 ..	U.K., Holl., U.S.A.
Italy ..	.. 1,684,000 ..	Germ., U.K.
Sweden ..	.. 1,599,000 ..	Germ., U.K.
Switzerland	.. 1,385,000 ..	Germ. 50, France 25
Spain ..	.. 1,323,000 ..	U.K. 50, Germ., U.S.A.
Norway ..	.. 1,112,000 ..	Germ., U.K.
Denmark	.. 1,104,000 ..	Germ., U.K.
Canada ..	.. 4,251,000 ..	U.S.A. 83
British India	.. 6,661,000 ..	U.K. 80
Brazil ..	.. 4,392,000 ..	U.S.A., U.K.
Argentina	.. 3,817,000 ..	U.S.A., U.K., Germ.
New Zealand	.. 2,756,000 ..	U.K. 40, Austral. 30, U.S.A. 15
Cuba ..	.. 2,384,000 ..	U.S.A. 84
South Africa	.. 2,221,000 ..	U.S.A., U.K.
China ..	.. 2,000,000 ..	Japan 60, U.K., U.S.A.
Philippines	.. 1,743,000 ..	U.S.A. 90
Australia ..	.. 1,679,000 ..	U.K. 60, U.S.A. 30
Egypt ..	.. 1,560,000 ..	U.K. 50, France 25
East Indies	.. 1,470,000 ..	Holl. over 67
Chile ..	.. 1,200,000 ..	U.S.A. over 50, U.K.
United States	..<1,000,000 ..	—

In 1913 Great Britain, Germany, and the United States were the chief countries exporting dyestuffs, their exports being valued at $15,000,000, $15,000,000 and $7,328,000, respectively, and this position was maintained during 1920. In 1921 prices fell heavily and the value of the exports during the first ten months of the year fell to $10,437,000 for the United States and to $8,818,000 for Great Britain, compared with $24,058,000 and $13,339,500, respectively, for the same period of 1920. The value of the world's trade in dyestuffs during 1921 was less than one-half that in 1920.

REVIEWS

MICAL TECHNOLOGY AND ANALYSIS OF OILS, FATS AND WAXES. *By* J. LEWKOWITSCH. *Sixth edition. Vol. II. Entirely revised by G. H. Warburton. Pp. xii.+959. London: Macmillan and Co., Ltd.*, 1922. *Price 42s. net.*

The many and widespread interests which are ncerned with the preparation and use of oils, ts and waxes, are of such magnitude, and their tional importance so great, that they rank ongst the great industries of the Empire. The orking-up of the prime raw materials, the pro- ction and preparation of which are of the utmost portance to many, if not all of our Colonies, in- lves such an amount of capital and labour that ere exists every justification for the production of encyclopædic treatise which should contain a atement of all modern improvements in the pro- ction, purification and manipulation of the rious oils, fats and waxes, as well as the fullest tails as to their analysis, composition and roperties.

Dr. Lewkowitsch's book is the only work in our nguage which approximates to this standard, nd his wide experience enabled him to write with uthority on the subject. There can be no doubt at his death before he had completed any more an the first volume of the fifth edition of his ok, which appeared in 1914, made it extremely ifficult to maintain in the later portion of that, nd also any subsequent editions, the high standard hich he had set. So long as the living personality f the author was behind his writings, the peculiar yle and diction which he adopted could be cepted, they were characteristic of the man, but is to be regretted that they have been retained the edition now current which bears a date eight ears after the author's decease.

It may be questioned always how far a revision ould involve alterations of text, but if revision is be anything more than reprinting, then state- ents in the older editions which refer to periods f time should be amended. In very many cases hroughout the volume now under review such ording as "during the last decade," "during the st few years," "recently," is found in sentences hich have been changed in no way since they ppeared in the 1909 edition. If any reason could e advanced for their appearance in the 1914 dition, surely none can be put forward for their resence in the new publication of 1922. Most of he statements so introduced have no bearing what- ver on current conditions.

The volume contains two chapters. The first, hich consists of 39 pages only, deals very briefly ith the commercial preparation of the raw aterials used in the oils, fats and waxes industries. t is to be regretted that so important a branch of he industry receives such scant attention, and specially is this so when up-to-date plant and ractice are ignored. Only two examples of this eed be cited. The paragraph on p. 16, dealing ith the Anderson "expeller" continuous oil- ress, although introduced by the word "recently," as not been altered since it appeared in the 1909 dition, and it altogether ignores, in its possibly ustified condemnation of the press for the purposes ndicated, its more modern and quite extensive pplication, especially in American practice, to the reliminary crushing of such oily materials as copra. Further, the square box-press, which has largely superseded the circular cage-press for the pressing of palm-kernels and copra, both in this country and abroad, is not mentioned.

The second chapter, which forms the major portion of the volume, consists of a series of monographs dealing with the principal oils of commerce, whilst lesser known oils are described in short paragraphs or tables. This undoubtedly is the most useful part of the volume, since it contains practically all the published information concerning the materials about which it treats, though it might be claimed that much of the older matter could be eliminated without any sacrifice of utility.

The outstanding need of the volume is an alphabetically-arranged index of its contents. In previous editions a general index has been appended to Vol. III of the work, and it is to be presumed that this will be continued, but the inconvenience of referring to an index in one volume in order to locate matter contained in another is obvious. The indexes of botanical and zoological names contained in this volume are of somewhat doubtful utility. In spite of the above-indicated shortcomings, the appearance of this volume must be welcomed by everyone who is concerned with industries involving a knowledge of the preparation and properties of oils, fats and waxes, as a large proportion of the information contained in it is not obtainable elsewhere without an immense amount of labour and extensive reference to innumerable other publications. From this point of view the work is most valuable.

JOHN ALLAN.

FOURTH REPORT ON COLLOID CHEMISTRY AND ITS GENERAL AND INDUSTRIAL APPLICATIONS. *Pp.* 382. *London: H.M. Stationery Office*, 1922. *Price 5s. 6d. net.*

This report, which is issued by a Committee of the British Association for the Advancement of Science under arrangement with the Department of Scientific and Industrial Research, is similar in plan to the three reports already issued, the subject-matter being arranged under two heads, namely, (1) classification according to scientific subject; (2) classification according to industrial process. The sections included under the first head are:—"Colloid Problems in Analytical Chemistry," by H. Bassett; "Cataphoresis: The Motion of Colloidal Particles in an Electric Field," by E. F. Burton; "Colloid Systems in Solid Crystalline Media," by C. H. Desch; "Molecular Attraction and the Physical Properties of Liquids," by Edwin Edser; "Membrane Equilibria," by W. E. Garner; "Disperse Systems in Gases," by W. E. Gibbs; "The Theory of Lubrication," by W. B. Hardy; "Application of Colloid Chemistry to Mineralogy and Petrology," by Alex. Scott.

The technical papers included under the second heading are:—"The Colloid Chemistry of Soap. Part II. The Soap Boiling Processes," by J. W. McBain and E. Walls; "The Concentration of Ores by Flotation," by Edwin Edser; "Colloids in Catalytic Hydrogenation," by E. F. Armstrong and T. P. Hilditch; "The Role of Colloids in Electrolytic Metal Deposition," by H. J. S. Sand; "Rubber," by H. P. Stevens; "Colloidal Fuels, their Preparation and Properties," by A. E. Dunstan.

If the various scientific and technical journals published during the last few years are examined only cursorily, one cannot fail to notice that colloid chemistry is attracting more and more attention, as is indicated by the large number of papers dealing with various aspects of the subject. This increased interest is indicated by the fourth report, which contains more than twice the number of pages in the third report.

With advance in knowledge it becomes increasingly difficult to offer a definition of colloid chemistry. Such substances as the proteins have been looked upon as typical emulsion colloids, but in recent years it has been shown that many of their properties can be explained by the application of ordinary stoichiometrical relations. Again, the work of Laue and Bragg, Langmuir, etc. indicates the existence of residual valencies at the surface of solids, and this, together with an increase in knowledge of the laws underlying the formation of complexes, will undoubtedly throw fresh light on the subject of adsorption, a subject which is particularly dear to the colloid chemist. This difficulty of definition is indicated by the subjects included in the present report, since some of them a few years ago would undoubtedly have been classed as pure physics and not as colloid chemistry.

A decade or so ago it was considered that the various processes of analytical chemistry could be explained by the application of the dissociation theory. Difficulties were then glossed over; now one endeavours to meet many of them by a consideration of the colloid chemistry involved. Prof. Bassett discusses the fundamental colloid phenomena underlying many analytical operations, especially in connexion with the formation, purity, filtration and washing of precipitates. Attention is also called to a phase of the subject which is generally neglected, viz., the colloid properties of filter paper, surfaces of vessels, etc., and there is a valuable section which illustrates the application of the principles discussed to various important analytical estimations.

In the section on cataphoresis, Prof. Burton summarises the main points of the subject, and includes recent work on technique carried out in his laboratories.

The dispersion of solid particles throughout a crystalline solid, when the state of sub-division is sufficiently fine, introduces colloidal characteristics of interest in metallurgy and mineralogy. Prof. Desch writes a critical article on the application of our knowledge of colloids to such questions as the hardening of steel and of certain non-ferrous alloys, and the colouring matters in crystalline minerals. Very often the use of the blessed word "colloid" is considered to offer an explanation of a subject which is little understood, as was the case with the word "catalysis," but Prof. Desch is careful to point out where it is doubtful whether the solution of a problem is to be found in the application of colloid chemistry.

Mr. Edser's article on molecular attraction and the physical properties of liquids is different from the others in that it consists mainly of the development of a theory of the author's on the law of molecular attraction. It is found that in all liquids the result of analysing the experimental data is to indicate that the molecules attract each other inversely as the eighth power of the distance separating them. Expressions are deduced for calculating the latent heats and surface tension of liquids. One
the assumptions made, and with which many wi
not agree, is that the molecules of a liquid an
those of its vapour are identical in structure so fa
as association is concerned, and the degree of ass
ciation does not vary with the temperature.

Mr. Garner discusses the potential difference
occurring at the surfaces of membranes in contac
with electrolytes, special attention being paid t
Donnan's theory. Loeb has recently made extende
use of the Donnan equilibrium in dealing with pr
teins, but this is not referred to. It would hav
been interesting to have had a criticism of Loeb'
results by an independent worker on the subject.

Gas-solid and gas-liquid disperse systems are
importance in connexion with various natur
phenomena, with industrial operations such as th
precipitation of dust, and with chemical warfar
and Dr. Gibbs gives a valuable *résumé* of the resul
hitherto obtained and of the underlying theory.

Mr. Hardy discusses the various theories
lubrication and then gives an account of his ow
theory and work on the subject. Dr. Scott gives
very valuable bibliography and discussion of th
application of colloid chemistry to mineralogy an
petrology, and is careful to point out many dire
tions in which further investigations are needed.

Prof. McBain and Mr. Walls give first a bri
account of actual soap-boiling practice, then
theory of soap-boiling based on laboratory and sem
technical experiments, and finally the application
the theory to the several industrial processes. Th
authors state that "neither scientist nor exper
enced soap-boiler is in a position even now to gi
a connected and reasoned account of all the ph
nomena upon which this vast industry is base
Improvements are still effected by purely empiric
trial." Nevertheless, the work of McBain and h
collaborators at Bristol University, in which the
is strict application of scientific method to
industrial problem, is making sure progress in th
direction of eliminating empiricism. This repor
together with Part I, goes a long way towards th
objects aimed at, namely, a clear description of th
experimental behaviour of soap and their solution
and the development of a rational theory to accou
for them, so that ultimately the various factors ca
be controlled quantitatively.

Mr. Edser's article on the concentration
minerals by flotation is one which contains a co
siderable amount of original work and many ne
observations. It is thought-provoking and will u
doubtedly give rise to much discussion and fre
experiment, since in many of his views he is total
at variance with many physical chemists, especial
with Bancroft.

In the hydrogenation of gaseous or liquid orga
compounds colloid phenomena are concerne
(1) because of the surface at which interacti
occurs; (2) when catalysts in the colloidal conditi
are employed. The various physical and chemi
conditions involved, as well as the various theori
of catalysis, are considered and critically discuss
by Drs. Armstrong and Hilditch.

The effect of colloids in giving bright and cohere
deposits from electrolytic plating solutions is
which has long been known, but it is only compa
tively recently that more or less satisfacto
attempts have been made to give explanations
the phenomena. Dr. Sand gives an interesti
summary of this subject.

Dr. Stevens's report on rubber is an extension of the first report published in 1917, the bibliography being brought up to date and the properties of rubber discussed from the colloidal view-point. The question of vulcanisation is treated in detail.

Dr. Dunstan's report on colloidal fuels is very brief, and refers, more particularly, to work done in the United States. It could have been expanded with advantage.

As will be seen from the brief summaries given above, the various reports are written by well-known workers on the subjects about which they write, and their importance to all who have to deal at some time or other with colloids cannot be over-emphasised. The results obtained in the study of colloid chemistry are now being utilised in so many branches of science, that the literature on the subject has become very scattered, and all interested in the matter owe a great debt to the special Committee of the British Association for the work it has done in arranging for the drawing up of such admirable and critical summaries.

T. Slater Price.

Modern Gasworks' Practice. *By* Alwyne Meade. *Second edition, rewritten and enlarged. Pp. xi+815. London: Benn Brothers, Ltd.*, 1921. *Price 55s. net.*

If anything more were required to confirm that he industry concerned with town-gas manufacture in the forefront of chemical-engineering industries -as regards size, capital value, extent of its amifications, and the multiplicity of its opportunies for rendering national service—this book by lwyne Meade would suffice. Those best able to udge tell us that there are very few chemical ngineers amongst us: there are many able echnical chemists who are poor engineers, and here are many excellent engineers engaged in the hemical industry who are very poor chemists. None ut a fully qualified chemical engineer—in the idealtic sense—could have compiled and written this ook on modern gasworks' practice. The author emonstrates unquestionably that he not only possesses a thorough theoretical knowledge of his ubject but that he is in the closest association in an xecutive capacity with many of the processes, lants and operations described and excellently llustrated in this voluminous work. The book is ell arranged, well bound and well printed, and the ublishers are to be congratulated on their part of e work. We would, however, suggest that it ould be an advantage if the *third* edition were ublished in two or three slightly smaller volumes, articularly as the author draws our attention to e fact that the bulk of the second edition is 50 per nt. greater than that of its predecessor; and "as t there is no indication as to when finality in this rection may be reached."

The book justly claims to be one on modern gasorks' practice, and all the advances that have been ade in the gas industry up to the middle of the ar 1921 are faithfully and adequately handled. would, however, have been better if the author d dealt less fully with obsolete plants and ocesses and if he had been contented with ferences to fuller accounts. Undoubtedly everying that is touched on is of great interest particular specialists, but the subject of modern sworks' practice is such an extensive one that the author cannot afford space to make the book an historical treatise on the gas industry. The author depends, perforce, for much of his information relative to the results obtained in plants and processes on accounts published, in good faith, by interested parties. This is a misfortune that is not peculiar either to this book or to the gas industry.

As the volume of work done by such research committees as the Gas Investigation Committee rapidly increases, it will become less and less necessary to depend on, and refer to, the less reliable workers. A perusal of this book brings conviction that the gas industry no longer depends for its progress on the "practical" man alone—with his rule-of-thumb methods and lack of vision—but is now at long last making good use of scientifically-trained men.

One here realises, too, the enormous debt the industry owes to the Fuel Department of the Leeds University for the work, of immediate value to the industry, which has been carried out by members of its staff during the last fifteen years. Few industries are served by the universities so well as the gas industry, and it is an excellent and rejuvenating thing that this should be so. Mr. Meade creditably draws heavily for his inspirations from the reports on work carried out at the Leeds University—re-assembling their results in more digestible form—and enhances the value of his book proportionately.

"Alwyne Meade" should be found on the shelves of all progressive gas engineers and students, as it is an incomparable book of reference and text-book combined.

E. W. Smith.

Grundzüge der angewandten Elektrochemie. Band I: Elektrochemie der Lösungen. *By* Prof. Georg Grube. *Pp. xii+268. Dresden and Leipzig: Theodor Steinkopff*, 1922. *Price* 8*s*. 6*d*. (10*s. bound*).

In many ways this book resembles Foerster's well-known "Elektrochemie wässriger Lösungen," but it is less detailed. It begins with 140 pages of theoretical principles, in the form usual in German text-books, and not always up-to-date. Thus, in considering dilution laws, no mention is made of Washburn's important experiments, and the work of Krüger and Krummreich on absolute potentials, although given extremely briefly without mention of the names, has no reference beyond Foerster's book. In other respects the literature references are usually good, and comprise work done in 1921.

The introductory section includes the lead and nickel-iron accumulators, the "combustion" cell, and electro-endosmose and its applications. The electro-deposition and refining of metals are next treated. The section on the electrolysis of alkali-chlorides (pp. 171—218), which deals with alkali, chlorine, hypochlorite, and chlorate, is very good; the descriptions of the principal cells are brief but clear, and numerical data are given when these are known. Electrolytic oxidation and reduction processes, the electrolysis of water, and the electrolytic prevention of boiler-corrosion follow, and there is a good index.

Prof. Grube's book is a very useful and concise text-book of the electrochemistry of solutions, and provides a readable account of an important branch of technology.

J. R. Partington.

OBITUARY

J. TAKAMINE

We are indebted to Dr. Allen Rogers, hon. secretary of the American Section, for the following facts concerning Dr. Takamine, an original member of this Society, who died in New York on July 22, aged 67 years.

Jokichi Takamine was born in Takaoka, Japan, and received his scientific and technical education in the Imperial Engineering College, now the Imperial University, of Tokyo, where he graduated in chemical engineering in 1878; later as a government student, he spent three years at the University of Glasgow. The degrees of doctor of engineering and doctor of pharmacology were conferred upon him by the Imperial University of Tokyo in 1899 and 1904, respectively. Among the many important positions he filled were those of chief chemist to the Department of Agriculture and Commerce, director of the Government Chemical Laboratory, and Patent Commissioner for the Empire of Japan. He founded the Government Saké Experimental Station, and also the Tokyo Artificial Fertiliser Co., which owns the first superphosphate works in the country; during Takamine's direction the capital of this company rose from 250,000 to 25 million yen.

Much of Takamine's best work was done in his private laboratory. He took out many patents on the improvement of *Moyashi* diastatic substances; he invented a process for extracting cobalt oxide from Japanese manganese ore which proved an invaluable aid to the pottery industry of Japan; and he developed the use of the improved *Koji* process in alcoholic fermentation. In the early 'nineties he settled in the United States, at Clifton, New Jersey, where he isolated the active principle of *Koji*, known as Taka-diastase, which has been much used in medicine, and also, under the name "Polyzime," in the textile industry, in cereal foods and in baking. In 1900 he isolated adrenaline, the active principle of the suprarenal glands, which has found such a wide application as a hemostatic agent. He is also the inventor of a process, still in use, for recovering glycerin from printers' rollers.

Dr. Takamine received two orders from the Emperor of Japan, in one of which, the Fifth Order of Rising Sun, he rose to Court rank; he was also appointed, by Imperial Decree, a member of the Imperial Academy of Science in Japan, of which the active membership is limited to sixty.

REVIEW

Vol. XLI] NOVEMBER 15, 1922 [No. 21

UNVEILING OF THE RAMSAY MEMORIAL

THE medallion tablet to the memory of Sir William Ramsay was unveiled in Westminster Abbey on November 3, by H.R.H. the Duke of York, in the regretted absence of H.R.H. the Prince of Wales, who had met with a slight accident in the hunting field on the previous day. The tablet, executed in bronze by Mr. C. L. Hartwell, A.R.A., represents in profile the head of the great chemist; it is set in a marble frame and bears the simple inscription: "William Ramsay, Chemist." During the short and impressive service, the Duke of York removed the veil which covered the tablet, and said:—"On behalf of my brother I ask the Dean and Chapter to accept this tablet as a lasting memorial to Sir William Ramsay, the great chemist." In accepting the memorial, Bishop Ryle, Dean of Westminster, said that it would be the duty of the Dean and Chapter of Westminster to preserve the mural tablet, and to add it to the galaxy of memorials to distinguished men of science placed in the adjoining North Aisle and including those dedicated to the memory of Darwin, Wallace, Lister, Adams, Stokes, Joule, and Hooker.

There was a large and distinguished congregation. Lady Ramsay was present, with many of her family and relations. The officers of the Ramsay Memorial Fund were represented by the Rt. Hon. H. A. L. Fisher, Sir Charles Sherrington, the Rt. Hon. Lord Chelmsford (vice-presidents), Sir Hugh Bell (chairman), Prof. J. Norman Collie (treasurer), and Dr. W. W. Seton (organising secretary). The large attendance of the Diplomatic Corps included Ambassadors (United States, France, Belgium, Japan, Spain, Germany); Ministers (Chile, Denmark, Finland, Greece, Lithuania, Netherlands, Serbia, Sweden); *Chargés d'Affaires* (China, Norway); representatives of the Italian Ambassador and the Swiss Minister; and several Consuls-General. Among the many representatives of Science were Prof. H. Le Chatelier (delegate of the French Academy of Sciences), Sir W. Bayliss, Sir G. Beilby, Sir W. Bragg, Prof. F. G. Donnan, Prof. F. E. Francis, Sir R. Glazebrook, Sir R. Gregory, Sir R. Hadfield, Sir H. Jackson, the Hon. Sir Charles Parsons, Prof. J. R. Partington, Sir R. Robertson, Prof. S. Smiles, and Dr. M. W. Travers. It had been arranged that His Excellency the French Ambassador should present the Prince of Wales with the Gold Medal of the Ramsay Memorial Fund, but this ceremony had necessarily to be postponed.

We take advantage of this occasion to offer our tribute to the memory of our Past-President, from the pen of one of his most distinguished pupils, Dr. Morris Travers, who was intimately associated with him in the discovery of neon, krypton and xenon.

WILLIAM RAMSAY

The beautiful ceremony in Westminster Abbey on November 3, was the world's homage to the genius of one of the greatest scientists of our time. His name is enrolled with those associated with the highest achievement by men of our race; it passes into history. Though much has been written on Ramsay's life and work since his death in 1916, it may still be permitted to those who were associated with him, many of them members of this Society of which he was one time President, to pay personal tribute to the memory of their well-loved friend and leader.

To one who was privileged to serve him for many years it seems that the quality in Ramsay's nature which drew men to him, was his unshakable belief in human integrity. Suspicion and distrust were absolutely foreign to him. Never did a student appear so worthless but that Ramsay had hopes for him. Over-confidence in associates may have led to the exploiting of his name, to his own grief and annoyance; but in his confidence in the reliability of fellow scientists lay the springs of some of his greatest successes. The discovery of argon, the discovery of helium, the part he played in the development of the chemistry of radio-active substances, had their origin in the belief that the facts stated by Lord Rayleigh, Hildebrand, and Rutherford, were worthy of acceptance and investigation, and were not mere errors of experiment. In pursuing investigations, those who served him knew that they had his entire confidence, demanding only an equal confidence in themselves, and in him. Scientific friends, students, and colleagues were freely admitted to his laboratory, in which there were no secrets.

It has been suggested that Ramsay was *lucky* in his scientific career. Nothing is further from the truth. He had hardly the advantage of a university training in the modern sense of the term. While in Germany he studied in a laboratory in which originality was at a discount. At Bristol he was loaded with the work and responsibility falling on the shoulders of the

Principal of a small and struggling college. In 1887 he took over the laboratory at University College in which research was a dead letter, and when the spirit of research throughout the country was at a low ebb. Yet in ten years he had built up a school of chemistry which drew students and investigators from all parts of the world.

Ramsay's early work, carried out under considerable difficulties in University College, Bristol, consists mainly of a series of brilliant experimental researches on the properties of liquids and vapours, with occasional excursions into other fields. During his early years in London he completed some of these investigations, carried out some important work on the molecular weights of liquids, and other researches in which his students took part. The building-up of a school of research was the object which he had in view, but he did not bind himself to any particular line of investigation. He wrote a large text-book of inorganic chemistry, undertaking this work partly with the view of arranging and systematising contemporary knowledge of inorganic chemistry on the basis of the Periodic Law. One edition only appeared, and it was never revised or rewritten. It is of historical interest, as the Periodic Law was the basis of some of his greatest discoveries.

During the early nineties the development of the new theories of solution gave a fresh direction to the study of chemistry, and Ramsay became keenly and critically interested in the work of the Continental school of chemists, which at the time, found many opponents in this country. He was not, however, inclined to follow in other mens' footsteps. Students in his laboratory worked at problems relating to solutions; but, although he was then casting about for new lines of research he did not take an active part in this work. It was Lord Rayleigh's observation of the abnormal density of atmospheric nitrogen which provided the key to the series of discoveries which occupied his individual attention for the last years of the century, and which determined the future course of his investigations.

Reading the original "argon" paper, one is impressed by the fact that, even when it was written, Ramsay realised that he stood on the threshold of greater discoveries. The discovery of helium, the logical sequel to the discovery of argon, confirmed him in the belief that these gases formed members of a series of terrestrial elements, and in the autumn of the year 1895 he definitely embarked on the search for the missing members of the group. Two years later, in his address to the Chemical Section of the British Association at Toronto, he took the characteristic step of describing the progress of the search for the "undiscovered gas," predicting its properties, and inviting competition in the quest. Three years after the discovery of helium the reward came to him in the simultaneous discovery of neon, krypto and xenon, but it was only after two furthe years of strenuous work that the five "rar gases" were completely isolated and thei properties fully described. The isolation o niton many years later set the crown on thi work.

These discoveries had their origin in Ramsay' power of grasping the significance of fact observed by others rather than of passin them over as possible errors of experiment The development of them was based upon clear understanding of the simple fundamenta laws of chemistry. The conduct of the lon drawn-out investigations, in face of real difficulty and often of adverse criticism, called fo enthusiasm, courage, and perseverance, an the character of the work demanded experimental skill of the highest order. Thes qualities Ramsay brought to bear on hi researches, and with them he in some measur endowed those who served him.

Space does not admit of further reference to Ramsay's scientific researches, nor to hi activities in connexion with scientific an educational organisations. Suffice it to sa that the election of the man most renowne for his investigations in the domain of scientifi chemistry to the office of President of thi Society, and his acceptance of that office may be regarded as a landmark in the histor of the relations of British science and Britis industry, which he did much to foster.

In building up the school of chemistry a University College, and in maintaining th spirit which pervaded it, Ramsay's personality was a dominating factor. Even in his busiest time he rarely failed to make a daily tour o the laboratory, seeing all but the junior students, and having a word of advice or criticism fo everyone. To the juniors he lectured personally, and would often visit the practical classes. Every student who passed more than a yea in the department was in turn invited to one of his Saturday evening dinners, and made to feel that he was a friend in whom the Chief and Lady Ramsay took a personal interest. Letters from former students and assistants invariably met with a cheery reply, generally containing something new and interesting.

Many of Ramsay's greater discoveries are, in a sense, complete in themselves. They were the forerunners of many recent advances in science and technology, which are based on the foundation which he laid. During the last two years of his life, years of war, he devoted more attention to matters affecting science and the Empire than to experimental chemistry. Had he lived we may believe that he would have been an active force advocating and promoting the principle of frank co-operation between men of science, and between those engaged in science and industry.

MORRIS W. TRAVERS.

SOME RECENT WORK ON ANTHELMINTICS

T. A. HENRY

IN a recent report Dr. F. A. Miller states that in the course of the anti-hookworm campaign, of which he is director, in olombia, out of 53,390 persons examined in 921, 49,940 (93 per cent.) proved to be infested nd that of 47,822 treated, 37,488 (78 per cent.) ere cured. This report relates to the work of ne of the many similar campaigns against ookworm now in progress in tropical countries nder the auspices of the Rockefeller Founation. Work on the same lines is also being arried on by Governmental and other agency, o that the number of people now being treated or hookworm disease (ancylostomiasis) proably runs into millions, and they still represent nly a fraction of the victims needing treatnent, 75 per cent. or more of the native popuation in many tropical countries being freuently infested with hookworm. Everyone ngaged in this work recognises that the best nethod of dealing with the disease is prevention, ut this implies the education of natives into leanly habits and the immediate provision f sanitary appliances on a gigantic scale, and hough neither is being neglected, both can nly be accomplished slowly.

It is clear that if mass remedial treatment is o be successful, the drugs used must be safe, fficient and cheap, and it is to the credit f the Hookworm Commissions that they spare o pains to secure these three desiderata in he order given.

Two species of hookworm are concerned, *ncylostomum duodenale* and *Necator americanus*. hese parasites infest the duodenum, where they e firmly attached to the intestinal wall and rotected by a copious exudation of mucus.

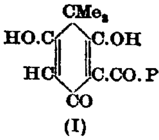
The worms (*Taenia, Ascaris, Ancylostomum*, tc.), which are parasitic in man and other nimals, are comparatively highly developed rganisms, and as such should be susceptible attack by drugs in various ways; but it eems to be true that, with the exception of the ixture of alkaloids known commercially as pelletierine," and possibly santonin, all the nthelmintics in use act by paralysing, more or ss completely, the external musculature of e parasites. Several of the text-books on harmacology and materia medica state that ere is, "pelletierine" again being an excepon, nothing specific about the action of anthelintics on worms, that the substances so used re toxic to both parasite and host, and that e host escapes damage from the drugs only ecause the latter are not readily absorbed. he case does not seem to be quite so simple as is, since there are numerous substances which lfil these conditions and yet the number of fective anthelmintics is small. In hookworm isease the drugs have to be given in comparaively large doses to secure a local concentration sufficient to render the parasites harmless and the amount of drug absorbed is often considerable, although the technique of administration is constantly being improved to avoid this secondary action. It is also difficult to explain on this view why santonin should be active against round worm (*Ascaris*) and inactive against tapeworm (*Taenia*), the reverse being true as regards filicic acid and its allies (extract of male fern), though both are believed to be effective in virtue of their action on the external musculature.

Perusal of the voluminous medical literature on the treatment of hookworm disease shows that a great variety of drugs has been used in practice, including extract of male fern, quassia decoction, a mixture of chloroform with eucalyptus oil, and in certain parts of South America the latex of two species of ficus, called higueron or higuerote. All these drugs still have their advocates, but in the organised campaigns against hookworm, the drugs used are β-naphthol, thymol and chenopodium oil, which are named in ascending order of importance. Many efforts have been made to extend this range of drugs, but the only addition that need be referred to is carbon tetrachloride, with which promising results have been obtained recently in Fiji by Hall, and have been confirmed by Nicholls and Hampton in Ceylon and by McVail in India. Carbon tetrachloride is said by Joachimoglu to be 50 per cent. more powerful as a general anæsthetic than chloroform and it is probably this greater activity which makes it more effective than chloroform since Caius and Mhaskar have shown that the latter merely acts on the worms as an anæsthetic and in their view is not a true anthelmintic. The soporific action of carbon tetrachloride on hookworm patients has been noted by McVail in India.

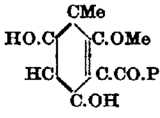
β-Naphthol and thymol are both phenols, and most of the recent work on possible new anthelmintics has been devoted to the study of phenols and especially derivatives of phloroglucinol and resorcinol, following a suggestion made by Fränkel that the active constituents of a number of well-known anthelmintics contain butyric or *iso*butyric acid residues, with or without phloroglucinol, *e.g.*, filicic acid derived from *Filix mas* and other ferns, rottlerin from kamala, kosotoxin from cousso flowers, and ascaridole from chenopodium oil. The examples are not very impressive since filicic acid and its allies are at best uncertain in their action, kamala and cousso flowers are now but little used, and ascaridole, though like other terpene derivatives it yields *iso*butyric acid on oxidation does not contain, strictly speaking, an *iso*butyric acid residue.

Following Fränkel's suggestion, Karrer and his co-workers have prepared an extensive series of condensation products of aliphatic acids with phloroglucinol and resorcinol analogous to filicic acid (Formula I) and aspidinol (Formula

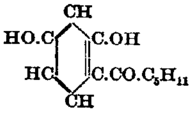
II) which may be regarded as the nuclear units on which the complex and more active constituents of *Filix mas* and other ferns are built up.



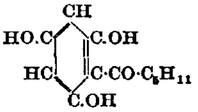
(I)



(II)

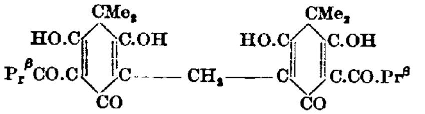


(III)

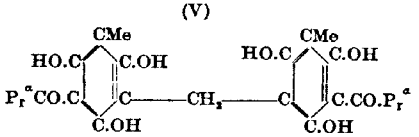


(IV)

Of these synthetic compounds Karrer has stated recently that the *iso*hexoyl derivatives of either resorcinol (reso*iso*hexophenone : Formula III) or phloroglucinol (phloro*iso*hexophenone : Formula IV) are the most promising, and that the *iso*acyl residue appears to confer greater activity than the normal acyl residue, phloro*iso*butyrophenone being twice as active as phlorobutyrophenone. The naturally-occurring fern compounds become more active with increasing complexity, albaspidin (Formula V) being more active than filicic acid (Formula I) and less active than filixic acid, which is represented by Boehm as containing three rings. The synthetic compounds on the contrary become less active with increasing complexity : thus methylphlorobutyrophenone condenses with formaldehyde in presence of alkali to form 2 : 4 : 6 : 2′ : 4′ : 6′-hexahydroxy-5 : 5′ -dibutyro-3 : 3′ -dimethyldiphenylmethane (Formula VI) which should have an activity similar to that of albaspidin, but is in fact less active than the starting material.



(V)

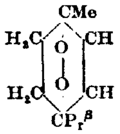


(VI)

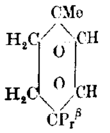
It is probable that the simple mono-, di-, and tri-hydric phenols are all capable of yielding anthelmintics of practical value in proportion as their solubility and toxicity are modified by the nuclear substitution of either alkyl or acyl groups. Phenol itself is used as a remedy for thread worms, but is too irritant for general use and that also applies to its methyl, ethyl, propyl, and butyl homologues, but thymol (methyl*iso*propyl phenol), which is solid at ordinary temperatures and sparingly soluble in water, is a valuable anthelmintic, which is not toxic to the host even in large doses, provi that it is given in the absence of oils or ot substances in which it is soluble and wh would increase its rate of absorption by t intestinal walls. Its isomeride, carvacrol, Darling has shown, is also a valuable anth mintic for hookworm, but being liquid it sprea and penetrates better than thymol, and therefore too irritant for use.

Attempts have also been made to lower t toxicity of alkylphenols by converting th into non-irritant esters, such as carbonat carbamates and *N*-dimethylcarbamates. O of these, thymol carbonate, is stated to ha given good results in the outbreak of hookwo disease which occurred during the boring of t St. Gothard Tunnel, but recent trials by I Wilson G. Smillie in Brazil (*private commu cation*) and by Caius and Mhaskar in Ind show that the drug is of little value. Anoth of these preparations, *p*-benzylphenyl carbama has been reported on favourably by Koslows as a remedy for oxyurids (thread worm Alkyl ethers of the phenols have been show to be inactive.

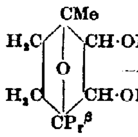
The other known effective remedy agai hookworm, chenopodium oil, has been examined recently in these laboratories and constituents isolated and tried in field oper tions in Brazil by Dr. Smillie as part of general investigation of possible new remedi for hookworm disease. The clinical result which are not yet published, show that the so constituent of the oil which is active agai hookworms, is the organic peroxide, ascarid (Formula VII), and that the variation fou by different observers in the action of chen podium oil is due largely to the varying qua tities of this somewhat unstable compone in the commercial oil. On heating, ascarido passes into the isomeride, ascaridole glyc anhydride (Formula VIII), and this on hydr tion yields a mixture of α- and β-ascarido glycols (Formula IX) which in turn can b converted into thymol and carvacrol. Th three intermediate products, which may and d occur in carelessly distilled oil, are all inactiv against hookworm so that this series of change begins with an active substance (ascaridole)



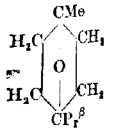
(VII)



(VIII)



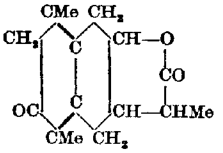
(IX)



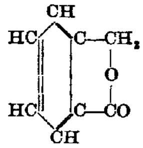
(X)

sses through three that are inactive and ends
th an active compound (thymol). It is
eresting in this connexion to mention that
ıeole (Formula X), which has had some
gue in the treatment of hookworm but has
en found by Smillie and by Caius and Mhaskar
have but little action, is fairly near to
aridole glycol in constitution, but the latter
fers from cineole in containing two secondary
ohol groups and, so far as they have been
ed, secondary and tertiary aromatic alcohols
ve proved useless against hookworm in man.
Ancylostomiasis is in the main a tropical
ease, and though it is not unknown in tem-
rate regions, the parasitic worms usually
evalent in Northern Europe, viz., *Ascaris*,
enia and *Oxyuris*, are much less dangerous
d receive less attention. Against *Taenia*
pe worm) the drugs most commonly used are
le-fern extract, the constituents of which
ve been discussed already, and "pelletierine"
nate; the latter is not the simple substance
name implies, but is the precipitate formed
the addition of tannin to an extract of
megranate bark and so contains all the
kaloids known to occur in the bark of which
o—pelletierine and *iso*pelletierine—probably
rm the most active constituents. "Pelle-
rine," according to von Schröder, is a specific
ison for *Taenia* spp.; thus *Taenia serrata*,
ich infests the intestinal canal of the cat,
ll live for several days in a warm (37° C.)
intly alkaline solution of sodium chloride,
t is killed in 5 to 10 minutes if 1 part in
,000 of "pelletierine" is added, whilst the
und worm (*Ascaris mystax*) is only killed in
uch stronger concentration of the alkaloid.

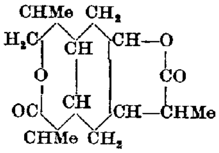
Of the drugs used against round worm
scaris spp.), the most important is santonin.
enopodium oil is as good or better, and its
e for this purpose is common in the United
ates, and may extend to other countries if
e present scarcity of santonin continues.
ntonin, as every reader of this *Journal*
no doubt now aware, is at present only
tained from one source—Soviet Russia—
ing made in a factory in Tashkent from
ntonica flowers (wormseed) collected locally.
reenish, Simonsen and Goodson have shown
dependently that it is also present in *Arte-
isia brevifolia*, found in India. According to
autenschläger, and in confirmation of obser-
ations by Trendelenburg, the activity of
ntonin is associated with the lactone ring
ormula XI), the sodium salt of the corre-
onding acid being inactive, an observation
hich is difficult to reconcile with the existing
se of sodium and other salts of santoninic
cid as anthelmintics, though it is true that
e sodium salt is no longer largely employed
wing to its toxicity. These observations
ppear to be based solely on the results of
xperiments in the application of the drugs
o worm muscle, and they need confirmation
y clinical trials. If confirmed they will be of considerable practical importance since Lautenschläger found that whilst open-chain lactones have no action on worm muscle, such action is not confined to lactone-groups in association with dimethylnaphthalene, as in santonin, but is also shown by phthalide (Formula XII), and its dimethoxy derivative (meconin) and can be increased by the replacement of one of the methylene hydrogen atoms by an alkyl group or diminished by similar substitution of an aromatic group, *e.g.* phloroglucinol.



(XI)



(XII)



(XIII)

It is interesting to note that the introduction of a second lactone-group into the santonin molecule, as in Wedekind's α-tetrahydrosantonilide (Formula XIII), reduces the anthelmintic action.

Wellcome Chemical Research Laboratories,
September 20, 1922.

THE PRESENT POSITION OF FAT-HARDENING

In a recent issue of the *Zeitschrift für Angewandte Chemie* (1922, pp. 437-440), Dr. W. Normann, one of the earliest authorities on the subject, discusses in detail certain technical, scientific and economic aspects of the fat-hardening industry. In the summary of the article which follows only brief references are made to those topics which have been treated recently in these columns (*cf.* J., 1922, 384 R, 392 R, 415 R).

The pivot upon which the whole art of fat-hardening turns is the catalyst, which nowadays is almost always the metal nickel. The noble metals that were used to a limited extent in the past have been abandoned owing to their prohibitive cost. Neither cobalt nor copper is employed alone; the use of mixtures of them with nickel has been proposed, but whether they have been utilised on a manufacturing scale is unknown to the author.

The method of preparing the catalyst has become practically a standard procedure, viz., the precipitation or decomposition of an easily decomposed nickel compound upon some inert material as carrier. Generally the carbonate is precipitated upon kieselguhr but sometimes gaseous nickel carbonyl is either decomposed upon a carrier or directly in the oil. Usually the catalyst is reduced in the dry state and then immersed in the oil, precautions being taken to prevent it coming in contact with air; but a class of compounds that has won much popularity includes the carbonate, formate and oleate of nickel, which can be added directly to the oil and there reduced with hydrogen at a temperature slightly above that commonly employed for hydrogenation. In this process the surrounding oil prevents the sintering of the metallic particles, consequently the nickel is obtained in an almost colloidal condition, the oil then having the appearance of ink. Whilst this method has the advantage of permitting the reduction and hydrogenation to be performed in one vessel, this gain is counterbalanced to some extent by the difficulties experienced in filtering the finished product owing to the extremely finely-divided state of the catalyst; but this can be mitigated somewhat by the addition of a carrier.

A process of American origin, based, however, on the researches of Prof. Frerichs, is the use of block nickel, that metal being obtained in very fine subdivision by grinding or milling it under oil or water. This catalyst works far better than might be expected. Moreover, very little care need be exercised in its preparation, and when spent, it is recovered in a very simple manner; after filtration it is re-melted, whereby the organic impurities are destroyed, and then cast and re-milled again to make it ready for further use.

Generally speaking, the methods of working employed in fat-hardening resemble very closely those used in the early days. Mechanical appliances have been introduced for the violent agitation and mixing of the hydrogen, oil and catalyst, but for the most part these are superfluous, for with a good oil the reaction proceeds quite smoothly without such extraneous aid. It must be borne in mind that the reaction is exothermic, consequently, to avoid overheating of the oil, the hydrogenation should not proceed at too great a pace.

The old controversy as to whether the nickel functions in the elemental state or as a sub-oxide has not yet been settled satisfactorily. That it is probably in the metallic form may be deduced from the mode of preparation from block nickel.

The catalytic "poisons" most likely to occur in the nickel salts used as starting material are lead, zinc, and sulphur. The halogens have been proved to be harmless; in fact, nickel has been employed as catalyst in reactions involving the substitution of halogens by hydrogen in organic compounds. Carbon monoxide, the most likely impurity in hydrogen made from water-gas, does not "kill" the catalyst, but merely renders it dormant, Normann having found that nickel inactivated by carbon monoxide can be revivified by treatment with pure hydrogen. Of the "poisons" in the oil itself, some may be removed mechanically by filtration through fuller's earth, and others are converted into harmless substances by raising the temperature of hydrogenation to 230°—250° C. Many patents have been granted for the preparation of catalysts which are said to be highly resistant to "poisons," but it is probable that all forms and kinds of catalysts are equally susceptible to them.

Of particular interest is the work of Rosenmunde and Zetsche, who found that when certain substances were added to the catalyst the reaction d not proceed to completion, as might be expecte but came to a definite halt at some intermediate stage. Their researches so far have not been extended to fat-hardening, where the possibility of making a catalytic mixture capable, say, of reducing linolenic and linolic acids to oleic acid might prove of practical value, as, for example, in the manufacture of the semi-solid fats used in cooking. According to Moore, at a proportionately higher temperature the remaining double bonds of an unsaturated acid are more easily reduced than the 9—10 bond in oleic acid; but Moore's observations are not sufficiently satisfactory to support this statement. During hydrogenation there are formed iso-oleic, elaidic and other hitherto unknown isomers of oleic acid that are not present in the original oil. This phenomenon cannot well be due to the wandering of the double bond, as is known to happen in the Varrentrapp method of fusing oleic acid with alkali, rather is it to be explained by the assumption that in hydrogenation no selective action is shown towards any of the two or more ethylenic bonds that may exist in a molecule, and that any double bond may be reduced as it comes into fortuitous and simultaneous contact with a particle of catalyst and hydrogen. In this manner, it will be seen that linolenic acid can give rise to three linolic and three oleic acids.

The formation of these different isomers is to a large degree rendered explicable by the idea outlined above, but another possibility to be entertained, though perhaps happening to a smaller extent, is that of dehydrogenation, which can be effected catalytically by nickel under certain conditions. Normann points out that often towards the end of the hardening the iodine value of the fat rises instead of falling to zero. Dehydrogenation of oils has, in fact, formed the subject matter of an American patent granted to Levey (U.S. Pat. 1,144,589), who claims that by treating oils at 220°—250° C. with a current of gas in the presence of a nickel catalyst he is able to convert a non-drying oil into one having a higher iodine value and with drying properties to correspond. Different gases may be used, even hydrogen, but best results are obtained with carbon monoxide. Oils with high iodine values but with inferior drying properties can be converted into good drying oils by a preliminary partial hydrogenation followed by this dehydrogenation process, for it is maintained that the hydrogen atoms split off are not the same as those primarily added.

In view of our very great ignorance of the colloidal state in non-electrolytes the following observations and inference of the author are of interest. As explained above, when a catalyst i prepared directly in the oil an inky-black liquid i obtained which is very difficult to filter. However after partial or complete hydrogenation of the oi the nickel tends to coagulate and become flocculen and consequently is easily filterable. This was firs remarked by Erdmann. Now when this nickel which may be either settled or filtered off, is adde to fresh oil it disperses in that medium and a inky-black fluid difficult to filter is again obtained Mixed with petroleum ether this same nicke remains flocculent and can be readily filtered, bu when mixed with benzene the nickel gives a brownish-black liquid which is unfilterable or very diff ult to filter. Normann suggests that the formation f this apparently colloidal solution of nickel is ssociated with the double bonds contained in the olvent.

Owing to the paucity of published data and tatistics relating to the fat-hardening industry and he natural reluctance of individual firms to dislose information concerning their production, it is ery difficult to obtain a true measure of the present position of the economic development of this omparatively new industry. During the last fteen years the industry has become firmly established and works for fat-hardening are now to be ound in all parts of the world. The first plant to e erected was that at Crosfield's in 1907, which ad an output of 2 tons per day. Although statements have been made to the contrary, the second plant to be operated was at the works of Leprince nd Siveke in Herford in 1908, whilst the third was rected by Wilbuschewitsch at Nijni-Novgorod in 910.

In 1914 there probably existed altogether 24 works for fat-hardening, 18 of which were in Europe, having an annual output of approximately 230,000 tons of hardened oil. At the present day here are about 60 factories in Europe alone. Of this number 11 at least are in Germany, but more than half of these are not controlled by German capital; this figure is probably underestimated, for t is extremely difficult to ascertain the precise number, a remark which also applies to the following information concerning other countries. The number of works at the present day in England is given as 3, in France 5, in Holland 5—6, in Belgium 2, in Denmark 3, in Norway 4, in Sweden 4, n Russia 2, in Bohemia 2, and in Hungary 5, only one of which is known to be working. In other European countries the number of works averages about one in each; in countries outside Europe, there are 14—15 works in the United States, 8 in Japan, 1 in Manchuria and 1 in Egypt. Owing to trade conditions it is more than probable that at the present time many of these works are either dle or not producing to their full capacity.

Practically all oils met with in commerce are used as material for hardening. The suitability and application of hardened fat in the manufacture of soap is now so well known that lengthy reference to it is unnecessary; at first a great deal of prejudice had to be overcome before it was employed. Of much more interest is the use of hardened fats for edible purposes, an application that quickly resulted after it had been established that they were not only digestible and wholesome but also completely assimilated by the body. In Germany most of the edible hardened fat is manufactured into margarine; in America its use for the preparation of lard substitutes seems to be preferred.

The above-mentioned 14—15 works in the United States have a total productive capacity of 142,000 tons per annum, but during the last few years their output has been little more than half this quantity, as is shown by the following annual returns: in 1919, 54,635 t.; in 1920, 81,891 t.; and in 1921, 98,071 tons. The oil hardened in these works was of vegetable origin, for fish oils are apparently not treated in the United States, though the possibility that this source of raw material will be utilised in the near future seems very likely. This hardened fat was used mainly for edible purposes, very little entering into soap manufacture, because it cannot compete against the considerably cheaper animal fats. In this connexion Normann quotes a reliable communication received from America to the effect that the fat-hardening industry in that country is in a parlous condition because the margin between the price of liquid oils and that of natural hard fats is less than the working costs of hardening.

The following figures give the amounts of hardened fat absorbed by the margarine industry in Germany during the war, when food restrictions were in force; in the year 1915, 4945 t.; in 1916, 12,978 t.; in 1917, 7714 t.; in 1918, 15,247 t.; and in 1919, 30,421 tons. The part played by the fat-hardening industry in Germany during the war cannot be too highly praised, for, supplied with the very worst of oils, such as whale, poor linseed, and very bad rape-seed oils, it had to convert these into tasteless and odourless fats, the shortage of other oils and fats suitable for edible purposes being very acute. Hardened whale oil, however, was in use before the war as an edible fat; in 1914 Denmark consumed 3000 tons of it in the production of margarine, for which purpose it is quite suitable. So enormous has been the demand for whale oil to supply the needs of the fat-hardening industry that the whale and similar sea animals have practically been exterminated in the northern hemisphere, and unless international restrictions are made to prevent it, a similar state of affairs appears imminent in the southern waters whither the whaling industry has migrated. A gradual diminution in the supply of this comparatively cheap oil may therefore be expected in the future, but this will hardly influence the industry of fat-hardening to any great extent for an abundant source of raw material is to be found in the vegetable oils.

NEWS FROM THE SECTIONS

NOTTINGHAM

The first meeting of the session was held on October 18, when the chairman, Mr. S. F. Burford, Public Analyst of Leicester, gave his inaugural address on "Industrial Chemistry, its Importance and Progress."

The Society of Chemical Industry, founded on broad and catholic lines, has been organised to pool the wealth of chemical knowledge. It is to our younger chemists, coming into this heritage, that we look for further developments. Many examples show how greatly the chemist has added to the sum of human happiness and security. This is partly known to the man-in-the-street, who makes many demands on his power and supposed omniscience. The commercial man, whilst appreciating the value of insurance against fire and trade risks, demands of the chemist immediate returns, and expects by placing a penny in the slot to make fortunes, like a broker, from the power of transmutation. In reality all exploration is costly. The disinterested worker places freely at the disposal of his fellow-men the results of laborious researches. Trading corporations must not be content to make their profits out of such results, but on their own account should subsidise research for the public, as well as for their own benefit. Examples were given of such enlightened action. On the other hand, civic corporations, in particular, have not yet risen to their responsibilities in the disposal of their waste products by financing schemes of investigation as a matter of public duty, and of great contingent benefit and profit.

MONTREAL

The first meeting of the Session 1922-1923 was held in the Queen's Hotel, Montreal, on October 16. The chairman, Dr. A. R. M. McLean, presided, and the speaker of the evening was the ex-President, Dr. R. F. Ruttan.

Dr. Ruttan recounted his experiences in Great Britain and France on the occasion of his visit for the Annual Meeting. He spoke of the hospitality so lavishly extended to him as a compliment to Canadian chemists rather than a personal one, and many interesting souvenirs of that meeting were passed round to the members. Dr. Ruttan also spoke of the status of the chemical engineer in the Old Country and the efforts that were being made to secure men trained to be good chemists and good engineers but not specialists, introducing the analogy of the general medical practitioner. Referring to the chemist in Canada he said: "No class in the community is more interested in such national questions as technical education, utilisation of waste products, controlling and directing the application of scientific methods to the development of industries and of the resources of the country. Members of no profession are so well qualified as are chemists to direct legislation along effective and economic lines. We chemists, as a body, are too much inclined to shut ourselves up in our own interests, whether academic or commercial. It seems time for the chemist to take greater cognisance of public affairs and to assume an active part therein."

In dealing with the need of closer union between not only academic and industrial chemists, but also scientific organisations generally in Montreal, Dr. Ruttan urged the formation of a Science Club. Such a club in Montreal would bring together the Natural History Society, the Montreal Chirurgical Society, mining, engineering, and other organisations which are now housed separately. In order to bridge the gap between academic and industrial chemists a fifth year should be added to the university course in which the student would, under direction and tuition, do work on industrial processes. He also spoke of the need of inducing the Legislature to create an advisory committee of chemists to act for the Government in connexion with the Customs and other departments, as he found there was no one who could advise the Government departments on questions that are now, more than ever before, arising in connexion with imports and the use of chemicals. The Government should be compelled to subsidise the exhibits of resources, production, and those showing the development of new chemical industries at the 1924 Imperial Exhibition, to be held in England to illustrate the natural resources of different parts of the Empire.

After Dr. Ruttan's address Mr. A. Neighorn moved a resolution, which was seconded by Mr. H. W. Matheson and adopted unanimously, that a prize of $50 be offered to a third-year McGill student for the best essay on his practical experience of chemistry as applied to industry.

Mr. G. E. Sanders, formerly of the Department of Agriculture, in charge of research on insecticides, spoke briefly on the development and spread of insects destructive to crops and trees.

GLASGOW

The new session was opened by a meeting held on October 20 in the Institute of Engineers and Shipbuilders, Glasgow. Mr. W. E. Moodie, the new chairman of the section, presided and introduced Dr. H. Hepworth, who gave a most interesting account of "The Syntheses of the Tannins."

Following a historical introduction, the lecturer reviewed the work of Emil Fischer and traced the various steps in the synthesis of pentadigalloylglucose, which has a molecular weight of 1700 and a rotatory power resembling that of natural gallotannin. It was emphasised that much of Fischer's success was due to the control which he was able to effect upon the hydroxyl-groups during a condensation, a control made possible by treating the hydroxy-compound with chloroformic ester prior to condensation. An example of such control was afforded by the synthesis of a depside, a substance able to coagulate gelatin and formed by the condensation of a hydroxyl-group of one molecule with a carboxyl-group of another. Such a substance was digallic acid formed by the condensation of two molecules of gallic acid. Reference was made to the synthetic compound prepared by Fischer shortly before his death in 1919, which had a molecular weight of 4021 and a molecule containing not fewer than 220 carbon atoms, and which had been prepared with the aid of phenylhydrazine, Fischer's "guiding star." This substance was the condensation product of tribenzoyldigalloyl chloride with the osazone of maltose and *p*-iodophenylhydrazine. The work of Nierenstein was then discussed and it was shown that Fischer's formula for gallotannin could not be upheld and correlated with the production of tetramethylglucose, as obtained by Nierenstein in the hydrolysis of purified gallotannin. In conclusion, it was stated that nothing was known regarding the constitution of the other natural tannins, except that they were not all glucosides.

EDINBURGH AND EAST OF SCOTLAND

Dr. H. E. Watt presided at the first ordinary meeting of the present session, held on October 24 in the Hall of the Pharmaceutical Society, Edinburgh. The Secretary announced that Mr. J. Henry, of Leith, had been approved by the Committee for admission as an Associate, and on the motion of Mr. J. Rutherford Hill this was approved.

The chairman then delivered his opening address entitled "Some Thoughts on the Training and Career of the Industrial Chemist." The importance of a university or college training for industrial chemists was emphasised. The training in pure chemistry should be as wide as possible, specialisation in any particular branch being left until the completion of the university course qualifying for the degree or the Associateship of the Institute of Chemistry. Additional subjects of study should include mathematics and physics, and, if possible, biology. Dr. Watt also discussed the uestion of looking for employment and gave some und advice to prospective industrial chemists on e bearing of candidates at interviews. The career the chemist was then outlined with many light nd humorous touches and much instructive riticism and advice. A good discussion followed which Mr. W. A. Williams, Dr. Lauder, Messrs. utherford Hill, Baxter, Cottrell, Merson, Ludlam, nd Williamson took part.

LIVERPOOL

On October 27, in the Muspratt Lecture Theatre f Liverpool University, Mr. W. M. Inman read a aper on "Developments in the Use of Bléaching gents for Textiles and Paper Pulp," of which an bstract is given below. Dr. G. C. Clayton, hairman of the Section, presided over a good ttendance.

Methods of bleaching did not change materially rom ancient times until the middle of the ighteenth century, Scheele's discovery of chlorine nitiating the first real development. Bleaching y chlorine gas was, however, not very successful, nd it was left to Charles Tennant to develop the pplication of Scheele's discovery. In 1798 Tennant repared "bleach liquor" by passing chlorine into ilk of lime, and subsequently solid bleaching owder, which obviated the difficulty of transport. Much attention was given to making a bleaching owder containing more than 35 per cent. of available chlorine, but the solid sodium and calcium ypochlorites were a failure owing to difficult and xpensive methods of manufacture. In recent ears liquid chlorine has been much used. In uture it is probable that the method of 1798 (*cf. s.*) will return to favour, the hypochlorite being tilised on the spot. This method is used in many aper mills in North America; the chlorine, from ank wagons containing the liquid element, is passed into stoneware towers down which milk of lime is flowing. In this way the bleach-mixing plant is dispensed with and there is less residual sludge. A comparatively small plant can furnish a large utput, and the process is economical. It is possible that the old-fashioned "gas bleach" for the resolution of lignified fibres may again come into prominence, especially if the gas be derived from liquid chlorine. In America the new paper mills use a liquid-bleach plant, but it is quite feasible to make bleach liquor from milk of lime and chlorine in the common type of bleach-mixer that is used in British paper mills. All that is necessary is to provide dip pipes through which the chlorine can be introduced. The mixer is filled with milk of lime and agitated at a fairly high speed. The chlorine is absorbed slowly at first but more readily later, and a bleach liquor of any convenient strength can be made. Alternatively, it is suggested to chlorinate the free lime which is present in all bleaching powders during the operation of mixing it with water to produce bleach liquor. The liquid chlorine is contained in 70-lb. cylinders and the content of one cylinder suffices to chlorinate 6 cwt. of bleaching powder. Advantages of this process are: reduction in amount of sludge; more rapid working due to quicker sedimentation; less bleaching powder is used and less irritant dust gets into the air. This process has been used in Germany for many years; it was first tried here in 1919. In the future the user will make his own bleaching agent from an alkaline base and liquid chlorine.

BRISTOL .

The second meeting of the Session was held in the University on November 2, when Mr. C. J. Waterfall presided over an excellent gathering numbering 60. Among the visitors present were members of the Bristol and District Boot and Shoe Trade Managers' and Foremen's Association. Mr. Stanley Hirst, of Messrs. Cox and Co.'s Successors, read a paper entitled "From Hide to Leather," and illustrated his remarks by showing numerous specimens and samples of tanning materials, leather made by various processes, and sources of damage to hides. An excellent discussion followed, and a vote of thanks to Mr. Hirst was proposed by Mr. M. W. Jones (vice-chairman) and seconded by Mr. Arthur Marsden. The president of the Boot and Shoe Trade Managers' and Foremen's Association expressed thanks on behalf of its members for the invitation to be present. In conjunction with the paper, arrangements were made for members to visit the tannery of Messrs. Cox and Co.'s Successors on November 8.

MANCHESTER

The meeting held on November 3, when the attendance was over two hundred, was the second of the intended series of annual joint meetings arranged by the Manchester Sections of the Society of Chemical Industry, the Institute of Chemistry, the Society of Dyers and Colourists, and the Manchester Literary and Philosophical Society. Dr. E. F. Ardern presided at the outset, and explained that as the arrangements for the meeting had been made by the last-named society, and would have been held in its rooms if they had been large enough, Prof. W. L. Bragg had been asked to preside. Prof. Bragg then took the chair and introduced Dr. F. W. Aston, who gave an address on isotopes, of which the following is the official summary:

Dalton's atomic theory postulated that atoms of the same element are equal in weight. Beyond mere speculation the first attack on the validity of this wholly unproved hypothesis was made about 1910, when Soddy put forward his theory of isotopes and predicted the existence of varieties of lead having different atomic weights, a prediction amply verified later. The same possibility was suggested in the case of the non-radioactive elements by the positive-ray analysis of neon. By this analysis one compares the weights of individual atoms, and this can now be done with an accuracy of one part in a thousand by means of the mass-spectrograph. This instrument gives a focussed spectrum depending only on the weights of the particles forming the positive rays, and as these are charged atoms and molecules, their weights can be directly compared. It is found that many, probably the majority, of the elements consist of mixtures of isotopes. Thus chlorine (atomic weight 35·46) consists of two isotopes of atomic weights 35 and 37 respectively. Some of the heavier elements are exceedingly complex, xenon having no less than nine constituent isotopes. By far the most important result is that the atoms of all elements except hydrogen have integral weights when expressed on the oxygen scale to a considerable degree of accuracy. This "whole number" rule enables sweeping simplifications to be made in our ideas of mass. All atoms may now be considered simply as different aggregations of primordial atoms. The latter are of two kinds, positive and negative, protons and electrons, the particles of electricity itself. The fact that the elements of fractional atomic weight are mixtures of isotopes of whole-number atomic weight explains at once anomalies in order, such as the atomic weights of argon and potassium. On Rutherford's nucleus-atom theory, isotopes are elements whose atoms have the same net positive charge on their nuclei (Moseley's atomic number) but different numbers of protons and electrons in these nuclei and therefore different weights. Isotopes have practically identical chemical and optical properties. Their separation is a matter of extreme difficulty and only the minutest changes of atomic weight have been experimentally detected so far. The weight of the hydrogen atom is found to be greater than unity; this is of great importance for if it were possible to transmute hydrogen into any other element prodigious quantities of energy would be liberated. This transmutation is probably going on continuously in the sun and other stars.

BIRMINGHAM

Dr. E. B. Maxted, chairman of the Section, presided at the dinner held in the Queen's Hotel on November 4, when the guests included Dr. E. F. Armstrong and Mr. and Mrs. F. R. O'Shaughnessy. To mark the retirement of Mr. O'Shaughnessy after 17 years' service as hon. secretary of the Section, the President, on behalf of the members, handed him a laboratory microscope with complete accessories and a scroll testifying to the esteem in which he was held, and Mrs. O'Shaughnessy was presented with a gift of jewelry.

In proposing the health of Mr. and Mrs. O'Shaughnessy, Mr. H. Silvester referred to the ability and tact with which the late hon. secretary had performed his duties and recalled that although the Section was formed shortly after the foundation of the Society in 1881, it remained in existence only a short time. Sir W. Tilden then initiated the Birmingham Chemical and Metallurgical Club, but as there were no facilities for publishing papers read at the meetings, the Birmingham Section was re-formed, largely through the enterprise of Mr. O'Shaughnessy. During his period of office the late hon. secretary organised annual meetings of the Society in 1907 and 1917, and 157 papers had been read before the Section. Dr. Armstrong observed that not only had Mr. O'Shaughnessy's work enriched chemical science but it was for the public benefit, and he hoped that the microscope would enable him to amplify it; on behalf of the Society he expressed deep indebtedness to the hon. secretaries of the Sections for their loyal service.

In returning thanks for the gifts Mr. O'Shaughnessy observed that the tendency had been to enhance the technical side of the Society's activities and pleaded for more attention to the social side.

The toast of the Society was proposed by Mr. E. R. C. Marks, chairman of the Midland Section of the Institution of Mechanical Engineers, who pleaded for closer co-operation between the mechanical engineer and the industrial chemist. Replying to the toast, Dr. Armstrong stated that this year the Society had a very definite policy, viz., to raise the position of the chemical profession to that of the legal, medical and engineering professions. Within the next few years chemists would have to decide whether they would rehabilitate their profession or be content to remain in the wilderness. Practice and research were necessary, but the importance of observing professional etiquette, and of cultivating a broad outlook and ideals, were not yet sufficiently recognised. Prof. A. R. Ling proposed the toast of "The Guests" and Mr. J. G. Smont, president of the Birmingham Metallurgical Society, who replied, remarked on the harmonious relations that had existed between that Society and the Section, and observed that if, in the past, metallurgy had developed mainly on the engineering side, metallurgists were now returning more to basic principles—to chemistry. Dr. E. B. Maxted, responding to the toast of his health, expressed the hope that the evening would mark the first of a long series of annual dinners. The credit for the success of the arrangements for the dinner was due to Mr. G. King, the new hon. secretary.

MEETINGS OF OTHER SOCIETIES

THE FARADAY SOCIETY

The latest of the series of useful discussions promoted by the Faraday Society was held, in conjunction with the British Cold Storage and Ice Association, on October 16 in the Institution of Electrical Engineers. Papers were received from several distinguished foreigners, Prof. H. K. Onnes and Dr. C. A. Crommelin, of the Cryogenic Laboratory, Leyden, and M. Claude, of Paris, but of these only Dr. Crommelin was able to attend.

"On the Lowest Temperature yet obtained" was the subject of Prof. Onnes's paper, and in it he describes attempts that have been made to prepare solid helium by the boiling of liquid helium under reduced pressure, the latest attempt—made in 1920—being given in detail. The actual pressure on the surface of the helium was 0·012 to 0·014 mm. and the lowest temperature 0·9° Absolute; but no solid helium was obtained.

Dr. C. A. Crommelin described in detail the methods used in the Cryogenic Laboratory in Leyden, and particularly those for liquefying various gases and obtaining any desired temperature below °C. and maintaining it constant within 0·01° C. The advantages of ethyl chloride as a refrigerating agent were discussed by Prof. C. F. Jenkin. The high inflammability of this substance can be counteracted by mixing it with ethyl bromide. Most metals are not corroded by it, but rubber and woods are affected. Moisture must be rigorously excluded from the refrigerating machines, since ice-crystals may be formed which choke the valves.

Dr. Ezer Griffiths and Mr. J. H. Awbery discussed the thermometric lag in cold-storage practice, a subject which they have investigated at the National Physical Laboratory; and the former, in a paper on some materials of low conductivity, described some of the lesser known substances which have been found to be very efficient insulators. Among these are "expanded rubber," or rubber in a highly cellular form, of density 0·06 (ordinary vulcanised rubber has density 1·5), and Balsa wood from Ecuador, which is extremely light, a cubic foot weighing from 5·7 to 8·6 lb., compared with 45 lb. per cb. ft. for mahogany. This wood has little strength but, unlike cork, it can be worked with ordinary wood-working tools. Other materials described were: fibres of *Kingia Australis*, eel grass, and compressed peat.

Mr. C. R. Darling contributed a short description of a thermo-couple designed for low-temperature work, and a paper of great practical interest on industrial methods of liquefaction and practical applications of low temperatures was read by Mr. S. K. Murray, of the British Oxygen Co., who gave a full account of the Linde and Claude processes, together with some figures of cost. The disused barium-oxide process of making oxygen is economically the equal of the air-liquefaction methods, but the oxygen produced by it is less pure. The secret of cheap oxygen is large liquid-air units worked to their full capacity. Ninety-six per cent. of the oxygen sold in this country is used in industry, mainly for metal-cutting. It is doubtful whether it is yet economic to use oxygen for enriching air for blast furnaces (a subject discussed by Mr. Cosmo Johns), or, in conjunction with steam, for the continuous gasification of fuel. The only uses of oxygen in chemical industry, known to the author, are in the manufacture of nitric and acetic acids in Germany. Practically all the oxygen used throughout the world is oxygen stored in cylinders; about 300 million cub. ft. per annum is distributed in this form in this country, even in the present bad state of trade. In France the output is about the same, in the United States three times and in Germany more than twice as much as in Great Britain.

Monsieur G. Claude's paper on the manufacture of hydrogen from water gas and coke-oven gas described his methods of separation by partial liquefaction. It would appear that the production of hydrogen from water gas has hardly any advantages over other processes, but the author believes that his process is likely to be of great service to the coke-oven industry, owing to its many indirect advantages, *e.g.*, the recovery of benzol and ethylene.

A paper which gave rise to considerable discussion was that by Mr. E. A. Griffiths on the use of liquefied gases in æronautical work. An efficient all-metal vacuum vessel was described in which either charcoal or silica gel is used as absorbent, and also a modified form of metallic vacuum vessel which permits the rate of vaporisation to be regulated.

SOCIETY OF GLASS TECHNOLOGY

The first meeting of the session was held in York on October 18, Prof. W. E. S. Turner presiding. In a lecture on "Processes and Methods of Mediæval Glass Painting," Mr. J. A. Knowles, of York, said that mediæval window glass was a potassium-calcium-silicate, and practically all the glass used for painting was imported, supplies for the school of glass-painting at York being derived from Hesse and other Rhenish provinces and for the London school from Lorraine, Burgundy and Normandy; the uncoloured glass used in the north of England was much whiter than that used in the south. The statement that no modern colours equalled those of old windows was erroneous. With the exception of "ruby" glass, mediæval coloured glasses were those most easily produced, and being made from impure native oxides containing other metals, each of which imparted a slight tint to the glass, the colours obtained were not pure but slightly secondary, so that they always harmonised. The glass at York, particularly that of the 14th century, was liable to corrode. There was no cure for pitting and corrosion, which were effects due entirely to bad manufacture, deficiency of silica, excess of alkali, and bad founding. Corrosion was not a sign of age.

A paper on "Modern Developments in the Making of Stained and Painted Glass" was presented by Mr. H. J. Powell, of London, who was unfortunately absent through illness. Decay of the actual substance of mediæval window glass was not inevitable; much Roman glass and window glass of the 12th and 13th centuries were perfectly preserved. Some mediæval glass, however, had become opaque and very friable, and all the observed forms of decay originated in the use of an excess of alkali, which caused the glass to become hygroscopic. Considering the haphazard way glass was made in mediæval times, it was more remarkable that most of it had survived than that a little of it had failed.

Members were given the opportunity of inspecting the Roman glass, etc. in the Yorkshire Museum, the windows of the Minster, and the workshops where glass from the latter was being treated.

SOCIETY OF PUBLIC ANALYSTS

The first meeting of the current session was held on November 1 in the Chemical Society's Rooms, Mr. P. A. Ellis Richards presiding.

In a paper on the "Colorimetric Estimation of Pyrogallol, Gallotannin, and Gallic Acid," Mr. C. A. Mitchell described the use of a ferrous-tartrate reagent which gives a violet coloration with the pyrogallic group, and which is applicable as a quantitative measure of that group in various compounds. Using this method a constitutional formula for gallotannin was deduced which agreed best with that proposed by Nierenstein. In determining gallotannin in presence of gallic acid, both substances are estimated together colorimetrically in terms of gallic acid or pyrogallol, the tannin is precipitated with quinine hydrochloride, and the gallic acid estimated in the filtrate. The difference between the two results, multiplied by a factor, gives the gallotannin. The method has been used to estimate tannin and gallic acid in various natural and commercial products, to follow the course of the enzymic hydrolysis of gallotannin, and so on.

Dr. H. E. Annett and Mr. M. N. Bose described "The Estimation of Narcotine and Papaverine in Opium" by a method which requires the use of only 1 to 2 g. of the drug. On adding sodium acetate to an aqueous opium extract under specified conditions, narcotine and papaverine are precipitated completely and narceine partially. The last-named is removed from the precipitate by washing with water, and the narcotine is purified further and estimated polarimetrically.

"The Estimation of Codeine" was the subject of a paper by Dr. H. E. Annett and Mr. R. R. Sanghi. The codeine is extracted with toluene from an aqueous alkaline extract of opium, converted into hydrochloride, re-extracted with toluene (any residual codeine being converted into hydrochloride), and weighed as hydrochloride (*cf.* J. 1920, 702 A).

A paper on "The Estimation of Morphine," by Mr. J. R. Nicholls, described a method based on the fact that if 2 volumes of 50 per cent. alcohol is shaken with one of chloroform and allowed to separate, the two layers are approximately equal in volume, the upper containing about one-third of alcohol and the lower consisting of 2 parts of chloroform to 1 of alcohol. If the 50 per cent. alcohol contains morphine liberated by ammonia, about 85 per cent. of the total alkaloid will pass to the lower layer; when this is run off, half a volume of alcohol added (bringing up the strength to 50 per cent), and the whole shaken with 1 volume of chloroform, the second layer contains about 85 per cent. of the remaining morphine. Three extractions remove over 99 per cent. of the base and in practice 4 extractions only are needed to remove more than 0·1 g.

In some "Notes on the Estimation of Potassium by the Perchlorate and Cobaltinitrite Methods," Mr. R. Morris described a modification of a previous method (*cf.* J., 1920, 767 A) to make it applicable to the direct determination of potassium in the presence of certain insoluble phosphates. A method is put forward of precipitating sulphates—which must be removed—with barium chloride, which obviates practically all loss of potassium in the precipitated barium sulphate. Drushel's modification of the cobaltinitrite-permanganate process gives good results, especially for small quantities of potassium; the precipitate should be washed finally with a semi-saturated solution of sodium chloride; the presence of sulphates is immaterial.

SOCIETY OF DYERS AND COLOURISTS

At a meeting of the Manchester Section, held on October 27, Prof. E. Knecht presiding, Messrs. L. G. Radcliffe and W. Gibson presented a paper on "A Hydroxystearic Acid and Some of its Derivatives," which was a continuation of a previous paper on the action of nitric acid on saponifiable oils (*cf.* J., 1920, 305 A).

The authors have prepared a hydroxystearic acid of m.p. 85° C. from an oleic acid by the action of sulphuric acid, as previously described, and from it have obtained, for the first time, the methyl ester in the form of white flakes (m.p. 46° C.), the ethyl ester (m.p. 48·5° C.), and an acetyl derivative (m.p. 32° C.), but they have failed to isolate a benzoyl derivative in a state fit for analysis. A study was made of the interaction of bromostearic acid and silver nitrite with the object of preparing true nitro-compounds of stearic acid, but no such compound was obtained, even when silver nitrate was used. By acting on hydroxystearic acid with nitric acid a yellow crystalline substance (m.p. 82° C.) was obtained from which derivatives were prepared, but the analytical results were not sufficiently concordant to enable a constitutional formula to be deduced. The yellow substance contains no nitrogen and molecular-weight determinations gave contradictory results; but it is possible that its molecular weight may be 291. The esters have been prepared.

INSTITUTE OF CHEMISTRY

The Sections for the Leeds area and Huddersfield were addressed by the Registrar on "The Present Position and Future Prospects of the Institute and of the Profession," on October 23 and 24, respectively. His address, he said, was intended to provide material for debate. He compared the position of the Institute with its position in the past, having regard to the services which it rendered to the community, and compared it also with that of similar bodies. The chartered professional institutions generally had become recognised as part of the machinery of the State; they supplied the hallmark whereby the trained practitioners in any profession could be recognised; they exercised greater influence and received greater recognition from the community than formerly. They existed for public service, but their most valuable work lay in upholding the status of their professions, whilst each individual member reaped the benefit of being acknowledged by his professional body as a whole. The result in the case of the Institute was the establishment of an organisation of nearly 4000 members with a very high standard of professional competency and integrity, an organisation which rendered the country good service and of which every member had good reason to be proud.

In the eye of the public there was still a misunderstanding as to the word "chemist," but he thought progress had been made in the matter; not so much with the man-in-the-street but with the people that count. Chemists were coming into their own title by the natural process of assuming it. They could not take any other.

The position of the profession might be gauged by the extent to which it was employed. After the war and at the end of 1920 only 13 members of the Institute were without employment, and even now, in view of the very large increase in the number of recruits to the profession and the depression in industry, it was remarkable that only 130, or less than 3 per cent. of their members, were seeking employment. Compared with other professions, the training for chemists was as prolonged, the order of intellect required was higher than most, and the services rendered, so far as they could be compared, were as valuable.

In the discussion at Leeds, the chairman, Mr. W. M. Mackey, in opening the debate, referred to Mr. Pilcher's long connexion with the Institute and to the growth of the Institute during that time. It was, he said, a great advantage, particularly to those about to enter the profession, to hear criticism from one who, although not a chemist, had an inside knowledge of the profession.

Mr. F. W. Richardson said that manufacturers and industrialists required educating as to the value of the qualifications conferred by the Institute. He was decidedly pessimistic in regard to the position of trained chemists.

Mr. B. A. Burrell said he was in substantial agreement with Mr. Richardson's views. There was no doubt that the profession of analytical chemistry was overcrowded and one wondered what was to become of the many young chemists who were being turned out by the universities.

Mr. F. W. Branson disagreed with Mr. Richardson's remark that manufacturers in West Yorkshire did not encourage members of the Institute of Chemistry.

Dr. R. B. Forster said he was glad to hear that Mr. Pilcher attached great importance to the word "chemist." He had always held the view that only those who were members of the profession were entitled to be called "chemists." They had made some progress and he felt sure they would ultimately succeed if they persisted. He did not agree with the pessimistic remarks of some of the speakers; it was true trade was bad, but employers were much more enlightened than formerly, and to support his argument he mentioned that out of the 31 students who took their B.Sc. in Colour Chemistry in Leeds University last June, only four were still seeking employment.

Mr. R. Gawler said that the Institute was sometimes described as the Institute of Chemists instead of the Institute of Chemistry. He considered the advancement of science to its true place in the national life a far loftier motive than might be read into the title "Institute of Chemists" by a member of the general public.

Mr. G. Ward, in proposing a vote of thanks to Mr. Pilcher, said that the lecturer had dwelt on many points which gave food for reflection. He did not agree with the deprecatory remarks of some of the speakers. Much of the future of the younger members lay in their own hands.

At Huddersfield, the chairman, Dr H. H. Hodgson, agreed that the work of the Institute was largely one of patriotism. The chemist was a valuable asset to the State. It was possible that if this country failed to develop its dyestuff industry the textile industry would eventually pass into the hands of the country possessing the strongest dyestuff industry.

Mr. H. W. Moss thought the note of optimism in the Registrar's address very useful at the present time, when a number of qualified and experienced chemists found it difficult to secure employment.

Mr. H. T. Lea put in a plea for a more comprehensive register of chemists to be available in all public libraries.

Mr. G. B. Jones urged the need of chemists on the commercial side of industry, so that customers might get into direct contact with those possessing a broad scientific outlook.

Dr. J. Bruce said that business men must realise that research could be made to pay. Results could not be expected at once. A good understanding between the chemist and the management was essential.

Mr. H. S. Foster deprecated the assumption that chemists are lacking in general culture. He thought that the Institute might usefully issue a pamphlet pointing out that a chemist of sound training without special experience is a better investment than one with special experience but an inferior training.

Mr. S. Robson suggested that chemists should get a place in the management by forcing out the non-technical man, and that this was largely a question of personality.

Dr. A. E. Everest thought the formation of local Sections was an enormous step forward in that it had brought about a more intimate relation between the individual chemist and the Institute.

Dr. L. G. Paul compared the status of the chemist in the works 40 years ago with that of to-day. There had been a vast improvement.

CORRESPONDENCE

PHOTOGRAPHIC SENSITISERS

Sir,—I am sorry that the note on "A Green Photographic Sensitiser" on page 293 R of your issue of July 15 escaped my notice until just recently, as it contains several errors which should not be passed over without comment.

The deficiency of sensitiveness which has longest withstood efforts to remove it is not in the green and greenish yellow as suggested, but in the blue-green in the neighbourhood of $\lambda = 5000$ to $5200 \mu\mu$. This point was certainly recognised by Sir William Pope in the paper in question, which contains the sentence: "It is noteworthy that the failure to sensitise gelatino-bromide plates for a short region in the bluish-green which occurs so frequently with sensitisers for the yellow and red regions of the spectrum, does not occur with the substance now described." The existence of this blue-green gap is, however, not such a drawback as is suggested, since it enables the use of at least a small amount of light in the manufacture and treatment of panchromatic plates which would otherwise have to be not only handled, but manufactured, in complete darkness.

Secondly, the suggestion that this is the first green sensitiser of which the constitution has been published, shows very slight acquaintance even with the work of Sir William Pope himself. In a paper published in the *Photographic Journal* in May, 1920, by Sir William Pope and Dr. Mills, at least four dyes are described which confer sensitiveness to the green and yellow green, and one of these has been in regular use for the manufacture of panchromatic plates for a considerable time.

The constitution of some of these dyes was discussed, if not satisfactorily settled, as long ago as 1905 by König, and later by Shepherd (Photogr. J., 1908, 300—318).—I am, Sir, etc.,

Ilford, Oct. 24, 1922. B. V. Storr.

In the interests of strict accuracy, thanks are due to Mr. B. V. Storr for his courteous correction of the unfortunate slip which was made in the insertion of the words "yellowish-green." The whole purpose of the note was, firstly, to show why our very busy eminent scientists thought it worth while to devote their talents to the preparation of dyes which confer colour sensitiveness upon the ordinary photographic emulsion; and, secondly, to intimate to the readers of the *Review* that, whilst the particular green sensitiser under consideration had in all probability been prepared at an earlier date by Dr. König, of Höchst am Main, to Sir William J. Pope must be accorded the honour of publication of the details concerning its method of manufacture and constitution. As Sir William Pope himself states, in the communication to the Chemical Society: "This substance . . . . the most powerful sensitiser for *green* light yet known for gelatino-silver bromide photographic plates. The new sensitiser is the simplest member of a *novel* series of compounds," the writer of the article may perhaps be excused the offence of having used the sentence beginning: "This is the first green sensitiser of which the constitution has been published"—the word "green" being used by the writer in exactly the same sense as that accorded to it by Sir William J. Pope.

The Writer of the Note.

STREATFEILD MEMORIAL LECTURE

THE METALLURGICAL CHEMIST

C. H. DESCH

On November 2, in the Finsbury Technical College, London, the Streatfeild Memorial Lecture was delivered by Prof. Cecil H. Desch, professor of metallurgy in the University of Sheffield, to whom the Streatfeild Medal was presented by Mr. A. Chaston Chapman, F.R.S., the Chairman. The Streatfeild Prize for excellence in practical chemistry was handed to Mr. F. L. B. Revis by the lecturer.

THE chemical industries have received an unusual share of attention during the last few years on account of their importance in the war and of their position among what are popularly but loosely called "key" industries. Whatever view we may take as to the economic conditions under which such industries best flourish, all who have any claim to speak on the matter are agreed that the first requirement, without which no chemical industry can live, is an adequate supply of trained chemists, not merely for the analysis of materials and products and for the conduct of routine manufacturing operations, but also for investigation and discovery. It is not enough for industrial chemists to preserve and use existing technical knowledge, but they must add to it. Many of us hold that the actual direction of the industry should be largely in the hands of such technically trained experts, and that the frequent absence of such direction is one of the most potent causes of weakness in the industry. The transfer of the control of manufactures from the technical chiefs to boards of financiers and commercial men is a serious fact of the day, deserving the careful attention of all who are interested in the relations of science and industry. It leads inevitably to concentration on finance rather than on manufacture, and to the making of profits assuming greater importance than the making of goods. To follow up this subject would lead me into controversial regions, and I must turn to the safer ground of technical training.

Whatever branch of industry we may take as an example, a training in its methods and processes must be based on a broad foundation of general science, that is, of mathematics, physics, and chemistry. Once that foundation, common to all technical work, has been laid, we may proceed to specialise. But not too early. Specialisation in science and in technology is necessary and inevitable, but it is an evil if uncontrolled, and may result in a dangerous narrowness of outlook. Some day, when we have escaped from the meshes of the examination system, we may see a truly scientific education in which the physical, biological, and social sciences will be so correlated that even the technological student of moderate attainments may gain a synthetic view of science as a whole, as a background to the special studies which are his immediate object. In the meantime we can take measures to avoid, by a thorough training in these three fundamental sciences, the dangers of a too partial view. In this respect the old Finsbury training was highly successful.

The present position of chemistry is a good illustration of the increasing tendency of science towards subdivision and specialisation. A chemist—without further qualification—is rarely met with at the present day. In his place, we meet with physical chemists, organic chemists, food analysts, colloid chemists, chemical engineers, and many other specialists. It is commonly taken for granted that a chemist who has chosen one of these specialisms as a life-study cannot be expected to have much acquaintance with any of the other departments of the science, and ignorance of other branches of chemistry is scarcely considered to be a reproach. We have all met with chemists who have become in course of time so intimately associated with some small section, such as the chemistry of the azo-compounds, as to abandon all interest in the remainder of the science. The opinion is widely held that chemistry is too vast a subject for an individual to master, and if by any chance an exceptional person should be found who persists in retaining an interest in the whole field of chemistry, refusing to regard his science as an aggregate of unrelated specialisms, he is lucky if he avoid the taunt of being a mere populariser of science, a smatterer among experts. I venture to hold that this view is wrong, and that chemistry needs more men who, whilst acquiring as full a knowledge as possible of some restricted field, yet retain a mental picture of the science as a whole, and follow with interest its general progress.

My subject to-day is the metallurgical chemist, the representative of one of those specialisms of which I have spoken. There is some excuse for his separate existence, for he has a history of his own. Whilst the alchemist, engaged in laboratory experiments with metals, was the ancestor of the modern scientific chemist, the practical metallurgist, extracting and smelting the ores of those metals, has a long record of independence. The miner and the metal smelter, the first scientific representative of whom was Georgius Agricola in the 16th century, laid the foundations of the new science of geology, whilst accumulating a mass of material to be utilised, when the time came, by the scientific chemist. Even now, theoretical chemistry finds a rich field of experimental facts in the processes of smelting and alloying metals, whilst the needs of the metallurgist have been the impetus to the development of a large part of analytical chemistry.

The dominating position of the metallurgical industries in our Western civilisation—all our industries, even that of agriculture, being so largely dependent on a supply of suitable metals, especially of iron and steel—gives particular importance to the metallugical chemist in an industrial society. His training is undertaken by special colleges or departments of universities, and has to combine instruction in the chemical and physical principles of metallurgy with practice in the typical operations of the works and laboratory. Quantitative analysis rightly occupies a foremost place in the training of chemists, no other practical discipline giving quite the same combination of manipulative skill with confidence in the reality of the facts observed and in the conclusions drawn from them. When metals are the special object of study, this character of work in quantitative analysis is particularly conspicuous, hence the stress laid upon it in any good course of metallurgical instruction. To make a full analysis of a high-speed tool steel, which may contain, in addition to carbon, silicon, phosphorus, sulphur, and manganese, which have to be estimated in every steel, nickel, cobalt, chromium, molybdenum, tungsten and vanadium, is an exercise demanding a high degree of skill and also an understanding of questions of valency, reactions of oxidation and reduction, and other matters of theoretical importance. The degree of accuracy required in such analyses for commercial and technical purposes is surprising to a chemist unaccustomed to such work, and far in advance of the standard usually accepted in academic laboratories. When a steel specification fixes an upper limit for the phosphorus of 0·40 per cent., and a delivery may be rejected if the analysis shows 0·41, and this is a typical case, great accuracy is essential, and the young chemist must be prepared to have his results challenged and the analysis repeated by referees in cases of doubt. Speed as well as accuracy are required, and the methods employed in works frequently differ from those adopted in outside laboratories, not in being less exact, but in being more rapid. The analysis of the bath samples taken from an open-hearth furnace during the working of a charge may be taken as an example.

It is true that the manipulative skill necessary to enable an analyst to estimate the usual elements in ordinary steels may be acquired by practice and by constant observation of expert workers, since the analytical methods have been reduced to a standardised routine, and a practised hand may make accurate analyses by following a prescribed ritual, without an understanding of the underlying principles. It is a fact that much of the work in steel laboratories and assay offices is performed by such empirically trained assistants, and it is not inconceivable that it may at some future time be done by mechanical means, as the composition of flue gases is now determined automatically by a CO_2-recorder. But when the analytical work embraces a variety of complex alloys, something more than mechanical skill and accuracy is required, and the analyst finds the necessity of a scientific training, and it may be said that no analyst devoid of chemical knowledge could deal satisfactorily with the wide range of materials passing through a modern steelworks laboratory. Dexterity in analysis, however, is only one of the requirements of the metallurgical chemist. Comparatively few of the graduates or holders of college diplomas in metallurgy intend to remain in the laboratory during their professional career. In many large steelworks it is the practice for the young graduate to enter the works laboratory, and to spend such time there as is necessary to become familiar with the methods, materials, and products of the establishment, and then to pass out into one of the other departments of the works, such as the melting shop, forge, or rolling mill. The head chemist is necessarily a permanent official, controlling all the analytical work, but his assistants may be drawn largely from such temporary colleagues.

Chemical knowledge is required in the conduct of other metallurgical operations, and the working of an open-hearth charge of steel, for example, is an operation on the large scale, involving the delicate control of a number of complex and highly interesting chemical equilibria. But the properties and the uses of metals depend on their physical condition as well as on their chemical composition, and it may be said with truth that metallurgy is the application of the laws of physics and chemistry to the special case of metals. Hence the necessity of a good knowledge of physics. Physical instruments are in every-day use in the works. For instance, temperatures are measured by means of the thermo-couple or the electric-resistance pyrometer, or, if too high for metal wires to be used, by instruments that measure either the total radiation or the intensity of radiation of a particular wave-length. Such instruments may be set up and read by an intelligent but untrained workman, but to direct their use, to calibrated them when installed, and to determine their errors after wear, calls for a good understanding of the principles on which they are designed and of the possible sources of error. The heat treatment of steels, again, is governed by a knowledge of their critical or transformation temperatures, and such knowledge is obtained by making certain delicate determinations of the development or absorption of heat, or of discontinuous changes in the volume, electrical resistance, or magnetic permeability, introducing a large range of instruments, so that a steel-works laboratory may rival that of a college in the completeness of its physical equipment.

Microscopical metallography, that wonderful method of investigation introduced by H. C. Sorby, has established itself so firmly that no modern metallurgical or even engineering works can afford to be without microscopical equipment. The mechanical and physical properties of metals and alloys depend on their crystalline arrangement and on the distribution of their constituents as well as on their composition. Physical chemistry has shown that alloys are to be considered as solidified solutions, and the metallurgical chemist has therefore to master the technique of metallography, which is not difficult, and also to learn how the structures observed are to be interpreted, which is less easy. The study is a fascinating one, and skill in it is one of the most valuable accomplishments that the young metallurgist can acquire. A later development has even found its way into industry. The work of Laue and the Braggs has shown how the internal architecture of metallic crystals, on which depend such properties as strength and ductility, may be determined by means of X-rays, and a whole new field of work is thus opened up.

There is another side of metallurgy besides that which deals with cast or worked metals that may appeal to many students, namely, that which concerns the mining and preparation of ores. For such work a training in geology is required, and the student may specialise in the study of raw materials, and undertake prospecting work or find occupation in connexion with mines. Every metallurgist needs an acquaintance with mineralogy in order to understand ores, fluxes, and refractories, all of which he encounters in his daily work. Above all, however, the metallurgist must be a chemist, so fully trained in the fundamentals of his science as to adopt immediately and unconsciously a scientific attitude towards the problems that present themselves in the course of his work. He must have a knowedge of the sources of information at the disposal of the chemist, and must be prepared to follow the progress of chemistry, closely as regards his own special section, and in broad outline that of the science in general. This involves the ability to abstract literature, if possible French and German as well as English.

It may be thought that I have been describing an Admirable Crichton, possessed of all the accomplishments, but such a training is actually within the capacity of a good student pursuing a three or four years' course after matriculation. All branches of industrial chemistry, metallurgy among the number, need a supply of such trained men as managers, chemists, and research workers, and the universities and colleges will have to provide, in an increasing degree, such men for the needs of industry. There is one danger against which I would warn metallurgical, or indeed any technical students. It is that of despising the practical man in the works, the skilled smelter, steel hardener, shop foreman, or roller, because he makes dogmatic statements in unscientific language. The skilled workman is usually right in his facts, allowance being made for some old prejudices, and his explanations are less absurd than they appear to the academically trained novice in industry. Long experience of metals in the workshop often gives a wonderfully thorough, and apparently instinctive, knowledge of their behaviour. Even the explanation may be merely the survival of an obsolete mode of expression. When one watches the process of puddling iron one sees at a certain stage of the process small flames on the surface of the molten mass. The puddler will explain that these are the "sulphur" burning off. The chemist, knowing that sulphur is not eliminated at that stage, and that the flames are of carbon monoxide, may regard the statement as nonsense. It is, however, merely a survival from the time when chemists generally used the word "sulphur" to denote the combustible constituent of any substance, and in this case the carbon is actually being removed, the puddler expressing the fact in the scientific language of an earlier generation. The trained chemist must learn to respect the knowledge of the practical man, and to utilise his wide experience in the construction of his own more orderly and logical system of technological doctrine and practice. The best way of avoiding the dangers that beset a purely academic chemist when he enters industry is to gain experience by direct contact while still pursuing the course of college instruction. This may be done, in most instances, by passing a part of each summer vacation in works, an arrangement for which metallurgical employers have ungrudgingly given facilities. Such experience is essential in order that the student may acquire the sense of the importance of scale on which success in technical processes so largely depends. So, too, he learns to know the machines and plant in a more direct way than from diagrams or models. Some engineering knowledge he must have, the outlines of which are imparted to him in his academic training, and whilst comparatively few metallurgical chemists specialise on the side of machinery, they must all be prepared to co-operate with engineers, and to understand their point of view.

As representing a university situated in the midst of a great industrial area, and in the closest touch with the dominant industries, I can speak of the vital importance of technical education to the city, the nation, and the wider civilised community. The methods of industry are changing; rule-of-thumb and secrecy are disappearing, and with the growing recognition that the reckless waste of natural resources is a crime against society, a more scientific period is in sight. All who look forward to that improved state of things will recognise with gratitude the pioneer work of Finsbury in that direction, the great services of its able and devoted staff, and the debt that all its students, of whom I am proud to have been one, owe to them, and not least among them to Streatfeild, the patient, admirably efficient, and well-loved teacher in whose memory this lecture has been established.

PERSONALIA

The Nobel Prizes for Chemistry for 1921 and 1922 have been awarded, respectively, to Prof. F. Soddy and Dr. F. W. Aston. The Prizes for Physics have been awarded to Prof. A. Einstein, of Berlin, and Prof. N. Bohr, of Copenhagen.

Dr. S. W. Stratton, for 21 years director of the U.S. Bureau of Standards, has accepted the presidency of the Massachusetts Institute of Technology; and Mr. F. B. Tough has succeeded Mr. A. W. Ambrose as chief petroleum technologist to the U.S. Bureau of Mines.

The Howard N. Potts medal of the Franklin Institute has been awarded to Messrs. C. R. Downs and J. M. Weiss, of New York, for their work on the catalytic oxidation of benzene to maleic acid and on the development of an industrial process for converting aromatic into aliphatic compounds.

The gold medal for the best paper presented at the Annual Meeting of the American Society for Steel Testing has been awarded to Mr. E. J. Janitzky for his thesis on "The Influence of Mass in Heat Treatment," and the second prize to Messrs. Gill and Bowman for their paper on "The Constitution of High-Speed Tool Steel."

Among the awards made by the President and Council of the Royal Society are:—The Copley medal to Sir Ernest Rutherford, for his researches in radio-activity and atomic structure; the Rumford medal to Prof. P. Zeeman, for his researches in optics; the Davy medal to Prof. J. F. Thorpe, for his researches in synthetic organic chemistry; the Buchanan medal to Sir David Bruce, for his researches and discoveries in tropical medicine; and the Hughes medal to Dr. F. W. Aston, for his discovery of the isotopes of a large number of the elements by the method of positive rays. The Royal medals have, with the approva of the King, been awarded to Mr. C. T. R. Wilson for his researches on condensation nuclei an atmospheric electricity; and to Mr. J. Barcroft for his researches in physiology, and especially fo his work on respiration.

NEWS AND NOTES

FRANCE

Industrial Notes

Chemical Industry.—The Chamber of Deputies is now considering a Bill to develop the production of sodium carbonate and caustic soda in France. Until recently there were only three factories producing these chemicals, all of which were situated in the district of Nancy, and consequently exposed to destruction in case of invasion. For this reason a company named La Société d'Etudes et Produits Chimiques was formed early in 1918, to manufacture sodium carbonate and caustic soda at Mouguerre, near Bayonne, but owing to the high costs of materials and labour, the progress made in the construction of the factory was very slow, production was not started until the end of 1919, and even now the daily output does not exceed 20—30 tons. The Government now realises the importance of a steady production in a locality not exposed to invasion, and it is considering the grant of a loan of 8 million francs, at 6 per cent. interest, to enable the company to raise the capacity to 100 t. of sodium carbonate (96—98 per cent.) per day, a quantity which could be converted into 75 t. of 72 per cent. caustic soda. Until the loan has been repaid the company cannot raise further money without the consent of the Treasury. This proposed rrangement is also interesting in that it probably ndicates the intention of the State to take in hand he organisation of production for war-time requirements.

Coal Dust as Fuel.—The question of finding a mbstitute for petrol as a fuel for internal-combustion engines loses none of its importance, and ests have recently been made in the northern nining areas on the inflammability of coal dust in arious degrees of sub-division and concentration. The results show that very finely-divided coal dust emains suspended in the air almost indefinitely, nd that when rich in volatile matter it forms a very xplosive mixture with air. Tests are now to be arried out to ascertain the possibility of using uch an explosive mixture in internal-combustion ngines. Progress has been made by the successful se in these engines of "colloidal" coal—a suspenon of "coal" dust in heavy vegetable oils—the ust being prepared from French lignites, and the ls derived from French West Africa. According Monsieur Lance, 150 g. of powdered lignite will eld on combustion in one cb. m. of air 825 calories, as much as 75 g. of petrol. Allowing for different nsities, 1 litre of petrol costing 1·80 francs could replaced by 1·45 kg. of pulverised lignite worth out 0·45 fr.

Metallurgy.—The following statistics of producon of pig iron and steel during the period nuary 1 to June 30, 1922, have been prepared by Comité des Forges de France:—

	1922	1921 1st half	1921 2nd half	Pre-war
	Metric tons	gain or loss per cent.		
Pig iron ..	2,294,895* ..	+27·5 ..	+42 ..	—49·5
Steel ..	2,057,406 t. ..	+33·7 ..	+31·5 ..	—41

* 34,895 t. in electric furnaces.

greatest increase in production of both iron steel has occurred in Eastern France, including raine. There are now 92 blast furnaces in ration, compared with 73 on January 1 last. Of total steel production, Thomas and Martin steel now represent 98·1 per cent.; the manufacture of Bessemer steel is declining steadily.

Extraction of Bromine and Potash in Tunisia

An article on the extraction of bromine and potash from the salt marshes at El Hanèche in Tunisia during the war is published in the September issue of *Chimie et Industrie.* Owing to the high price and insufficient supplies of bromine then being obtained from the United States, a factory was erected at El Hanèche, which from April 28, 1916, up to the date of the armistice supplied a total of 1050 metric tons of bromine to the Allies. To-day the factory no longer exists, but it was in operation long enough to provide the essential data that would be required to establish a bromine industry in Tunisia. The remainder of the information given is covered by an article which appeared in the *Bulletin de la Société d'Encouragement* in Jan.-Feb., 1919, and was abstracted in this *Journal* (1919, 146 R).

AUSTRALIA

British Phosphates Commission

The report of the Commission for the year ended June 30, 1922, states that exports from Nauru and Ocean Islands reached the record total of 364,251 tons, of which 72·96% went to Australia, 4·70% to New Zealand, 4·59% to the United Kingdom, and 17·75% to other countries. This output approaches the maximum possible with the existing plant. Sales of phosphates and sundry credits amounted to £1,304,740, and the cost of phosphate f.o.b., together with £222,521 for interest, sinking fund, etc., was £688,957, and freights £613,097. The credit balance of £2685 was transferred to reserve account, and cash in hand amounted to £18,853. The phosphate rights, plant, etc. are valued at £3,325,770 and stocks at £298,250. Liabilities are divided as follows:—British Government, £1,571,483; the Commonwealth, £1,517,113; and New Zealand, £577,860.—(*Ind. Austr.*, *Aug.* 31, 1922.)

Cane-Sugar Crop in Queensland

Returns published by the Registrar-General of Queensland show that in 1921 the crop from 184,513 acres of sugar-cane was 2,287,416 tons, which yielded 282,198 tons of sugar (94 n.t.) and 10,734,399 gallons of molasses. In 1920 the crop from 162,619 acres was 1,339,455 t. and the yield of sugar and molasses 167,401 t. and 6,175,868 galls., respectively.—(*Ind. Austr.*, *Aug.* 10, 1922.)

Lead-Poisoning at Broken Hill

The final report of the Barrier Technical Commission appointed to report on health conditions at the Broken Hill mines states that of 6538 mine workers examined, only 61, or 0·9 per cent., were found to be suffering from lead poisoning, and only 27 of these had worked exclusively underground. Among surface workers, 5 out of 823 general labourers, and 1 out of 774 mill-hands were found to be affected. It was concluded that all men working in or about the mines were exposed to the action of lead circulating in the blood, but chemical analyses showed that the concentration of lead was low. The Commission recommends that susceptible persons be removed from exposure to lead poisoning and that the disease be made notifiable in certain localities.—(*Mining Mag.*, *Sept.*, 1922.)

CANADA

Industrial Notes

The Canadian Salt Company has commenced the manufacture of liquid chlorine at Sandwich, Ontario. The present output is ten tons a day.

The Hull Electric Co. has acquired the riparian rights to the Paugan Falls, on the Gatineau River, Quebec, about 35 miles north of the city of Ottawa. The company will establish a hydro-electric plant with an ultimate capacity of 150,000 h.-p., at a cost of approximately $10,000,000.

The Shawinigan Water and Power Co. is contemplating the development of 150,000 h.-p. at Gray Falls, on the St. Maurice River, about six miles below Shawinigan. This work will be commenced next spring, and will entail an investment of approximately $10,000,000 to $15,000,000.

Lakefield, Ont., will probably be the first place in Canada at which the development of electric power from surplus heat will be carried out. The Canada Cement Co. is planning to secure 2000 h.-p. for its new plant there by converting the waste heat from the kilns into electrical energy, which will be utilised to raise steam. This system is successfully operated in other countries.

The experimental lignite-briquetting plant, near Bienfait, Sask., which is under the direction and control of the Advisory Council for Scientific and Industrial Research, and upon which $1,000,000 has been expended, is not giving satisfaction. The Press states that the Federal Minister of Mines is not satisfied and is calling for an independent report upon the plant. It is intimated that the Government is not favourable to further expenditure under the present circumstances. The ex-Minister of Mines had certain features of this undertaking investigated and the report was unfavourable.

Mining and Metallurgy

The Manganese and Steel Foundry, Ltd., of the United States, is erecting a branch factory in Sherbrooke, Quebec.

The Globe Mining Co., operating about 36 miles from Cranbrook, British Columbia, has discovered a seam of sienna from 8—10 feet wide.

The Government of Quebec announces that the royalty on asbestos has been reduced from $5·00 to $2·50 per ton. The reduction, however, is subject to certain provisions contained in the Order-in-Council.

The returns of the Department of Mines, Ontario, for the first half of 1922 show a record gold production of 476,322 oz., and it is probable that the value of the output for the full year will exceed $20,000,000. The production of silver was 4,774,666 oz., and that of copper, nickel, and cobalt also improved.

The offer of the British Government to collaborate in financing the Coast Range Steel Co., British Columbia, is contingent upon thorough investigations being made independently by the Provincial Government, the Dominion Government, and the British Government; if satisfactory, the last-named will advance certain monies to be expended in Great Britain on purchasing equipment for the steel-mill.

The estimated value of the minerals produced in the Dominion during the first six months of 1922 is $57,682,944, metals being worth $26,475,544 and non-metals $21,207,400. This result shows an increase, in value, of 9·1 per cent. over the coresponding period in 1921. The principal returns are as follows:—Coal $24,346,959, gold $12,410,202, silver $5,997,199, lead $2,882,047, natural gas $2,448,824, copper $2,337,093, asbestos $1,894,232, nickel $1,401,820, zinc 1,370,460, and salt $849,133. Owing to strikes there is a marked decline in the production of coal, nickel, and copper.

The entry of the H. W. Johns-Manville Co., of New York, into the Quebec asbestos mining area, by securing an option upon the Martin-Bennett properties, and the erection of a large plant for the manufacture of all kinds of asbestos products, has been followed by the possibility of the company obtaining possession of the Black Lake and East Broughton properties, controlled by Jacob A. Jacobs, Montreal. The American company is not going to have the field to itself, as a large British asbestos firm, with head office in London, has decided to merge with an Eastern Township (Quebec) mining firm, and the Asbestos Manufacturing Co., Ltd., of Montreal. The new company will be known as the Asbestos Manufacturing Co. of Canada, and its capital will be $2,000,000. The present plant, at Lachine, Que., will be enlarged and improved to meet the requirements of the new company, which will manufacture packing, textiles, and all kinds of asbestos products. It is probable that the Hon. P. J. Paradis, M.L.C., will be the president of the new company.

UNITED STATES

Earnings of Chemical Companies in 1920

Financial returns for 1920 forwarded to the internal revenue authorities by 5826 manufacturers of chemicals and allied products, disclosed a total gross income of $5,565,125,606 and a total net income of $344,929,904, on which taxes amounting to $98,163,376 were paid. Only 3047, or 52·3 per cent., of the companies reported a net income; the remainder had a gross income of $1,027,030,330 and a deficit of $96,439,756.—(*Oil, Paint and Drug Rep.*, *Oct.* 2, 1922.)

Talc and Soapstone in 1920

The total production of talc and soapstone in the United States in 1920, according to the U.S. Geological Survey, was 224,290 short tons, valued at $3,090,265, an increase of 21 per cent. in quantity and 31 per cent. in value compared with 1920. Output increased in all producing States, except North Carolina, which, however, is only a small producer. No soapstone is imported, but the import of talc, 22,680 t., was the largest on record. Imports from Italy returned to the pre-war level, and those from France recovered substantially, but the largest quantity (15,123 t.) came from Canada. As there were no exports of talc, the apparent consumption was 246,970 t., the average value per ton being $14.34.

Investments in Chemical Education, 1920-21

The National Research Council has collected the following information concerning the amount of money invested in the teaching of chemistry in about three-fourths of all the universities and colleges in the United States during the academic year 1920-21:—

The 417 institutions that reported possessed buildings and equipment valued at approximately $28,230,784, in addition to new buildings under construction and their equipment valued at $7,553,300, the latter sum including $2,000,000 for Cornell University and $1,866,900 for Yale University. Endowment funds received during the year totalled $525,868, and the cost of maintaining the chemistry and chemical-engineering departments, including salaries, chemicals, etc., was $7,739,970. There were 3643 graduates and 109,128 undergraduates taking courses in chemistry, and 302 graduates and 5585 undergraduates studying chemical engineering (where a separate department is maintained). The State of New York had the largest amount, viz., $6,790,015, invested in chemical education.—(*J. Ind. and Eng. Chem., Mar.*, 1922.)

SOUTH AFRICA

Life of the Rand Gold Mines

The Transvaal Chamber of Mines estimates the ore-reserves of the Rand gold mines as follows (million tons):—Producing mines 695; old producers, closed down, 60; partly developed, but not promising, 60; undeveloped areas 225; total 1040 million tons, or sufficient to last 50 years at a high rate of production or 70 years with normal vicissitudes and a languishing end. Extensions of the gold field to the south-west are probable, but when once the great mines are exhausted there will be no chance of revival under conditions at present conceivable.—(*Mining Mag., Sept.*, 1922.)

GERMANY

The Gasification of Crude Brown Coals

In order to elicit possible solutions of the problem of completely gasifying raw, ungraded, earthy brown coals with a high moisture content, the Brennkrafttechnische Gesellschaft is offering a prize for open competition. Competitors have to submit either a process or a plant and must supply an illustrated account supported by accurate quantitative data. The Gesellschaft acquires the copyright of all theses submitted but will have no right to use the processes described.

High-Pressure Steam

According to the *Industrie-und Handels-Zeitung* of October 1, a steam turbine is being erected in Berlin which will work under a steam pressure of 1600 lb. per sq. in. The steam is discharged from this turbine at about 190 lb. per sq. in. and then enters an existing turbine in which its expansion is completed. It is stated that the technical difficulties of generating steam at this high pressure have been overcome by using the recent invention of a Swede and that the experiments made have given very good results.

Is Radium a Medicament?

A German court of justice decided that radium is not a medicament because its action, like that of Röntgen rays, is purely physical, and because when used it does not suffer an appreciable loss within a limited time. This ruling has, however, recently been put aside by the Berlin Court of Appeal on the grounds that according to the methods of preparation and packing, radium is clearly intended for use in curing, alleviating or preventing diseases in man and animals, and the case is to be re-tried in another provincial court.—(*Chem.-Z., Sept.* 23, 1922.)

"Weinschenkite," a New Rare-Earth Mineral

In the *Berichte* for October 14, F. Henrich reports the occurrence of a new mineral containing 52·47 per cent. of rare earths (about 4 parts of yttria to 1 of erbia), and 30·2 per cent. of phosphoric anhydride, the loss on ignition being 16·42 per cent. These figures agree fairly well with the formula XPO_4+2H_2O (X=Er, Y, etc.). The mineral, which has been named "Weinschenkite," occurs in small quantities in the iron-ore district of Amberg-Auerbach in Bavaria, and appears as white, felted, round masses, and also as stellate needles on limonite. A very rare mineral containing 2 to 3 per cent. of rare earths and 13 per cent. of calcium oxide named "pseudo-wavellite" occurs in the same locality.

BRITISH INDIA

First Forecast of the Indigo Crop

The following statistics refer to the six provinces which contain practically the whole area under indigo in British India:—

First Forecast

Province	Area (acres)		Yield (cwt.)		Yield per acre (lb.)	
	1922-23	1921-22	1922-23	1921-22	1922-23	1921-22
Madras	102,600	114,500	23,000	28,000	25	27
United Provinces	35,000	42,000	4,200	4,800	13	13
Bihar & Orissa ..	35,200	39,900	4,300	4,900	14	14
Punjab	37,500	21,200	7,600	2,900	23	15
Bengal	7,300	11,100	300	400	5	4
Bombay and Sind (including Indian States).	9,300	8,600	1,600	1,500	19	20
TOTAL ..	226,900	237,300	41,000	42,500	20	20

—(*Ind. Tr. J., Oct.* 19, 1922.)

GENERAL

Manchester College of Technology

The degree of Bachelor in Colour Chemistry has been created at this college with the object of training chemists for the dyestuffs industry. From the present session onwards it will be possible to obtain the degree of B.Sc. Tech. in the section of colour chemistry. At the annual meeting of the Evening Students' Chemical Society the following officers were elected:—President: Prof. F. L. Pyman; Vice-presidents: The Principal, Prof. Knecht, Capt. Sinnatt, and Messrs. Huebner, Radcliffe, Roberts and Allan. Joint hon. secretaries: Messrs. S. Rowbottom and J. Haslam.

The Logwood Industry in Haiti

Logwood is one of the leading articles exported from Haiti, and the United States is the chief consumer. Statistics showing the reserves of logwood are not available, but the Bahon district, which produces well-matured wood, yielding one barrel (about 500 lb.) of extract per ton, is estimated to contain 500,000 to 1,000,000 tons. Large quantities have been obtained from the district around Port de Paix and Molo St. Nicholas, but the district near Cape-Haitien is largely exhausted and the wood now obtained from it is of secondary growth. Haitian logwood is mainly exported in a crude form, but shipments of extract are increasing, and an American corporation has erected plant at Grande Rivière at a cost of $150,000 to produce 400 barrels of extract per month. At present the industry is only occasionally active, and exports of logwood have declined from 108,106 tons in 1920 to 33,434 t. in 1921; in 1920, 31 t. of extract was exported, as compared with 119 t. in 1919. Prospects are not favourable, but trade would improve with a revival in the textile industry of the United States.

Prospects of an Alcohol Industry in Palestine

The Department of Commerce and Industry of Palestine has collected information relating to the possibility of establishing an alcohol industry in the country. Imports of alcohol in 1921–22 were 561 tons, and the production was 117 metric tons, all from grape juice; also 0·62 tons made in experiments on the fermentation and distillation of durra. Barley and wheat are suitable raw materials as they yield 31 and 33 litres of alcohol per 100 kg. of grain, respectively, and production is in excess of the demand. The durra crop is another useful source, and maize, which yields 19 to 37 l. per 100 kg., could be grown in certain areas if a market were available. The potato crop, though increasing, is too small to be used except for food, and the use of sugar-cane, now being grown experimentally, for the manufacture of power alcohol, would be too costly. Data are needed of the yields from prickly pears and acorns, of which ample supplies are available.

Monazite in the Malay Peninsula

An account of the occurrences of monazite in the Malay Peninsula, and of the properties and identification of the mineral, has been prepared for the Federal Council of the Malay States. There is good reason to believe that monazite is present in the granites and granitic rocks of Malaya, but probably not in quantities worth exploiting. It is found in many localities in detrital deposits, often in association with tin ore, and occurs most abundantly in the alluvium of the rivers of Kemaman, a concentrate from which contained 5·30 per cent. of thoria (ThO_2). The content of thoria in monazite from other localities is given as follows (per cent.):—Sempam (concentrate) 8·38, Baias Tujoh (sample) 4—5, Dindings 8·7, Puchong Babi 3·40, Kulim (Kedah) 3·53, Kelantan 9·41. Proximate analyses of specimens from the three last-named localities showed contents of 66·27, 64·05, and 60·00 per cent., respectively, of ceria, lanthana, and allied oxides. A copy of the paper may be consulted at the Malay States Information Agency, 88, Cannon Street, London, E.C. 4.

The World's Production of Sugar

Figures showing the world's production of sugar in 1921–22 and the preliminary estimates of the 1922–23 crop are given below:—

	1921–22	1922–23
	Thousands of Short Tons.	
United States:		
Beet	911	581
Louisiana cane	290	208
Cuba	4,000	3,600
Porto Rico	385	510
Dominican Republic	225	
Java	1,650	1,659
Australia	299	300
Fiji Islands	65	52
Mauritius	200	250
Natal	150	140
Formosa and Japan	425	325
British India	2,500	2,500
Europe	4,088	4,600
Other countries	2,302	2,275
Total	17,490	17,000

—(*U.S. Com. Rep., Sept.* 4, 1922.)

Fertilising Value of Basic Slags and Rock Phosphates

In the *Journal of the Ministry of Agriculture* (Sept., Oct., 1922) Dr. G. Scott Robertson summarises recent work upon the relative value of different types of basic slag and rock phosphate. On hay and pasture rock phosphates produce the same type of improvement as the most soluble types of open-hearth basic slag, and they are more effective than the open-hearth, low-soluble fluorspar slags. In districts with high rainfall and acid soil the efficiency of the low-soluble slags may approximate closely to that of the more soluble types. In general, the value of the fluorspar basic slags is 50—70 per cent. of that of the high-soluble slags. Rock phosphates were found to have a much higher fertilising value than has been admitted, and on sour, damp soils they may even prove superior to the best grades of basic slag.

Mercury Ore in China

The chief deposits of mercury ore in China occur in the provinces of Kweichow, Hunan, Yün-nan and Szechwan, of which the most important is that in Kweichow, which consists of a broad belt of cinnabar associated with stibnite and extends into Hunan. The largest mines at Yuanshankiang, 15 miles from Lungchikow, were opened in 1898 by a foreign company, but development has been slow. Cinnabar occurs in Hunan to the west of Fenghuangting, near the Kweichow border, and the chief mines are at Hontzeping and Tatungla. This mineral is also obtained by washing in the bed of streams in western and northern Yunnan, and especially in south-western Szechwan. At Hangeho, in the Yenyuan district of Szechwan, a mine worked on a fairly large scale supplies cinnabar to the important vermilion industry at Chungking.—(*Ch. of Comm. J., July* 7, 1922.)

Organisation of the Mining Industry in Russia

After Soviet government had been established in Russia, the industrial resources of the country were placed under a Supreme Board of Industrial Economy which controlled a number of general committees appointed to administer particular industries; the chemical industry was one of these, but a specific Section of Mines was not formed until the end of 1919, and in the following year a Council of Mines was also appointed. The organisation of the Council was very systematic, but it did not work, owing to lack of skilled direction, political friction, deficient means of communication, etc. Commissions of specialists were sent from time to time to inspect and report upon mines, particular attention being given to the coalfields in South Russia owing to the fuel crisis. In the summer of 1921 these coalfields were organised in a separate unit, and some improvement ensued; but the petroleum industry in the Caucasus remained in a critical position and metalliferous mining practically ceased. In October of the same year a general reorganisation took place, and the Council of Mines was converted into the General Administration of Mining Industry, the general committees becoming sections each under a technical department consisting o mining specialists.

The only important work done by the Genera Administration has been the collection of statistica data, and the compilation of geological and othe reports which will be of great use to the investor Very little real work has been done on the mine. during the last four or five years, and there is a great lack of tecnnical equipment.—(*Min. and Met., Aug.*, 1922.)

REPORTS

Report of the Food Investigation Board for the Year 1921. *Pp. 47. London: H.M. Stationery Office, 1922. Price 2s.*

The Report of the Food Investigation Board for 1921 includes accounts of a number of investigations of interest to the chemist, especially in the sections dealing with the work of the Meat Committee, the Oils and Fats Committee and the Fruit and Vegetables Committee.

The only point to be noted in the report of the Fish Preservation Committee is that autolytic reactions were found to proceed in the liver of herrings stored at the low temperature of about -7° C.

The report of the Meat Committee includes an account of researches carried out by Miss D. L. Foster and Miss D. M. Moyle on the effect of exposure to low temperature on the lactic-acid metabolism of amphibian muscle, the results of which have already been published in the *Biochemical Journal*, as have also the results of an investigation on the source of energy of muscular contraction. It was shown that during chopping, rigor and recovery from fatigue there is a change rom glycogen to lactic acid or *vice versa*; another mportant fact that has been discovered is that the muscle possesses the power of synthesising hexosephosphate from glucose and sodium phosphate. Miss Foster has also repeated experiments on the ffect of the rate of freezing on the autolysis of beef. She has confirmed her earlier observation hat the more rapidly the beef is frozen the more closely does the autolysis on thawing follow the course in that of fresh unfrozen beef.

The inquiry of the Fruit and Vegetables Committee follows three main lines, the preservation of apples by cold and gas storage, the chemistry of the ripening processes and the diseases of the stored fruit. The results of the cold storage tests have shown, as might be expected, that 1° C. is a better temperature of storage than 3° or 5° C. It also appears that the soil on which the apple trees grow influences the capacity of the fruit for storage, a silt soil being more suitable than clay or greensand, whilst chalk, clay and fenland are stated to be progressively less suitable. But as the fruit was not all gathered from trees of the same age it is not clear how far the results are really to be attributed to soil differences or to the age of the tree, or possibly to other factors.

The gas-storage method consists in keeping apples in an atmosphere containing 5 to 8 per cent. of oxygen, and 12 to 15 per cent. carbon dioxide, the rate of respiration of the fruit being presumably reduced by this means. In this connexion the rate of respiration of the apple Bramley's Seedling was followed throughout its storage at three temperatures: 2·5°, 10° and 22·5° C. The rate of respiration at first increases, reaches a maximum and then falls. At the three temperatures employed the maximum is reached on the 180th, 28th and 7th day of storage, respectively.

Mrs. M. W. Onslow has investigated a large number of fruits for the presence of oxidising enzymes; the results have already been published in the *Biochemical Journal*. Work has now been commenced on acids in the apple, and methods have been devised for the estimation of malic acid and malates, including titration and estimation of acid and malates as the lead salt. Special attention has been devoted to the estimation of the acid in small quantity. Tests for a number of enzymes in the apple have been made and tyrosinase and reductase have been detected.

In the work of the Oils and Fats Committee Prof. R. Robinson and his collaborators have continued investigations on the nature and constitution of the acids occurring in natural fats. Work on the synthesis of unsaturated acids of the C_{18} series has been continued; octyl bromide was condensed with the compound $AgC{\vdots}C\cdot(CH_2)_8CO_2Me$ in boiling isoamyl ether and this gave a small yield of the ester, $CH_3(CH_2)_7-O{\vdots}C\cdot(CH_2)_8CO_2Me$, which after catalytic reduction and hydrolysis gives homostearic acid. Heptyl bromide leads in the same way to stearic acids.

Prof. A. Lapworth and Mrs. L. Pearson have commenced the study of oleic acid and have come to the conclusion that the subject needs complete revision; the existing methods for isolating the acid are unsatisfactory, and the properties of the pure substance have not been ascertained with certainty. A method has been devised by which the proportion of saturated acid in the final product is reduced to a minimum; this is based on freezing out the ether or benzene solutions of the mixed lead salts with subsequent recrystallisation of the barium salts from mixtures of moist benzene or toluene and amyl or ethyl alcohol. Other investigations carried out under the auspices of this committee include one on the constitution of mannitol fat (the synthetic fat obtained by the interaction of mannitol and olive oil) by Miss H. Gilchrist, and a study of the conditions affecting the formation of fat by yeast by Dr. I. S. MacLean.

Accounts of the work of the Engineering Committee and the Canned Foods Committee are also included.

Report on Tanganyika Territory for the Year 1921. *H.M. Stationery Office, 1922. Cmd. 1732. Price 6d.*

Sisal and coffee of excellent quality are grown in the Tanganyika Territory (formerly part of German East Africa) chiefly by European planters, and the cultivation by natives of groundnuts—for which the conditions are very favourable—is extending. The cotton crop of 1921 was poor, owing to late planting and the ravages of insect pests, whilst the output and quality of copra were unsatisfactory. Lack of transport facilities prevents an extension of agricultural production, but it is proposed to increase the value and decrease the bulk of crops by partial manufacture on the spot. There are several experiment stations and a veterinary laboratory. A survey of the forests has shown the presence of large quantities of valuable timber such as cedar, yellow woods, West African mahogany, mangroves, etc.; a concession has been granted to exploit the Rau Forest (Kilimanjaro area) and tenders have been invited for leases of the mangrove forests.

When the Mining Ordinance came into force in June, 1921, 395 claims were registered for prospecting for gold, silver, diamonds, copper, asbestos, mica, molybdenum, coal, salt, and soda, and exclusive licences were granted to prospect for coal over a total area of 950 sq. miles in four localities.

There are indications of the presence of petroleum, but exploration is forbidden pending the enactment of legislation.

Except the Nyanza (Gottorp) salt mines, which are worked by the railway and supply salt to the Congo, and a small salt factory maintained by the Administration in the south-west area, there are no manufactures of commercial importance in the territory. Soap, ice, soda-water, etc. are made on a small scale for local use, but the produce of the country is exported in a raw state.

In 1921 imports were valued at £1,426,125 and exports at £1,246,870, representing increases of £308,000 and £784,000, respectively, compared with 1920. Among the exports were:—Sisal 7923 tons, cotton 1096 t., hides and skins 356 t., copra 4514 t., groundnuts 8448 t., and beeswax 183 t. The United Kingdom and British possessions supplied imports to the value of £1,384,125 and took 72 per cent. of the exports.

REPORT ON THE ECONOMIC AND FINANCIAL SITUATION OF EGYPT, DATED APRIL, 1922. *By* E. H. MULOCK, *British Commercial Agent for Egypt, Cairo. Department of Overseas Trade. Pp.* 39. *H.M. Stationery Office*, 1922. *Price* 1*s.*

The financial situation of Egypt on March 31, 1922, was more satisfactory than it was a year previously, in spite of low prices for cotton and general trade depression. The total foreign trade for the calendar year 1921 amounted to only £E. 91,864,046, as compared with £E. 187,348,024 in 1920, exports falling 35 per cent. to £E. 36,356,062, and imports 45 per cent. to £E. 55,507,984. The United Kingdom took 47 per cent. of the exports and the United States 18 per cent., whilst the imports were derived mainly from the United Kingdom 37 per cent., the United States 15, France 7, and Germany 3 per cent. German firms are making great efforts to regain their trade by offering to complete, at pre-war prices, contracts that were made before the war and abandoned, and by other means. Compared with 1920, the total imports from Germany increased by nearly 50 per cent.; those from the United Kingdom fell considerably below 50 per cent. The Leipzig Fair brought German firms much trade, but now that they demand payment in foreign currency, their competition may be less strong. In comparison with the United Kingdom, Germany supplied more glassware, indigotin, coal-tar dyes and paints, but less chinaware and fewer medicinal preparations. Some of the chief classes of imports and exports were evaluated as follows:—

	Imports		Exports
		£E.	
Hides, skins, leather goods	534,665	..	443,248
Spirits, beverages, oils	3,817,557	..	238,406
Paper, etc.	998,545	..	106,801
Stone, earthenware, glassware	1,128,880	..	6,933
Dyestuffs, tanstuffs, colours	467,233	..	53,241
Chemicals, medicinal products, perfumery	2,399,716	..	309,955

In agriculture the area planted to cotton was restricted and the crop much reduced. An extension of the control of sugar importations was advocated on the ground that the 57,000 acres under cane, grown for the refinery, would be reduced by one-half if sugar were imported freely. No progress in the mining and industry was recorded, but active prospecting for petroleum was undertaken in new areas. The Government continued drilling operations on both sides of the Gulf of Suez and proceeded with the erection of a small refinery. The Anglo-Egyptian Oilfields, Ltd. produced, mainly at Hurgada, 178,284 metric tons of crude petroleum, as against 145,226 t. in 1920. Home production is insufficient to meet requirements and large quantities of petroleum products have to be imported. In consequence of reduced demand the output of manganese ore fell from 77,562 t. in 1920 to 55,065 t. in 1921, but phosphate production rose by 7211 t. to 122,024 t., although the demand was poor and many mines were closed. A small Egyptian firm has begun to make dry colours and mixed paints at Helouan, near Cairo, utilising materials from mines worked by the ancient Egyptians. The firm intends to erect shortly a large factory with a capacity of 20,000 tons of dry colours and 2000 t. of mixed paints per year of 300 days.

OFFICIAL TRADE INTELLIGENCE

(From the Board of Trade Journal for October 26 and November 2)

TARIFF CUSTOMS EXCISE

Australia.—Drawback of the full duty may be allowed on imported ammonium and potassium nitrates used in manufacturing explosives within the Commonwealth when such explosives are exported.

Belgium.—An export licence is no longer required for sugar, syrups and molasses.

Bulgaria.—Information on the new customs tariff can be obtained from the Department of Overseas Trade.

Canada.—Crude groundnut oil for refining for edible purposes is transferred to the list of duty-free goods.

Ceylon.—The text of the revised schedule of import duties is given in the issue for November 2.

Federated Malay States.—All rubber goods manufactured in the F.M.S. are exempted from export duty until September 1, 1927.

Germany.—Increased import duties have been levied on certain kinds of perfumery, wares of soft indiarubber, hollow glassware, and wares of precious metals.

Guatemala.—Import duties have been reimposed on building materials, *e.g.*, cement, fibro-cement, tarred roofing material, galvanised sheets.

New Zealand.—It is proposed to abolish the 25 per cent. *ad valorem* duty on certain goods imported from countries with depreciated currencies and to replace it by an *ad valorem* duty to be determined from time to time. The agreement for reciprocal tariff treatment with Australia has been passed.

Portugal.—Until further notice, agricultural fertilisers may not be imported.

Spain.—The text of the tariff treatment accorded to British goods under the new commercial treaty with Spain is published in the issue for November 2. Among the chief goods affected are coal, earthenware, iron, steel, metals and products thereof, coal-distillation products, paint, varnish, alkali silicates (solid), insecticides, fungicides, soap, glycerin, superphosphate and chemically-prepared phosphatic fertilisers, salts of nickel and cobalt, and rubber tyres.

Trinidad.—Amendments to the import duties ffect glass, glassware, kinematograph films, lard, ard substitutes, matches, metals, vegetables, ssential and perfumed oils, soap, and paper. In nost cases the duties under the British preferential ariff are half those of the general tariff.

OPENINGS FOR BRITISH TRADE

The following inquiries have been received at the epartment of Overseas Trade (Development and ntelligence), 35, Old Queen Street, London, S.W. 1, rom firms, agents or individuals who desire to epresent U.K. manufacturers or exporters of the oods specified. British firms may obtain the ames and addresses of the persons or firms referred o by applying to the Department and quoting the pecific reference number.

Locality of Firm or Agent	Materials	Reference Number
ustralia ..	Glassware, cellulose products, artificial silks	446
" ..	Galvanised iron, porcelain ware, crockery, glassware	412/7/1*
Belgium ..	Varnish, enamel, colours	456

GOVERNMENT ORDERS AND NOTICES

Safeguarding of Industries Act. *Part I.*—The Board of Trade has received a complaint that "Sodium phosphate, mono-, R. Sodium phosphate, di-, and R. Sodium phosphate, tri-," have been improperly included in the lists of articles dutiable under the Act. (The prefix R was added to the item "Sodium phosphate, tri-" on April 6, 1922.) A further complaint has been received in respect of "sodium phosphate," and the complainants have notified their intention to object to the inclusion of other listed items, such as sodium pyrophosphate. As this complaint goes outside the precise terms of the list, the Board will contend that the only valid complaints received by it are those relating to mono-, di- and tri-sodium phosphate. The complaint will be submitted to the Referee, and interested persons should communicate immediately with the Assistant Secretary, Board of Trade, Great George Street, London, S.W. 1.

REVIEWS

Les Progrès de la Métallurgie du Cuivre. *By* Auguste Conduché, *Professor in the Faculty of Science at Rennes. Encyclopédie Léauté. Pp. xii+271. Paris: Masson et Cie., and Gauthier Villars et Cie., 1922. Price 14 francs.*

This little book attempts to give not only a scientific description of the metallurgy of copper, and of the chemical reactions which come into play, but also a summary of recent progress, and of the appliances and installations employed. Its scope may be judged by the fact that no less than 76 pages, nearly one-third of the whole book, are devoted to a description of the properties of copper, its compounds and alloys, 15 to roasting copper ores, 27 to blast-furnace smelting, including pyritic smelting, 10 to reverberatory smelting, 49 to matte-treatment (including converting), 30 to the treatment of complex ores and wet processes, 12 to fire-refining, and 27 to electrolytic refining.

The standpoint of the author throughout is theoretical, reactions are as a rule very well described and equations correctly given, but the descriptions of the appliances and of the operations followed are alike weak; such details, for instance, as the fuel consumption in various operations, the percentages of copper in mattes and slags, and the relative weights of each material produced are usually lacking, whilst data of cost are conspicuously absent.

It is a fact often lost sight of that there are two Metallurgies, the one a science, the other an art. The Science of Metallurgy is only a specialised branch of applied chemistry, concerned with the properties of metals and their alloys, their preparation by various methods, and the way in which the properties of both are modified by the presence of impurities, by heat treatment, etc. Investigation of these points often leads to commercial results of the highest importance, yet in its essence the science of metallurgy is a branch of pure science. Contrasting with this, the Art of Metallurgy may be defined as the "art of extracting metals from their ores and utilising them in such a manner as to yield the maximum of profit." The science of metallurgy is well dealt with by the academic professor, who in the investigation and recording of facts finds himself upon surer ground. With the art of metallurgy, the professor is too often not only out of touch, on account of his purely superficial knowledge and his ignorance of the essential details of operation and of manipulation, which can only be acquired by long experience, but frequently also out of sympathy, because these details, being dependent upon many variable factors, cannot be reduced to exact figures or tabulated, as can chemical or physical data. The present work exemplifies in characteristic fashion the limitations of the theoretical man in describing processes with which he is familiar only through his study of current literature. The chapter on blast-furnace, pyritic, and reverberatory smelting are all weak from the point of view of practical detail, and contain many statements which are either very incomplete or actually incorrect.

The author revives, for instance (p. 102), the old fallacy and bugbear of the theoretical man that "slags too rich in iron may give rise to the production of iron bears"; whereas experience proves that iron bears are never formed where there is plenty of iron to give a fusible slag and fast running; their formation is due to deficiency of iron and excess of silica, alumina, or lime, which gives rise to a high temperature of formation and slow running.

In order to ascertain the depth of matte in a settler, it is hardly necessary (as stated on p. 111) to "plunge into it a bar of *red-hot* iron," (!) and then note that after withdrawal "thanks to the greater conductivity of the matte, the part of the bar plunged therein takes a tint visibly darker than that which was exposed to the layer of slag." The ordinary well-known method of plunging in a slightly warmed bar and withdrawing after a few seconds shows clearly the level of the matte bath by a crust of congealed slag adhering to the bar above that level and a nearly clean red-hot bar below, corresponding to the depth of the bath of matte. The author describes (p. 112) the discharge of molten slag from a settler as taking place "periodically," by which is meant "intermittently." Such practice must be altogether unusual in copper smelting, if not unique, although intermittent tapping of lead slags from large reverberatory settlers is frequently adopted. In describing the practice at Anaconda the author states, on p.116, that the slags at the Washoe smelter formerly contained lime and ferrous oxide in the molecular ratio of 2:1. This was never the case, and the statement gives a misleading impression; the highest average percentage of lime in the slag was about 26 per cent., as against 22—23 per cent. FeO, which, in molecules, is only as 1·5:1.

The chapter on converting is perhaps the best in the book and presents fewest blemishes. At the top of p. 151, however, with reference to casting the converter copper in moulds, the author says "care being *often* (sic) taken to leave in the converter the rich slag which will serve during the following operation"; it may be remarked that, provided the slagging after blowing to white metal has been properly done, there will be very little slag left at the end of the blow, and what little there is generally accumulates near the mouth of the converter, from which it has to be chipped off after the operation of casting is completed.

Perhaps the weakest chapter of the book is that dealing with wet methods. No mention is made of the leaching of sulphates at Chuquicamata or of the ammonia leaching process, which, after having been discarded several times on account of operating details, has scored a marked success in Arizona, and is now to be adopted on a large scale in Central Africa. The description of the Huelva cementation process is by no means good. In explaining the oxidation of pyrites, for instance, the author says that in presence of air and of water, ferric sulphate and sulphuric acid are formed, whereas it is well-known that in the presence of a moderate amount of moisture ferrous sulphate is formed directly, and ferric sulphate only forms through a further absorption of oxygen in dilute solution.

The chapter on electrolytic refining is quite a good outline from the theoretical point of view, although, as usual, lacking in detail as regards the appliances employed and the operations carried out.

To sum up, it may be said that although too sketchy to be of use to practitioners of the art of copper metallurgy, the book will form a useful outline of modern practice from the point of view of the comparatively elementary student of the subject, for whom it is obviously intended; and it may even be of some use to those practically engaged in other branches of metallurgy, as throwing some sidelights upon their own work.

H. F. Collins.

Practical Tanning. *A handbook of modern practice and processes as applied in the manufacture of leather and allied products.* By Dr. Allen Rogers. *Pp. xxv.+699. London: Crosby Lockwood and Son,* 1922. *Price* 45s. *net.*

This work is based upon earlier editions bearing the same title, written by Louis A. Flemming. It has been modernised by the contributions of Dr. Rogers and his associates, and by the inclusion of a considerable amount of matter from other sources. The various processes of leather manufacture are ably dealt with in a style that will commend the volume to most practical men. The articles upon Unusual Tanning Processes by the author, Pigment Finishes by C. B. Kinney, and Patent Leather by G. W. Priest contain much interesting information, and as each has special knowledge of his particular subject, the contributions are of distinct value. The book contains many original illustrations, the subject matter is well arranged, is reasonably free from typographical errors, and the detailed table of contents affords a ready means of access to any desired information. The British reader should remember that the American gallon is roughly 17 per cent. smaller than the English gallon.

Dr. Rogers is aware of possible differences of opinion on some of the topics with which he deals, but it is not appropriate to discuss them here. At the same time, certain erroneous statements are made which call for comment. The assertion (page 496) that whilst sulphuric acid plumps hide, hydrochloric acid in certain dilutions has a depleting action, is contrary to fact. Various investigators have shown that under similar conditions the latter has even a greater swelling effect than the former. Dealing with the depickling of sheepskins, two working methods are suggested: (a) treatment with sodium bicarbonate—salt solution, and (b) a sour drench of bran and salt. The former is quite rational, but it is not apparent why a sour (*i.e.*, acid) drench is suggested as an alternative to the alkaline solution, and a simple brine solution would appear to be more effective for the purpose intended.

The Glossary of Terms used in the industry contains many errors and some superfluous definitions. Thus "depleting action" is referred to as "any action which tends to loosen the hair and epidermis," whereas in tannery usage it has no different meaning from that suggested by an ordinary dictionary definition. Similarly "tan" is wrongly defined as "any material which will prevent the putrefaction of hide substance." Common salt and all raw-hide preservatives would be classed as tanning agents according to the glossary. It is surely unnecessary to inform the reader that a lamb is a young sheep, and a kid a small goat! In its present form the glossary might have been omitted with advantage.

As a whole, the book is of distinct value to the practical tanner, as it contains much helpful information, but some assertions must be accepted with a certain amount of reserve.

Douglas McCandlish.

Die Methoden zur Herstellung kolloider Lösungen anorganischer Stoffe. *By* **Dr. The Svedberg.** *Third edition. Pp. xii.+507. Dresden and Leipzig: Theodor Steinkopff, 1922. Price 14s., bound.*

The issue of this new edition, an unaltered reprint of the second edition, of Svedberg's well-known work, testifies to its continued usefulness and value. From the comparatively small dimensions of the first edition the work has now grown into quite a large volume, in harmony with the general expansion which has taken place in the study of the colloidal state. In this volume, the author brings together most usefully the different methods which have been employed for the production of the colloidal form of different substances, and has thereby rendered a great service to other workers in this department of study and investigation. The methods for producing the colloidal state fall naturally into two groups, condensation methods and dispersion methods. In the former group one has, for example, methods depending on reduction, oxidation, and hydrolysis; whilst in the second group peptisation and electrical-dispersion methods find their place. The book is well written, the descriptions of preparations are clear, and full references to the original literature are given. The work is one which every worker in the domain of colloid chemistry will find indispensable.

Alex. Findlay.

Laboratory Manual of Colloid Chemistry. *By* H. N. Holmes, *Professor of Chemistry in Oberlin College. New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1922. Price 10s. net.*

The book before us is one which will be welcomed by every university teacher of chemistry who desires to introduce his students to the study of the colloidal state of matter. The rapid extension of chemistry in various directions has made it necessary to supplement the old courses in practical chemistry, consisting of inorganic analysis and organic preparations, with experiments in physical chemistry, electrochemistry, etc. And so the importance, from the practical point of view at least, of the study of the colloidal state is making it necessary to supplement the lectures on colloid chemistry, which must form a part of every honours course, by work in the laboratory. The work of organising and carrying through such a course will be greatly helped by the book which Prof. Holmes has written at the request of the Colloid Committee of the National Research Council of the United States. The experiments described by the author cover a very wide range and give scope for selection on the part of the teacher. In this selection, the teacher is helped by the author, who has suggested courses for medical students, students of agriculture or ceramics, students of geology, and students of industrial chemistry, as well as a general course to meet the needs of the student of pure chemistry. The value of the book is greatly increased by references to the literature and suggestions for collateral reading. The work is excellent and will, it is hoped, facilitate the introduction into our university courses of practical instruction in colloid chemistry.

Alex. Findlay.

OBITUARY

ALEXANDER CRUM BROWN

By the death of Emeritus Professor Alexander Crum Brown, at his residence in Edinburgh on October 28, at the ripe age of eighty-four, chemistry in Britain loses one of the most noteworthy figures of a passing generation, and a wide circle of scientists and others privileged to know him loses one of the most warmly esteemed of friends. Born in Edinburgh in 1838, he received his school education at the Royal High School there, and at Mill Hill. He then became a student at Edinburgh University, where, at the age of twenty, he graduated as M.A., and three years later, in 1861, as M.D. In the following year he obtained the degree of D.Sc. from the University of London. At an early age he seems to have been specially attracted to chemistry, most probably having had his attention turned in that direction through the circumstance of his maternal uncle, Walter Crum, himself a noted chemist, being engaged in chemical industry in the west of Scotland. At any rate, his M.D. thesis was a purely chemical one. After obtaining his medical and science degrees in Britain, he spent a year in Germany, where he made many life-long chemical friends, and where the work for his first published chemical paper, on the conversion of mucic acid into adipic acid, was carried out. A speculative vein with respect to theoretical chemical conceptions, which more or less distinctly characterised most of his subsequent contributions to chemistry, was evidenced in his M.D. thesis "On the Theory of Chemical Combination." At the date of its presentation, this thesis contained much that was in advance of the time, and, moreover, it foreshadowed a feature which became markedly noticeable in his later writings and in his dealings with affairs; that is, a far-seeing anticipation of the direction in which further investigation was likely to lead, and of the eventual consequences which would result from some line of action.

The speculative aspect of Crum Brown's mind and his strong liking for theoretical matters are well illustrated by a consideration of the diverse chemical subjects which engaged his particular attention, and by an examination of his treatment of these subjects in his original memoirs. In these connexions his papers or addresses on the theory of isomeric compounds, on the phlogiston theory, on chemical constitution and graphic formulæ, on the basicity of acids, on solution and osmotic pressure, on the ions of electrolysis, on the Le Bel—van't Hoff hypothesis, and (in conjunction with the late Sir Thomas R. Fraser) on the connexion between chemical constitution and physiological action may be recalled, and there are none of these subjects to which he did not contribute something of real and permanent value, either by experiment or by suggestion. The Crum Brown—Gibson rule concerning the position taken by replacing groups entering mono-substituted benzene derivatives also deserves mention here. In addition to the subjects just mentioned, Crum Brown, either alone, while occupying the chair of chemistry in Edinburgh University, to which he was elected in 1869, or in collaboration with pupils or assistants (Letts, Walker, and others) carried out investigations on the rusting of iron, on trimethylsulphine and thetine compounds, on the electrolytic synthesis of dibasic organic acids, and on a variety of minor subjects, all the time maintaining a remarkable flow of new and ingenious devices for attacking unsolved chemical problems.

Besides his pre-eminent position as a chemist, Crum Brown was a versatile philosopher, widely-read in other scientific subjects, including mineralogy, crystallography, and physiology, as well as in general literature; he was, also, a linguist of unusual attainments. Of the charm of his alert, vivacious personality as a host, as a *raconteur*, as a man, much might be written by one who held a sufficiently gifted pen. Failing the latter, it must suffice to quote one illustration of the man speaking for himself, as he did in the concluding words of his opening address to the Royal Medical Society in 1896:—

"Gentlemen, there are some things you need which cannot be got in lecture-rooms or laboratories, in dissecting rooms or in museums. I do not now refer to the priceless treasures, Honesty, Truth, Courage, Modesty, Kindliness, all that we include in our idea of a noble and good man; we should all covet earnestly these gifts and seek to increase more and more in them. I speak now of attainments of a more special sort—the power of easy and accurate expression, the power of quickly and correctly grasping ideas expressed—perhaps not very well expressed—by others. . . . These things can be had here. 'Iron sharpeneth iron; so a man sharpeneth the countenance of his friend.' And friends here learn to sharpen each other's wits without ceasing to be friends. We learn here to give and to take pretty outspoken criticism without any fear of taking or giving offence. I am speaking in the presence of many who know all this as well as I do, of many who could speak the praises of the Society far more forcibly and far more effectively than I; but I do not think there is anywhere any one who could do it more heartily."

LEONARD DOBBIN.

REVIEW

Vol. XLI] NOVEMBER 30, 1922 [No. 22

UNVEILING OF THE WAR MEMORIAL TO LT.-COL. HARRISON AND OTHER FELLOWS OF THE CHEMICAL SOCIETY

ON November 16, in Burlington House, London, a large number of Fellows of the Chemical Society and many representatives of other scientific societies attended the unveiling of the War Memorial to Lieutenant-Colonel E. F. Harrison and other Fellows by the Rt. Hon. the Earl of Crawford and Balcarres. The memorial, executed by Mr. E. Gillick, consists of a large bronze medallion depicting a trench scene at the moment of the approach of a gas cloud; the medallion is mounted on a slab of Italian (Lamartine) marble and below it are inscribed the names of thirty other Fellows who gave their lives for their country during the Great War. The memorial is erected on the south wall of the landing on the first floor in the Chemical Society's rooms.

Sir James Walker, president of the Chemical Society, presided, and Sir George Beilby, chairman of the Harrison Memorial Committee, made a statement concerning the origin and destination of the memorial fund. To that fund, he said, £1640 had been subscribed, and the committee had decided to use a portion of it for the erection of a permanent memorial, and to devote the remainder to the provision of a prize of approximately £150, to be awarded every three years to the chemist, man or woman, not above thirty years of age, who had made the most meritorious original contributions to chemical science during the preceding five years. The prize would be awarded upon the recommendation of a committee comprising the presidents of the Chemical Society, the Society of Chemical Industry, the Institute of Chemistry, and the Pharmaceutical Society. He asked Sir James Walker to accept, on behalf of the Chemical Society, the custody of the memorial and of the trust deeds of the fund.

In accepting the trust, Sir J. Walker remarked that the institution of the prize would commend itself to all as a most wise election. A capable investigator at the outset of his career was adequately provided for by scholarships, etc., and late in life he generally had received, indirectly for the most part, some reward for his work, but there was a period when the substantial encouragement of such a prize would prove a determining factor in his development.

The Earl of Crawford and Balcarres then delivered an address in which he referred to the sadness of such occasions, when the closed book was reopened, and to the compensation and comfort brought to those who mourned by the acknowledgment of heroism and public service, and the recognition of exceptional skill and distinction. He congratulated the committee and the Society on having chosen a sculptor of note, on having placed at his disposal an admirable site, and on having given him full freedom to develop his idea. In eloquent phrases he recalled Colonel Harrison's great achievement in combating "the most terrible assaults ever directed by science against an army in the field," and then passed to an appreciation of his character. Harrison had the power of concentrating the accidents of knowledge and intelligence and of directing them into a consistent and specific channel. He had the power of interrogation, combined with intuition, which enabled him to anticipate developments and thus meet in good time the progress of enemy attack. Honour was also due to the other Fellows of the Society whose names were recorded on the memorial: men of conspicuous ability in their own departments of research, men of character and promise, whose precious lives were ended prematurely. Among these was Andrea Angel, who died in January, 1917, in the disaster at Silvertown, where he returned into a blazing building, knowing it to contain people in danger of their lives, and so perished.

Lord Crawford then unveiled the memorial; "The Last Post" was sounded; there was one minute of silence; and "The Reveille" announced the completion of the ceremony.

In a few words Sir James Walker thanked Lord Crawford for performing the ceremony and for his address, and reminded those present that he (Lord Crawford) was an artist and writer on sculpture, well fitted to judge the artistic merit of the memorial; and that he had enlisted as a private in the Royal Army Medical Corps, and so had witnessed the ravages of poison gas and the success of the protective measures employed against it.

A photograph of the memorial is reproduced on the art inset; opposite to it is a similar reproduction of the Ramsay Memorial, which was described in our last issue.

ANTICORROSIVE AND ANTIFOULING COMPOSITIONS

P. E. BOWLES

THE advent of the iron ship, with all the great improvements it made in shipping conditions, brought in its wake to a very serious degree the troubles of corrosion and fouling. By "fouling" is meant the accumulation of marine growth, which often assumes incredible proportions. The writer has seen weed-growths two feet in length on a vessel, coated with inferior compositions, which had been riding at anchor in home waters for six months. One can imagine, then, what the appearance of an unprotected ship's bottom would be like after a twelve-months' voyage in tropical seas!

The problems of corrosion and fouling soon demanded the urgent attention of the entire shipping industry, and so serious was the subject that Admiralty experts were at one time quite prepared to condemn the use of iron ships as men-of-war because of their weakness in these respects. In a report dated 1863 the Controller of the Navy gave as one of the reasons why he preferred wooden ships: "The rapidity with which the bottom of an iron ship gets foul, and the immense loss of all the ship's qualities that follows from the adhesion of marine zoophytes. No practical remedy has been found for this serious disadvantage; repeated docking and cleaning is the only palliative."

It is unnecessary to argue at this present period the case of Wood v. Iron for shipbuilding, but it is interesting to note that the Admiralty aimed very high when it considered a composition to have failed which did not keep a ship's bottom clean during the whole time of her commission, say from three to five years! This ideal has never been approached, and if one dared to play the rôle of prophet it might be stated that such immunity never will be realised. Modern metallurgy may succeed in rendering ships free from corrosion, but it is almost inconceivable that a permanent force ready to do battle against the myriads of marine organisms, fighting in their native element, and itself suffering no wastage, should ever be discovered. At the same time modern ships' compositions have played an enormous part in keeping the iron fleets of the world at sea and the units of those fleets in an efficient condition.

The modern accepted practice, which experience has proved to be right, is that the ship must primarily be protected from corrosion. All of the antifouling compositions in general use contain constituents which, in the presence of sea water, induce corrosion, so, in addition to the corrosive action of the sea water on iron itself, one has to protect the ship from the corrosive effect of the antifouling composition.

The ideals to be sought after, then, in making an anticorrosive paint are that:—

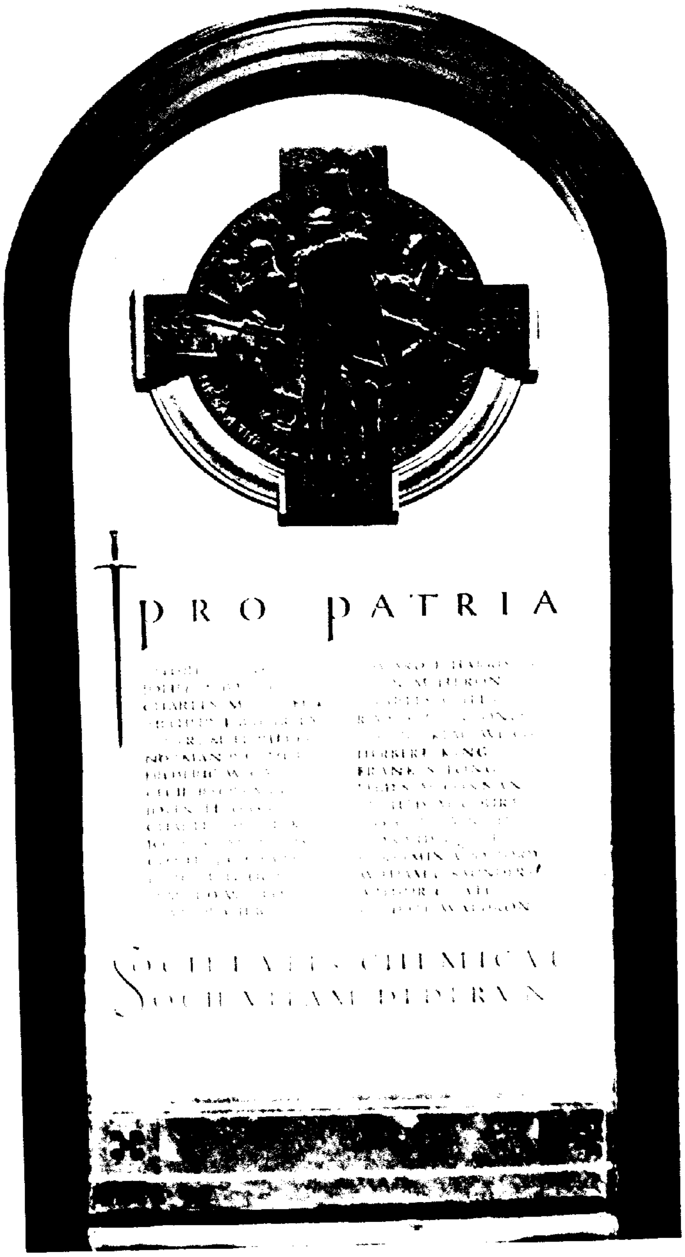
(*a*) It should be waterproof, as only by excluding the water from iron can corrosion be prevented.

(b) It should remain entirely undisturbed on the application of the coat of antifouling composition; failure in this respect is referred to in the dockyards as "lifting" or "breaking through."

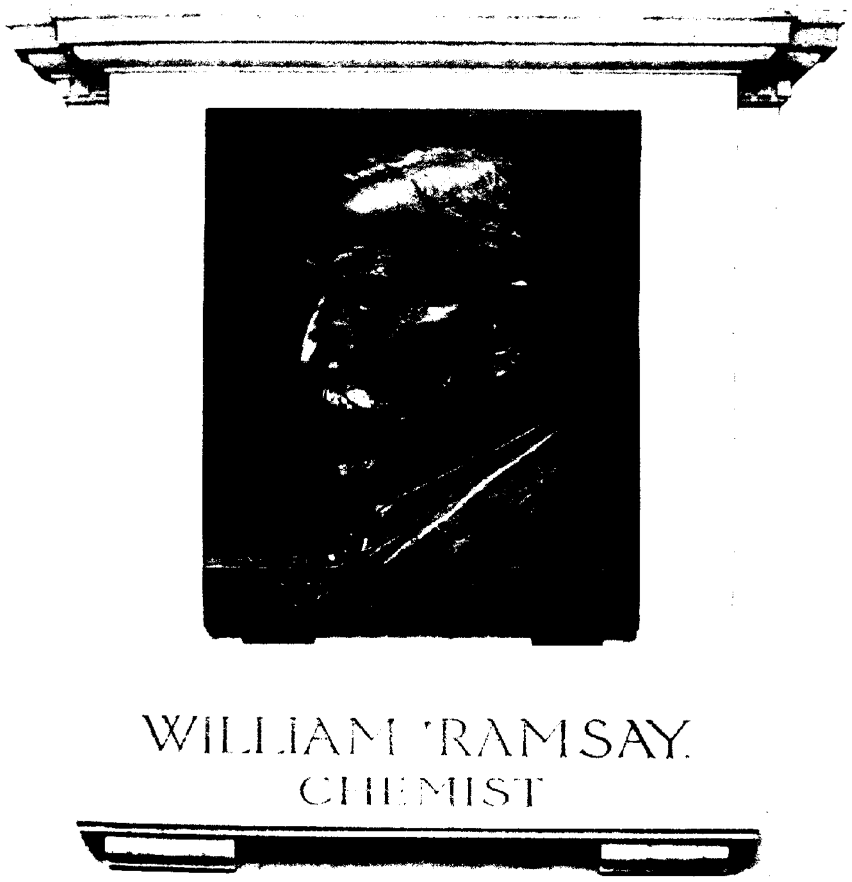
These conditions would be comparatively simple to fulfil if it were not for the fact that modern dry-dock practice demands compositions which dry very rapidly. The most waterproof varnishes are those made from linseed oil and linseed oil containing gums, resins, etc. Oil-varnishes dry by oxidation, and their use is absolutely barred on account of the time taken in drying. "Dry dock" is a courtesy title, as most dry docks are dripping wet, the air laden with moisture and the ship's sides "sweating." Under these circumstances many days would probably be required before a linseed-oil varnish would dry. Ships' compositions must, therefore, dry, not by oxidation, but merely by loss of solvent. Since this remark applies also to the antifouling coat, which also contains solvents, the difficulty of making a priming coat that will dry rapidly and be unaffected by the solvents of the second coat will be readily appreciated. As already stated, the finishing coat is invariably one which induces corrosion, consequently one must condemn unhesitatingly any compositions which show signs of breaking through, and, moreover, view them with grave suspicion if the priming and second coats are of approximately the same colour, thus tending to mask the breaking through.

The difficulty can be overcome by using dissimilar solvents for the two compositions and employing as the base of the priming coat materials that are not brought into solution again by the solvents in the antifouling compositions.

Certain gums, gum mixtures, resins—sometimes in simple solutions, sometimes hardened



Memorial to Lt-Col. E. F. Harrison and other Fellows of the Chemical Society, erected in the Society's rooms, and unveiled by the Rt. Hon. the Earl of Crawford and Balcarres, on November 16, 1922.



Elliott and Fry

Memorial to Sir William Ramsay, unveiled by H.R.H. the Duke of York in Westminster Abbey, on November 2, 1922.

by partial neutralisation with lime—are commonly used as a vehicle, and iron oxide as a pigment, together with, in low-grade anticorrosive paints, some cheap inert filler. This would be thinned down with naphtha or some similar solvent that evaporates rapidly. Shellac solutions are excellent for forming hard waterproof films, but the high price of the material, together with the fact that methylated spirit is used as a solvent, has driven them out of the market.

By far the most satisfactory products, however—those which meet the requirements very well from all points of view—are certain pitches and asphalt solutions. By blending asphalts with pitches a mixture can be obtained which satisfies the conditions required. Moreover, since such solutions dry very rapidly, a small quantity of linseed oil can be incorporated, ending a desirable toughness to the film without unduly hindering the drying. Much patient research was required before the right blend could be found, and the composition, as well as the method of manufacture, is a secret ealously guarded by the manufacturers. The pigment used in these asphalt primings, like the others, is iron oxide, and the solvent is tar oil. The colour is naturally very dark, and would show very readily through the coat of antifouling composition should any lifting occur.

Having now protected the vessel against corrosion, the equally important question of preventing the accumulation of marine life comes up for consideration. The reduction in knots of a high speed ship, even when only slightly foul, is very great, and to counteract it entails an enormous extra expense in coal.

A glance at the photograph (Fig. 1) makes this easily realisable. This shows a sheet of iron which, after being coated over all with an anticorrosive paint, was then coated on different sections with six experimental patches of antifouling compositions. The top left-hand strip was given only the priming and no antifouling coat. The plate was immersed in Genoa harbour for two or three months, and shows the capability of compositions to resist fouling. The second patch has entirely failed, being as foul as the strip at the top left half, which has no antifouling composition at all. Had a ship been coated with this composition its speed would have decreased very rapidly.

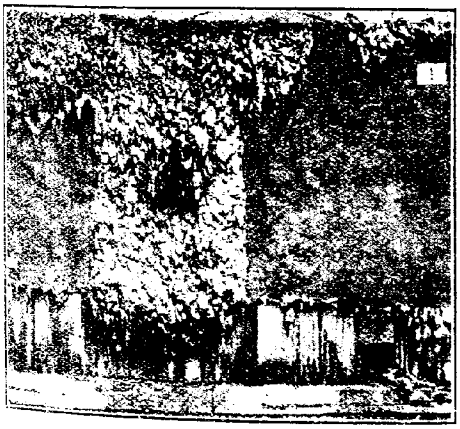


Fig. 1

The object of the antifouling composition is to surround the ship with a solution which is toxic to both animal and vegetable marine organisms, so that these are destroyed whilst still of microscopic size. There was at one time a theory that ships might be kept free from fouling matter by the gradual disintegration of the composition, so that the organism could only obtain a very insecure foothold, which would be even less secure the larger it became. This " exfoliation " theory had at one time many adherents, but the fact remains that, so far as the writer is aware, no successful antifouling composition has been prepared which is free from poisonous substances.

Bearing in mind the remarks already made with regard to quick drying and " non-lifting " of the priming coat, the problem resolves itself into one of designing a composition containing toxic materials which will dissolve slowly in sea water, and thus maintain a strongly antiseptic film surrounding the ship. Obviously, then, the choice of a suitable vehicle or varnish is of outstanding importance. If it is too impervious to moisture the sea water cannot dissolve the poisonous substances, which then for all practical purposes might as well be absent; if, on the other hand, the varnish does not hinder the solvent action of the sea water, the composition loses its toxicity too rapidly, and although the composition may be good in other respects, as an antifouling medium it has ceased to function. One can consider the varnish of a composition when painted out to be in the nature of a honeycomb, the tiny hollows of which are filled with pigments and poisons. If the poisons are of such a character that they are only very slightly soluble, then a large-mesh honeycomb is desirable so as to allow free access of the sea water; if the poisons are readily soluble, then the honeycomb should be made as small as possible. With this purely pictorial idea in the mind it is easy to see that the temperature, *i.e.*, the latitude in which a ship is steaming, plays an enormous part. A composition which might prove highly successful in the North Atlantic would be almost worthless in tropical waters. Since the majority of steamers trade in all quarters of the globe, the paint manufacturer must perforce content himself with attempting to meet average conditions.

Ordinary antifouling compositions nearly always have iron oxide for a pigment, which in the better class is always of a high quality, imparting to the paint the brilliant red so beloved by dock officials, to whom, of course, the artistic effect should be a matter of supreme indifference, since the primary function of the composition is to prevent fouling.

The question of settling of the paint presented some difficulty to the earlier manufacturers, but has been largely overcome by the use of better ground pigments made possible by the superior machinery which the modern manufacturer has at his disposal.

Almost every conceivable type of gum and resin is used by different makers in their efforts to arrive at an ideal varnish. Amongst others may be mentioned resin, copal, dammar gum, Borneo gum, and artificial resins of the type of coumarone resin; but this short list might be considerably extended.

Of the bodies used to render the compositions toxic, salts or compounds of copper and mercury are of first importance; arsenic compounds come next.

The copper in red compositions is usually in the form of cuprous oxide, which, by being carefully precipitated, can be obtained as a permanent, brilliant dark-red powder; this, when used in conjunction with iron oxide, imparts to the composition an attractive appearance. It is the gradual solution of this material which is responsible for keeping the vessel surrounded with a skin of antiseptic sea water, and is inhibitive to the growth of marine organisms, more particularly those belonging to the vegetable kingdom. Cuprous oxide is also made electrolytically, but experience has shown that this is somewhat inferior in antifouling properties to that prepared by the precipitation method, and at the same time more likely to induce corrosion, probably owing to the small quantity of metallic copper which it invariably contains. Where a red composition is undesirable, *e.g.*, for submarines, other salts of copper are used; but, of course, only those which have a low degree of solubility, such as emerald green, $Cu(C_2H_3O_2)_2.3Cu(AsO_2)_2$, copper carbonate, copper thiocyanate and, rarely copper cyanide. These are usually employed with zinc oxide, as a base or pigment, which itself is mildly antifouling. Yellow hydrated cuprous oxide is also used to a small extent. Copper has been introduced in many other forms in organic combination, of which copper resinate, oleate, stearate may be quoted as typical examples. In practice the free acidity is neutralised, entirely or partly, with some suitable copper compound and the resultant product incorporated in the vehicle of the antifouling composition.

Mercury is usually added to the composition in the form of oxide or sulphide. Sometimes also mercurous chloride is used, but superior results have been consistently obtained from the use of organic compounds. By this means a given quantity of mercury can be spread over a larger area, owing to the small percentage of mercury in the organic compound. For instance, mercuric dinaphthyl, with a molecular weight of 454, will enable, other things being equal, a given weight of mercury to be spread over a far larger area than if the same weight of mercury were in the form of, say, the oxide. The high cost of mercury prevents its being used lavishly on a commercial scale; and this makes the preparation of organic compounds advisable. It is an unfortunate fact that no cheap and efficient substitute for mercury has been found. From the shipowner's point of view, however, in the long run it is still more costly to use compositions which do not contain mercury.

Unfortunately, arsenic, although used by some manufacturers, appears to be of very little use unless in combination with copper, as in emerald green. One would anticipate from a knowledge of the properties of arsenic oxide and arsenious oxide that either one or the other, or a judicious mixture of both, would be a suitable poison for antifouling compositions; but anyone who has experimented with these materials would soon part with any preconceived optimism. In the writer's opinion, they are practically useless.

In this short article it is neither desirable nor possible to deal with the great variety of materials which has been pressed into the service. Nor can the problem of keeping ships' bottoms free from corrosion and fouling be considered settled; at the same time, however, good-quality compositions have achieved much, and shipowners can feel that under normal trading their vessels' bottoms will be kept in a reasonably good condition for periods of from nine to twelve months.

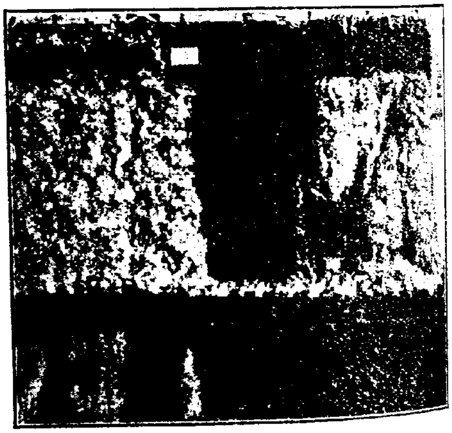

Fig. 2.

The annexed photographs show more experimental plates and demonstrate how cautious one must be in predicting the effect of materials when in the form of compositions. All these experiments were designed as improvements on a well-known standard brand, which was painted right across the top in Fig. 2 and the top right-hand strip in Fig. 3. Actual trial, which is the only reliable test, has shown the modifications to be wrong. Only by this process of elimination can the best results be achieved. As in actual practice most vessels are in dry dock on the average at least once in twelve months for purposes other than painting, the manufacturer of modern compositions can claim to have kept pace with the naval architect, for whilst in dry dock it would be folly to float a vessel again without seizing the opportunity to give her fresh coats of composition.

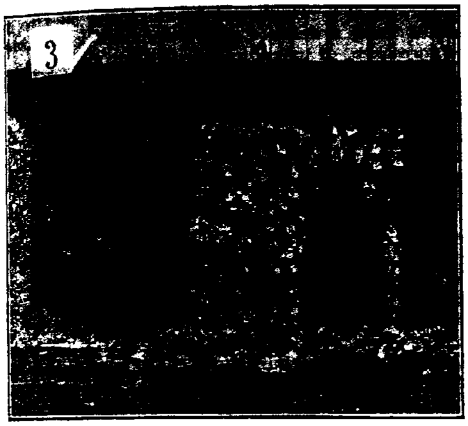

Fig. 3.

EMIL FISCHER'S RECOLLECTIONS

SIR WILLIAM J. POPE

At the time of his death, on July 14, 1919, in his 67th year, Emil Fischer was the most universally respected figure in chemical science. He exercised a great personal influence over his students, he had written his name large on many chapters in pure and applied chemistry, and he was recognised by all as an honest, straightforward man who had done much to enhance the status of his science.

Whilst excellent biographical notices of Fischer's life and work have been published, such as those by M. O. Forster (Trans. Chem. Soc., 1920, 117, 1157) and Kurt Hoesch (Berichte, Sonderheft, 1921), the knowledge that an autobiography was in existence still aroused keen interest. This autobiography has been published recently as "Aus meinem Leben,*" and a few copies have reached this country. Recognising the intense scientific and academic interest of the period covered by Fischer's active life, most chemists had anticipated that this work would appeal to them in the same way that Hofmann's "Zur Erinnerung an vorangegangene Freunde" appealed to a former generation of chemists; in this expectation they will be disappointed. Fischer's personal narrative is so entirely unworthy of the position which he occupied in science that its publication will bring a sad disillusionment to many.

Most chemists have probably pictured Fischer to themselves as a man of uncommon intellectual gifts—which he certainly was—and of the wide general interests which we ordinarily associate with the possession of such gifts. One would have anticipated that so undisputed a leader in chemistry as Emil Fischer would have been keenly interested not only in all scientific subjects but also in the humanities and in the great world-movements of which he was a witness. "Aus meinem Leben" shows clearly that, apart from his interest as a specialist in organic chemistry, Fischer was oblivious to everything save the most casual happenings connected with those with whom he came into daily contact.

This little volume of 200 pages was written whilst its author was in convalescence at Carlsbad and Locarno. It opens with the enumeration of countless relatives concerning the majority of whom only trivial details are recorded; it is difficult to believe that any person with a well-stored mind could pass two periods of repose away from home at the age of 66 extracting this vast amount of casual knowledge from the recesses of his mind and rigidly suppressing all his greater experiences. Fischer refers frequently to his indulgences in beer-drinking and tobacco-smoking, and suggests in a veiled kind of way that immoderation in these pursuits may possibly have been responsible for his later bodily infirmities. One joyous evening convinced him, he tells us, that nothing in the world compares with beer as a solvent for official and social distinctions and for establishing equality among human beings. Amongst his other simple pleasures he mentions music, but says nothing to indicate that he regarded this art as other than a distraction of the same order as his card-playing. Fischer was at the impressionable age of eighteen when the Franco-Prussian war of 1870 broke out. He mentions the war and records a few minor details concerning the way it affected his relatives. He refers several times to the war of 1914-18 as this "accursed war," but, apart from this and the loss of two of his sons, he expresses no views on a subject so remote from organic chemistry; he does indeed hope that a young relative, married in Australia, has been spared the intolerance extended towards his countrymen in the English colonies.

For Fischer politics apparently did not exist. True, he often experienced difficulty in securing financial aid for chemistry from governments, but he treats untoward occurrences of this kind with amused resignation and uses political party names merely as a nomenclature. He was in the lap of the gods and unaccustomed to question their decrees.

---

* "Aus meinem Leben," von Emil Fischer. Emil Fischer Gesammelte Werke, herausgegeben von M. Bergmann. Pp. 201. Berlin: Julius Springer, 1922. Price (at date of issue), 38 marks.

In 1885 Fischer visited Corsica. Passing through Paris, he dropped his gold watch on the boulevard, but returned after a few steps and picked it up. At Marseilles he demanded a few thousand francs on a letter of credit and had to wait because the bank was short. He informs us that the " vendetta " was still practised in Corsica and that a charming account of this barbarous custom is given in an excellent novel by Prosper Mérimée, entitled " Colomba.' He omits to tell us, in connexion with his earlier visit to Denmark, that Shakespeare wrote " Hamlet."

Hundreds of great names flit through the pages of these recollections. With each one is associated some petty and often sordid detail. We are told that Graebe's horse-laugh attracted the attention of all the guests in the dining-room of the Grand Hotel in Territet and that Pechmann lost most of his fortune at Monte Carlo, but the master says no word in praise or appreciation of the services rendered by these two celebrated chemists in the development of their science.

It seems to be possible in Germany for an individual of great intellectual endowments to achieve eminence in some narrowly confined branch of science and still to remain ignorant of all those weighty matters which lie outside the limited domain in which he is supreme ; this is perhaps responsible for much that has happened during late years. One of my friends recently visited a German scientific man of high standing and was informed by him that England must be in a desperate state ; that we have so many unemployed living at the Government charge, that the State has boarded out great numbers of them in Austria because they can be maintained there at a less cost than in England. The statement must be true, because it has appeared in all the German newspapers ! A similar detachment from human concerns led Fischer to sign the notorious manifesto of the 93 in September, 1914, justifying the violation of Belgian neutrality ; a few years later he expressed regret at this ill-considered action.

The unfortunate impression made by Fischer's recollections was evidently foreseen in Germany, and the earlier part of Kurt Hoesch's life, published by the German Chemical Society, consists in a journalistic paraphrase of the recollections in which the trivialities are submerged under a flood of Teutonic sentimentality. Hoesch is astonished to find so little mention of the war of 1870, and explains it somewhat naïvely by saying that Fischer's character was an international one, and that he was a good European or, indeed, a super-European. " Aus meinem Leben " affords no support for this ingenious proposition.

NOTES ON THE DETERMINATION OF "MIXED ACID"

W. H. PATTERSON

Various methods have been employed for the analysis of " mixed acid," *i.e.*, mixtures of nitric and sulphuric acids, such as are used in nitration, or the spent acid left after nitration. The present notes are based on experience in comparing known methods of analysis or modifications of them.

Total acid is easily determined by titration with standard caustic soda. The alkali is added from a burette to a weighed amount of the acid to be tested until a definite pink coloration is obtained in presence of phenolpthalein (the alkali being standardised under similar conditions). In another method the acid is added to a definite volume of the alkali in presence of methyl orange until a red colour is obtained, and the excess acid is titrated with caustic soda until the colour becomes pale yellow and finally turns pink after adding phenolphthalein.

Nitrous Acid.—For the separate determination of nitrous acid the well-known permanganate method is best, and it is satisfactory for fresh acid. With spent acids, in which the nitrous-acid content is high and organic matter is always present, titration with permanganate needs careful control. The method may be employed in analysing waste acid from TNT manufacture, containing matter not readily oxidised by permanganate. The influence of organic matter is shown by its effect on the end-point when the titration is performed at different temperatures up to 100° C. The method, however, is inapplicable to waste acids from the manufacture of picric acid, as oxalic acid is invariably present. Therefore some other method of estimating nitrous acid in presence of organic matter must be used, or other methods must be adopted which distinguish between the total nitrogen and the nitrogen in nitric acid. A useful method of estimating nitrous acid alone is to add the sample to be tested to a strong solution of potassium citrate, free from carbonate, in a Lunge nitrometer. The sample is washed in with more citrate solution, and a concentrated solution of potassium ferrocyanide added; the amount of nitric oxide evolved corresponds with the nitrous-acid content of the sample. This method tends to give low results.

The analysis of mixed acid also involves the determination of the total nitrogen acids, and the nitric or the sulphuric acid. Methods which are generally applicable, and which may also be used for nitrates or nitrites in most cases, can be tabulated as follows : —

Total Nitrogen Acids.—(1) Nitrometer method. (2) Reduction to nitric oxide by ferrous chloride in acid solution. (3) Reduction to ammonia by the Arndt method, the use of Devarda alloy, electrolytic reduction, etc. *Nitric acid:* (4) Direct titration with ferrous sulphate. (5) Nitron method [after elimination of nitrous acid]. *Sulphuric acid:* (6) By evaporating off the nitrogen-containing acids and titrating the sulphuric acid directly. *Nitric acid and sulphuric acid:* (7) By double titration with barium hydroxide and sodium carbonate.

Methods (3) and (5) are not discussed in this paper; most of the other methods have been so long in use that it is difficult to quote references to the original literature.

Determination of Total Nitrogen-Acids

(1) *The Nitrometer Method.*—The use of a calibrated nitrometer is usually held to give correct results, but large errors may occur if the apparatus is not manipulated correctly, and especially if a large number of tests has to be made. Emphasis is laid on this point because the author has experience of two large works where serious discrepancies were found in the results of routine estimations. Two nitrometers which nearly always showed large differences were examined and the divergence was found to be due to a difference in the tap-connexion which had led to different ways of using the nitrometers. An experiment which accentuates the error can be carried out as follows:—The nitric-oxide gas is expelled through the cup after an estimation has been made, and some of the acid lying on the mercury is allowed to enter the cup, thereby becoming exposed to the air. If this acid is drawn back into the nitrometer, or the walls of the cup are washed with pure sulphuric acid, and this is again shaken with the mercury, without adding any more nitrate, a further quantity of nitric oxide will be evolved which may amount to one-half the volume originally obtained. This production of gas can be repeated indefinitely and appears to be due to oxidation of the gas in contact with air to peroxide, which dissolves in the acid on the walls of the cup. A similar phenomenon may occur to some extent in the bore of the tap. Nitrometers should, therefore, always be constructed with a side-tube and cup connected by a two-way stopcock with two parallel diagonal bores (Greiner-Friedrichs cock). The gas can then always be expelled through the side tube, never through the cup, and each bore of the tap is used for one purpose only. About 5 c.c. of 90 per cent. sulphuric acid should be used with the sample in the nitrometer. Acid of greater strength must, according to Lunge, be avoided, and weaker acid gives a low result. A sample treated with sulphuric acid diluted to 50 per cent. gave as result 26·1 per cent. nitric acid, but when treated with the same amount of acid of 90 per cent. strength, 26·3 per cent. Also, with the more dilute acid, the action is slow at first and the mercury blackens and loses mobility.

(2) *Reduction to Nitric Oxide.*—The method of reducing to nitric oxide by ferrous chloride in acid solution, known as the Schlösing-Grandeau or Tiemann-Schulze method, has been modified by De Koninck and others (*cf.* Lunge-Berl., "Chemisch-technische Untersuchungsmethoden," 7te Auf. I., p. 783 *et seq.*). To compare this with other methods the following modification was used:—The ferrous chloride solution and the hydrochloric acid were boiled in a flask until free from air, and the flask was connected through a mercury seal with the gas-measuring tube, the drop of the delivery tube to the mercury being greater than the barometric height. The sample of acid to be tested was added to the flask by a tap-funnel. The volume of gas evolved may either be reduced to N.T.P. and calculated as nitric acid, or it may be compared with a standard volume of nitric oxide obtained from a known amount of pure nitrate or nitric acid. The two methods give slightly different results. Using spent acid and the nitrometer method, the results agreed within 0·05 per cent.; with fresh acid a result within 0·12 per cent. could be obtained by careful measurement and correction of volume, but when an old standard volume is used the result may be too high by 0·2 per cent. or more. The liability to error is greatest in making a first estimation with a fresh charge of ferrous salt. It has been proposed to extend the method to the determination of nitrous acid (*cf.*, Meisenheimer and Heim, Ber., **38**, 1905, p. 3834) by reduction to nitric oxide with potassium iodide; Raschig, Ber., **38**, 1905, p. 3911), separate determination by titrating the free iodine in an atmosphere of carbon dioxide; (Strecker, Ber., **51**, 1918, p. 997) estimating the nitrite in neutral solution as nitrogen, after decomposition with a very large excess of ammonium chloride. No attempt has been made to compare these methods with others mentioned.

Determination of Nitric Acid

(4) *Direct Titration with Ferrous Sulphate.*—It has often been doubted whether even approximate results can be obtained by this method, which dates at least from 1847. Bowman and Scott (Chemical News, **114**, 1916, p. 39) showed that if properly carried out, it could safely be used for estimating nitric acid alone in presence of other acids (with some exceptions) or of nitrites. Since then a modification of the method has been shown to be capable of giving results agreeing within 0·1 per cent, with those obtained for nitric acid determined by the nitrometer, or for pure nitric acid estimated by direct titration.

The ferrous sulphate solution, made by dissolving the pure crystals in 30 per cent. sulphuric acid, is added directly from a burette, and the end-point is marked by the formation of the brown colour due to interaction between ferrous sulphate and nitric oxide. The conditions necessary to obtain results accurate within 0·1 per cent. are as follows:—(*a*) An excess of sulphuric acid must be used; hence the sample to be titrated, about 0·5 g., is mixed with about 100 c.c. of concentrated sulphuric acid. (*b*) The flask is kept at a temperature of under 30° C. in water and agitated during titration. (*c*) The factor of the ferrous sulphate solution is determined just before use by standardisation against a known amount of pure nitrate or nitric acid. This procedure eliminates most of the error due to change in volume of the ferrous sulphate solution (which has a large temperature-coefficient), error by different observers in judging the end-point, and also the error due to the small amount of solution necessary to give the end-point colour, *i.e.*, to effect reduction to nitric oxide. A sharper end-point might be obtained if most of the colour due to formation of ferric salts were eliminated by titrating with stannous sulphate, containing some ferrous sulphate, in a neutral atmosphere.

Determination of Sulphuric Acid

(6) *By Titration after Evaporation of the Nitrogen Acids.*—This method, which is used on the ground of convenience, was carried out for purposes of comparison as follows:—About 1 g. of the sample was run into a porcelain evaporating-basin (diam. 7 cm.). After evaporating for at least 30 minutes on a water-bath, 1 c.c. of water was added, the liquid stirred with a small glass rod kept in the basin, and then heated for 15 minutes more. The sulphuric acid was then titrated, using methyl orange as indicator. Experiments showed that this

method could give almost correct results, but it was not always reliable, the sulphuric acid content being in some cases more than 0·5 per cent. too high.

DETERMINATION OF NITRIC AND SULPHURIC ACIDS

(7) *By Double Titration.*—This titration described by Langbein (Z. angew. Chem., 13, 1920, p. 1227) may be slightly modified as follows:—Total acid is determined by titrating the hot or boiling solution with barium hydroxide, using phenolphthalein as indicator. A known amount of standard sodium carbonate is then added in excess, the precipitated barium sulphate and carbonate are filtered off, and the excess of sodium carbonate titrated with standard hydrochloric acid, using methyl orange to show the final end-point. This method gives low results for nitric acid, but it is speedy, and there is no error due to the precipitate passing through the filter paper. It is accurate enough for corrections in bomb calorimetry, for which purpose it was used by Langbein, or even for the determination of the sulphur content of a fuel, since under the conditions of combustion or explosion in compressed oxygen, sulphur is oxidised completely to sulphuric acid, and is found, together with nitric acid, in the liquid in the bomb.

ELECTROCHEMICAL DEVELOPMENTS IN ITALY

Industrial conditions in Italy are very different from those to which we are accustomed in Great Britain. The main problem which confronts the Italian technologist is the high price of fuel, due to the fact that home supplies are negligible; on the other hand he has abundant water power. These circumstances tend to promote chemical development along electrochemical lines, and as one consequence much attention has been devoted since the war to the production of electrolytic alkali. The development of this industry was hampered at first by the usual difficulty of finding an outlet for the chlorine, which is produced simultaneously, but this problem appears to have been solved successfully and on somewhat original lines, with the result that an interesting group of industries has been established. Some of these developments are described briefly in the following notes.

The imports of caustic soda into Italy are considerable, but have dropped from 19,844 metric tons in 1916 to 13,921 t. in 1921. The total internal consumption is about 22,000 t. per annum, of which only 5,943 t. was produced in the country in 1913. To-day the potential internal production, if all the works were working at full capacity, would approximately cover the demand.

At the Pomilio Electrochemical Works (L'Elettrochimica Pomilio) near Naples, caustic soda is produced in Pomilio-Giordani electrolytic cells in which the yield per unit of current is about 93—95 per cent. of the theoretical. There are three batteries of 100 cells each, and each cell takes 3000 ampères. The output per 24 hours is 10 tons of 100 per cent. NaOH, obtained as a solution of 120 to 140 g. per litre, which is worked up in the evaporators and fusion pots to soda lye of the commercial strengths 38—40° Bé. and 48—50° Bé. and to fused caustic of 72—74° English degrees. Under Italian conditions it is, of course, necessary to reduce to a minimum the fuel charges for evaporation; by using electrically-driven heat-pump evaporators and so utilising the thermal energy of the fuel to the utmost the company has succeeded in reducing the coal required to evaporate each cubic metre of water in the production of 48 Bé. caustic lye to 16 kg., as compared with 48 kg. with multiple-effect vacuum pans, 210 kg. by heating with indirect steam, and 260 kg. by direct firing. Naturally this extreme economy of coal is only effected by the auxiliary use of electric current to the amount of approximately 230 kw. per cb.m. The caustic fusion pots are also of special type, coupled in parallel or in series, with tangential heating and recovery of the heat of the chimney gases which are said to reduce the fuel charges to 75 per cent. of those incurred by using pots of less recent type. The chlorine is used for the manufacture of bleaching powder, synthetic hydrochloric acid (for which purpose the hydrogen from the batteries is also utilised), sodium hypochlorite and zinc chloride; in future it is to be used for the production of potassium and aluminium chlorides, alumina and silica from the leucite of the volcanic rocks in the neighbourhood. The chlorine is also utilised in producing pure cellulose from hemp fibre and other raw materials. Three thousand tons of bleaching powder is produced yearly in leaden chambers; the hydrochloric acid plant has a capacity of 2000 t. per annum, and 160 t. per month has been actually obtained. The annual production of sodium hypochlorite is 2000 t., which is absorbed by local textile and other industries; and the output of 50 tons per month of zinc chloride is supplied to the State railways for the impregnation of sleepers.

The Pomilio company is now producing pure cellulose by the Cataldi process in a recently erected works, the output being 7 to 8 tons per day. In this manner an outlet has been found for the surplus chlorine, and the development is expected to have a very good future. The main raw material is hemp fibre, which is the dry residue from the beaten and macerated hemp plant. The annual production of this material in the Province of Naples is 25,000 tons. Hitherto this product has been used only on a small scale for fuel. The method of treatment is essentially Cross and Bevan's analytical method of estimating cellulose, adapted for industrial purposes, and consists in treating the fibre successively with dilute caustic alkali solution, moist chlorine, and again with dilute caustic alkali. The main precaution necessary on the manufacturing scale is careful regulation of the access of chlorine, as otherwise excessive heating takes place and the fibre is destroyed, or even charred. Large quantities of hydrochloric acid are evolved. Other raw materials are used instead of hemp, namely poplar wood, esparto and straw. The quantities required for the production of 100 kg. of poplar cellulose are: moist chlorine gas, about 28 kg.; coal about 15 kg.; bleaching powder (for subsequent bleaching) about 6 kg.; and sodium hydroxide, in dilute solution, 5 kg. To produce 10 tons of cellulose per day by this method only 50 workpeople are required and about 80 kw. of electric power. The amount of water required is not greater than in other processes. A plant of the above-mentioned output requires about 1500 sq. metres of covered floor-space. The above figures represent a maximum of chlorine and minimum of caustic soda, the object being to balance the ultimate demand for these two materials, but the quantity of chlorine can be considerably reduced if the consumption of alkali is increased. The alkali is used in a very dilute condition.

A further possible outlet for the surplus chlorine on a very considerable scale has been found in the production of synthetic hydrochloric acid and its use for decomposing the volcanic rocks which abound in Italy, and which represent the richest and largest source of potassium compounds known. It is calculated that the leucitic rocks of the active and extinct Italian volcanoes, of which six are included in the computation, contain in round figures nearly 8800 million tons of potassium oxide, or rather more than is present in the Stassfurt deposits, and about 25 times as much as in Alsace. It appears to be comparatively easy to separate from these rocks, by ordinary magnetic and other mineral separation methods, leucite, $K_2O.Al_2O_3.4SiO_2$, of a purity of about 90 per cent., and containing therefore about 19·5 per cent. of potassium oxide. It has been found that finely-divided leucite is readily attacked in the cold by hydrochloric acid, forming a solution of potassium and aluminium chlorides on the one hand and a residue of silica, which can be washed, sieved, and sold at a low figure, on the other. The solution of the mixed chlorides also contains small amounts of iron salts and silica in solution. Processes have been patented by Giordani, Pomilio, Blanc and Jourdan, and are being worked out on a semi-industrial scale, for the treatment of the acid solution of the mixed chlorides by several methods. By the first of these, a large part of the potassium chloride is recovered by cooling; the solution is then neutralised and the remaining silica thus precipitated is filtered off. The solution is freed from iron electrolytically, and electrolysis is also employed to precipitate the alumina, the production of aluminates being avoided by the use of a neutral catholyte. The chlorine and hydrogen produced during electrolysis are recovered and re-utilised. Alternatively, the solution of the mixed chlorides is successively subjected to such temperatures and pressures as to dissociate or otherwise separate each ingredient in turn. The solution of the chlorides is heated to 300°—600° C., and the chlorides of iron and aluminium, and even those of calcium and magnesium, are successively decomposed with recovery of hydrochloric acid. The aluminium chloride can also be separated by utilising its diminished solubility in presence of excess of hydrochloric acid in the cold.

By the methods indicated, products of the following degrees of purity have been obtained:—Potassium chloride crystals, KCl 99·7%, water 0·25%: free from silica, iron oxide or alumina; aluminium chloride crystals, Al_2O_3 17·5—19·7%, K_2O 0·91%, Fe_2O_3 trace: free from silica and lime; alumina, Al_2O_3 99·8%; SiO_2 0·19%: free from iron oxide and lime. It is important to note, bearing Italian conditions in mind, that by certain of these processes the leucitic rocks can be treated successfully without the use of any fuel whatsoever. As instancing the enormous amount of raw material available for this outlet for electrolytic hydrochloric acid, it may be noted that during the last eruption of Vesuvius in 1906 about 200 million tons of volcanic ash was ejected.

NEWS FROM THE SECTIONS

AMERICA

At a meeting of the American Section, held on October 20 in the Rumford Hall of the Chemists' Club, New York, the Grasselli Medal was presented by the chairman, Dr. Harlan S. Miner, to Mr. W. H. Fulweiler, of Philadelphia. In making the presentation Mr. Miner spoke as follows:—

The American Section of the Society of Chemical Industry is highly favoured in being able to give some tangible recognition to the meritorious papers presented at its meetings. The Grasselli Medal and the conditions controlling its award are distinctly American in character. The fact that it is awarded for the paper which, in the opinion of the Medal Committee, offers the most useful suggestions in applied chemistry, makes it peculiarly appropriate to an industrial society. This is only one of many ways in which the donors are advancing the profession of chemistry in the United States. The Committee of Awards has this year unanimously chosen as the recipient of this honour Walter Herbert Fulweiler, of Philadelphia, in recognition of the paper which he presented at the March meeting of the Section, entitled "Chemical Problems in the Gas Industry."

Born in Philadelphia on January 3, 1880, the medallist graduated from the University of Pennsylvania in 1901, with the degree of B.S. in chemistry. Having decided to devote his attention to the gas industry, he first accepted a position as chemist in one of the stations of the Philadelphia Gas Works. We next find him as cadet engineer and later as superintendent of manufacture of the Kansas City Gas Co. Returning to Philadelphia in 1907, he entered the Department of Tests of the United Gas Improvement Co., becoming chief chemist in 1913 and chemical engineer to the company in 1920.

As might be expected, Mr. Fulweiler's work in connexion with the gas industry has been of a very practical nature, and has had a decided economic application, although he has by no means ignored the purely scientific side of his subject. With an intimate personal knowledge of the industry, both from an American and a European point of view, he constructed one of the first waste-heat boilers on a water-gas set. Then he assisted in the design and erection of the first American type of vertical retort at Manchester, N.H.

The utilisation of some of the ill-smelling by-products of the gas industry is worthy of note in this connexion. Our medallist developed and introduced the successful road-binder known as "Ugite"; also the first cold patching-material made from tar which is now extensively used in road maintenance. He invented the "cut-back" method of manufacturing tar products used in the surface treatment of roads, and also devised an apparatus for determining the binding value of pure bitumens in road construction.

The refining of benzol products recovered from illuminating gas was thoroughly investigated, particularly with reference to the production of toluene. Like other loyal chemists connected with our "key" industries, he collaborated with the Ordnance Department during the war, studying particularly the manufacture of toluene. In addition to reporting on several methods for producing this material, so urgently needed at that time, he developed and perfected a process for its manufacture by a heat treatment of Californian distillates, and assisted in the construction and operation of two plants to work this process, one at Los Angeles and the other at San Francisco, the former having a production of 3 million galls. a year at the time of the armistice.

Another subject upon which Mr. Fulweiler worked during the war period was the development of a motor fuel for our air service, finally producing one, as a by-product from the operation of the toluene process, which, under tests at the flying fields, enabled the training plane to climb about 5 per cent. faster and with an economy in fuel consumption of about 8 per cent. This fuel consisted essentially of 60 per cent. unsaturated hydrocarbons, 30 per cent. benzol, and 10 per cent. paraffin hydrocarbons. Refined by a special process, it was found possible to eliminate gumming and corrosion.

In more recent years our medallist has made a very extensive study of the petroleum oils used in the gas industry, with special attention to the development of methods for their identification. These researches, which are still in progress, involve the preparation of a large number of hydrocarbons from different series and the determination of their physical constants, among which are several unusual ones, such as magnetic rotation, electrostatic double refraction, and absorption spectra, particularly in the ultra-violet.

An examination of the many published articles from Mr. Fulweiler's pen indicates still further the great diversity of his researches and developments. A paper on "Physical Theory of Coal Carbonisation," as early as 1908, was awarded the Beale Medal by the American Gas Institute. This was followed by "Theory of Flame and Mantle Illuminosity," "Physical Characteristics of Ferric Oxide," "Purification of Water for Gas-making Purposes," "A Source of Light, giving a Continuous Spectrum in the Ultra-Violet," "The Development of Modern Road Surfaces," "Destructive Action of Motor Traffic on Road Surfaces," and "Refractory Problems in the Gas Industry."

The subjects of wood-preserving and of refractories, both vital to the economic success of a gas plant, have received very careful study, as have also the many intricate problems involved in gas purification. In this field researches have been conducted to determine the nature of the sulphur compounds in illuminating gas, and also the chemical reactions involved in the purification by iron oxide and its subsequent revivification.

These and other papers, in addition to the one for which this medal is awarded, demonstrate conclusively that the industry, which had its inception over a century and a quarter ago in a relatively crude way, now maintains its important position as a result of systematic scientific research and control. Notwithstanding the volumes that have already been written describing the work of the scientists in this and earlier generations, our medallist has found new fields to investigate and has achieved results that have materially advanced the industry in which he has chosen to labour.

We are glad to find a man who will freely impart the information obtained through his researches and experience, and is willing to publish papers which, as our donors suggest, "offer useful suggestions" to his colleagues.

On behalf of the American Section of the Society of Chemical Industry, I am honoured in presenting to you, Mr. Fulweiler, this beautiful medal, no so much as an incentive to spur you on to other and increasing activities, for you do not seem to require such a stimulus, but as a token of appreciation from your many friends in the chemical profession. May you ever see in it an expression of our good-wil and may it bring you much happiness throughout a long and useful life.

Following the presentation, Mr. F. E. Hartman read a paper on "Ozone Generation, and the Industrial Application of Ozone," which contained, *inter alia*, the results of some original work on the action of ozone in accelerating the drying of paints and varnishes, and in bleaching linseed oil. A further paper, by Mr. E. Feikel, on "The Effect of Ozone on Organic Compounds," discussed the general properties of ozonides and the action of ozone on each of the more important groups of organic compounds.

LONDON

The first meeting of the new session was held on November 6 in the Engineers' Club, London. The chairman, Mr. E. V. Evans, presided, and announced that a joint meeting had been arranged with the Biochemical Society on January 8, 1923 to discuss the subject of micro-organisms and thei application to industry.

Further, Mr. Evans stated that the Committe had been fortunate in obtaining the consent of Dr E. F. Armstrong, the President of the Society, t address them on this occasion. He did not propos to introduce Dr. Armstrong or to talk of hi achievements: he was known to all of them, an his merits were everywhere recognised. The Counci of the Society was really to be congratulated o having obtained Dr. Armstrong's consent to b President of the Society at the present moment because he (Mr. Evans) could assure them that th responsibilities being undertaken at the presen time really necessitated a man of Dr. Armstrong' calibre. He (Mr. Evans) was one of those who wer perfectly confident of success in the new venture that they were to undertake with Dr. Armstrong a their leader.

Mr. Evans then called upon Dr. Armstrong t give his address on "Some Problems in Chemica Industry."

Dr. E. F. Armstrong, in the course of his address said:—Some few weeks ago your secretary did m the honour of insisting that I should come her to-night, and I understood I was to address you i Burlington House. I, therefore, prepared a elaborate scientific address suitable for the fou walls of that august establishment, but when heard suddenly, a day or two ago, that the meeting was to be here, the only thing to do was to bur that address and to make remarks more appropriat to the occasion. I am not at all certain whethe one ought not to say that the move is perhaps a wis one.

The subject which concerns all members of th Society of Chemical Industry, members of th chemical fraternity, more than anything else at th moment, is the means of our livelihood. Th Chemical Society has entrusted to it the safeguard ing and advancement of chemical science. We i this Society have rather different functions to fulfi functions which I would like to suggest to you call for other qualities than those of being, I will not say a mere chemist, but merely a chemist. "The Society of Chemical Industry" was the title given to us by our founders, 41 years ago, but to-day I think we ought to call ourselves the Society for the Promotion of Chemistry in Industry. It is very difficult to define chemical industry; those who formed the Association of British Chemical Manufacturers had very much wider ideas as to what was a chemical manufacturer than has proved to be the case. Those engaged in many branches of manufacture, who, it was thought, were chemical manufacturers, have chosen to regard themselves, not as chemical manufacturers, but as manufacturers of a particular article, and, in consequence, have not allied themselves to the chemical industry. I fear that the tendency at the present time is to restrict more and more the term "chemical industry" to the very definitely chemical industries. If we take as our title "the promotion of chemistry in industry," then nearly all industries become chemical industries, because chemistry is at the foundation of all.

The Status of the Chemist

Our Society, more than any other, represents the chemists of the country. Our efforts are supplemented to-day by the Institute of Chemistry, a body which is worthy of all praise. There was, in the past, a tendency to confine the Fellowship of the Institute to the restricted, although eminent, classes of chemists known as consultants and analysts, but that tendency has gone, and to-day the Institute is enrolling within its ranks, either as Fellows or Associates, everybody who is worthy of being called a chemist. In addition to the Institute we have the British Association of Chemists, of which I have a very high opinion. I regard it as the left wing of the party, and a party without a left wing is almost no party at all; we must have stimulus from within. I think both the Institute and the British Association of Chemists, and certainly ourselves—the non-political mother society—have all the same mission. We want to see the status of the chemist placed on a high plane, and I shall regard it as my duty, whenever you give me the opportunity to speak publicly, to state the fact as clearly as I can for the benefit of the outside world, that we chemists do claim to be a body of very highly trained, highly skilled professional men. Our training has been that of method, scientific method. We are gifted with certain knowledge which enables us, so to speak, to take things to pieces, and with an ability to predict events, because of our knowledge of chemical properties. Still more, some of us are in the position of exercising constructive thought, and I want to put very definitely that the nation has in its chemists a body of men in whose hands a great deal of the future of civilisation rests. If we are to take up this honourable position that we claim for ourselves, we must, like the doctors and the lawyers, have a very high standard of professional conduct. Remember, the British public is our judge. We must not despise the British public, because, although slow, it is sure, and its judgment is, in the long run, correct. And here I want to enter a strong protest against the action of certain chemists in misleading the public. I do not think any chemist has any right to set his name, much less its qualifications, to documents which are published in company prospectuses and elsewhere with intent to mislead. Of course, I am making these remarks without reference to any individual. I wish to emphasise the necessity of no chemist setting his name to documents that may mislead the public. The public is essentially gullible, but it has a long memory, and if Mr. X——, F.I.C., F.C.S., deceives the public once, the public will in future regard all F.I.C's. and F.C.S's. as of the same stamp. It is also time publicly to enter a protest, not against the use of the term "chemist"—because that has long since passed beyond our control—but against the qualified chemist in any way doing anything to perpetuate the existence of the unqualified chemist. During the war the mistaken policy of the Government in sending chemists into the trenches caused a shortage at home, and all sorts of unqualified men had to be brought into the factories. They did fine work, and it is to their credit, but during the recent trade slump the employer has parted with these men wholesale, unfortunately, thinking they were representative chemists, and I fear that it will take a considerable time to live down some of the mistakes made at that time.

The Rusting of Iron

Another matter for our consideration is whether chemists, as a class, contribute as much as they might to the general good of the community. Sir Robert Hadfield has calculated that there is an annual loss to the world of 40 million tons of iron and steel as the result of atmospheric corrosion, and that the monetary value of this loss is about £500,000,000 per annum. Sir Robert Hadfield has put some of these facts together in a recent number of the Royal Society's *Transactions*, and he calls attention to the fact that this is the first paper dealing with the subject that has appeared in those *Transactions* for 100 years. Now, think of it; a chemical factor which causes the loss of £500,000,000 per annum dealt with once in a hundred years by our leading scientific society! I am, of course, aware that the Institution of Civil Engineers and similar societies have considered this subject; and that there are many firms who specialise in anti-corrosive preparations; and one is very glad to note that these firms have recently come together and formed an association; but is not this state of things rather a reflection on the chemist? At a certain college in Kensington the students were not taught chemistry in the conventional way, but they had put to them the problem of what happens when iron rusts; many of these students have since become engineers. Teachers of chemistry have not favoured the Kensington method, and if any chemist mentions iron rust in public it probably causes more ridicule than attention.

Smoke Abatement

Our attention has recently been directed to the Smoke Abatement Bill, which, I believe, was fathered by Lord Newton and introduced into the House of Lords. That Bill is, presumably, based on the report of a commission, reports of committees, and investigations undertaken by a great number of active men who have long made a hobby of this particular question. The researches of these people, however, prove that four-fifths of the smoke nuisance in our industrial centres and great towns is due to the domestic fire; but the Bill does not mention the domestic fire; all it does is to select the manufacturer and threaten him with increased penalties. Of course, there are manufacturers to-day, and always will be, who let a great deal more smoke into the air than they would like to, but I am rather doubtful if it is the business of the manufacturer to prevent smoke. If a person sets out to produce a particular substance, he becomes an expert in its manufacture, often to the exclusion of everything else; he spends his capital, and puts his energy and brains into the business. There are certain standard pieces of plant which he has to buy from those who specialise in that plant, and he expects to find it of the highest and most up-to-date quality. One would not, of course, expect the soap-maker to experiment with boilers. Why should he? Nor the biscuit-maker to experiment in smokeless fuels or some new type of powdered fuel. That kind of work ought to be done by the chemical fraternity generally, acting with the engineers and the particular people who specialise in these types of plant. I believe that one of the greatest advances that we, as a Society, have made during the past five years will be found to be our Chemical Engineering Group, because that Group is very earnestly and sincerely trying to bring chemists and engineers together to solve these common problems.

WATER-SOFTENING

There are many satisfactory methods of softening water, and one of the most interesting and novel is that based on the extraordinary power of zeolites, both natural and artificial, to exchange bases. When a hard water containing lime and calcium and magnesium salts is passed over a zeolite, the sodium of the zeolite is exchanged for calcium and magnesium; the artificial zeolite—Permutit—is used extensively for this purpose. A material of this kind is really a very remarkable one, of which, as chemists, it is perhaps well worth our while trying to form a mental picture. In this problem structure—surface activity—plays a very important part. The preparation of Permutit, formerly made as the result of a fusion process, and later by precipitation, involves processes which have an adverse effect on structure. We know little of how natural zeolites (two of which are quarried in the United States and sold under the fancy names of "Boronite" and "Refinite") are formed, but, judging by their activity, it appears certain that their structure must have been adversely affected—from our point of view—in the process of formation. It struck us that it ought to be possible to prepare a much more satisfactory material by milder means. Zeolites are complex alumina silicates of unknown constitution, and we, therefore, took solutions of sodium silicate and sodium aluminate and mixed them in concentrations and under conditions of temperature which were found to be the most suitable. A few minutes after mixing, the whole mass sets to a jelly. When exposed, the jelly gradually dries to a solid material, a dried "gel," which in the apparently dry state contains about 50 per cent. of water. This material is very active in exchanging its sodium for calcium and magnesium, in fact, we guarantee it to exchange 5 per cent. of its dried weight, and we have obtained an exchange of 7—8 per cent. So far as our experience goes, the exchange in the natural materials is only 0·25 per cent., and for Permutit 1·6 per cent.; so that we have produced a substance which is at least four times as active as similar materials, either produced naturally or artificially by rougher methods. This is an example of the inter-relationship of chemical action and preservation of surface. When the material, prepared as indicated above, is placed in a suitable cylinder and water run through, the substance that is left after the soluble by-products of the initial reaction have been washed away is of constant activity and can extract definite amounts of calcium and magnesium from water passing over it at a very high rate of flow. The process can be reversed almost instantaneously by passing through the filter a relatively concentrated solution of common salt, the calcium and magnesium being washed away and replaced by sodium. The material has been named "Doucil," and is believed to be represented by the formula $Al_2O_3.Na_2O.5SiO_2$.

TECHNICAL JARGON AND PROFESSIONAL UNITY

The necessity for clear thinking and clear expression is as great as ever it was. To-day it is practically impossible for anyone to have a really good working knowledge of theoretical chemistry because so much of the literature is replete with jargon and complex technical terms. Plain language is also essential in dealing with workmen; and if we do not use it on public occasions we shall continue to assist the undesirable process of splitting up into small separate organisations. In that connexion I am of opinion that more harm is done to the cause of chemistry by the formation of new societies than good is done to any particular branch. Surely the scope of this Society, or, if you prefer it, that of the Chemical Society, is sufficiently large to satisfy the needs of all. Without a closer union than exists at present, the voice of the profession and industry will never be heard to its full effect.

DISCUSSION

The chairman said that Dr. Armstrong had dealt with a number of subjects which should form an admirable ground for discussion. He himself had taken some interest in the question of smoke abatement, and was of the opinion that Lord Newton's Bill was a little premature. As a chemist retained by a gas company, he naturally knew of a very valuable smokeless fuel. At the same time he knew that distillers of coal were beginning to realise that there would always exist a demand for solid fuel in every house, at least during the present century, and although he was very appreciative of what coal gas could do, yet he realised that solid fuels were also required. There was no reason why, in the future, there should not be—and he believed there would be—an admirable solid fuel which would not be as expensive as coal. At the same time he felt that, although smoke abatement was required, it was useless for a committee to make recommendations which might very largely influence the progress of industry when four-fifths of the trouble arose from the domestic grate.

Mr. W. J. U. Woolcock said that Dr. Armstrong had done very good service to chemistry and chemical industry in making the chemist feel that he could not be a chemist alone; that if he was going to do the real kind of thing which he was capable of doing in the world, he had not only to be a first-class chemist in his own subject, but he had also to take a rather wider view of his responsibilities with regard to the public. It was essential that every member of the Society should be a little point of propaganda in order that the general community might realise what the chemists really meant by calling themselves chemists. Dr. Armstrong did not say, but he might have done, that the Smoke Abatement Bill was dead, just as every other Bill was. It was, he supposed, one of the most stupid Bills having some bearing on chemical industry which had ever been brought to light.

Mr. Walter F. Reid, in referring to the Smoke Abatement Bill, said that chemists had no reason whatever to fear the new Bill, which would be introduced into Parliament as soon as it was possible to do so. The old one had defects that were due to the fact that the officials who drafted the Bill would not put into it what they had been asked to. When an influential deputation went to the authorities who were entrusted with this matter, the best spokesman and the most convincing advocate in favour of the Bill was a distinguished chemical manufacturer. If they asked too much, they would get nothing at all. It was quite impracticable to prohibit the use of coal in the grates already in existence, but it was well known that the closed stoves used on the Continent utilised three or four times the heat that our open fires did and that all the necessary household operations could be performed with them; and the atmosphere was not polluted. When the new Bill was introduced he believed they would find that some of the chief difficulties would have been surmounted. The great difficulty hitherto had been to prove the emission of what was erroneously called "black" smoke. As soon as the material in the smoke became black it was soot, but legally it was smoke, and the case had been stretched and many convictions obtained in respect of a large volume of a dark material. That would be altered, and there would be some tests which might possibly be useful and fair to the public and fair to the manufacturer. Reference had been made to the want of union among chemists and the starting of new societies. They had tried the Group system so as to include other industries in their Society, as in the case of the Chemical Engineering Group, but when the effort was made to have another one in connexion with the important paint and varnish industries, the Council of the Society did not see its way to offer the facilities that had been given to the Engineering Group. The consequence was that an Institute of Paint and Varnish Technologists had been successfully formed, and that body would in future deal with the enormous industry connected with paints, varnishes and oils, to the exclusion of the Society of Chemical Industry. In that connexion, he felt that one or two words of Dr. Armstrong rather hinted that the paint and varnish trade might object to anything that was done to prevent corrosion of metal, but that was not so. One of the chief objects of the Institute was the promotion of means for preventing corrosion and oxidation of metals. The figures given by Sir Robert Hadfield were most convincing, and it really was a disgrace to chemists that they had never been able to find anything that would cover iron or steel in a simple way and prevent the enormous waste of money that was going on. Finally, he would like to make a suggestion with regard to new words in chemistry. If the Publication Committees of the chemical societies were to keep a list of those new words which appeared and were put forward as being necessary, and if they compared that list from time to time, an authoritative statement might be made as to the adoption of each of them.

Dr. Ormandy congratulated the Committee of the London Section on the move it had made in leaving Burlington House. The President's address was an excellent augury for the future of the Society. It pointed to the probability of that closer co-operation between the Council and the members which was so eminently desirable, and which, in the opinion of many, had hitherto been lacking. He was also gratified to hear the President and the chairman speak so highly of the services rendered by the Chemical Engineering Group. The President was hardly fair to the chemists in his strictures regarding their work in relation to the rusting of iron and steel. Much had been done; there was a vast literature; and probably through the work of the metallurgical chemist in the production of non-rusting iron and steel the problem would find solution. Having been connected with the "Permutit" process, he was interested in the President's remarks regarding the more active zeolites, but he was under the impression that the Permutit Company was making the zeolites along the lines outlined that evening. For the production of water practically free from dissolved substances, the lime-soda process, combined with an electrical process, was making great headway on the Continent.

Dr. Stephen Miall said he had not been mixed up with chemistry for many years, but he had noticed a very great difference in the attitude of the public towards lawyers and the attitude of the public towards chemists, and he believed that this was due to the fact, as Dr. Armstrong, Mr. Reid, and others had said, that chemists did not make themselves intelligible to the public, and also to the fact that chemists looked at things too much from their own individual point of view. The result was the tendency to split up into small societies which had also been referred to. Whether it was right or wise that that state of affairs should exist was another matter, but he noticed in the chemical profession a large number of journals each dealing with one particular branch of chemical industry or of pure chemistry, and appealing to a limited audience. That was not so in the law at all. He supposed there were far more lawyers than chemists—and it might be monstrous that there should be—but the law did not have a number of journals each with a circulation of a few hundreds or a few thousands; lawyers had combined together to a much greater extent than chemists. They ought to be grateful to Dr. Armstrong for advising chemists to have a better conceit of themselves and show the public that they deserved not only the prominence that they had now, but the increasing prominence which they were going to have in all matters of civilisation in the future.

Mr. W. Cullen said he had had a great deal to do with lawyers recently, and his experience had not given him a very great admiration of the manner in which they made themselves intelligible to the ordinary public. With the general tone of the President's address and Dr. Miall's speech he was in entire agreement. He himself belonged to the old type of chemist, and he sometimes felt hopelessly discouraged when he tried to keep himself up to date with the terrible technical jargon of to-day. He hoped this aspect of Dr. Armstrong's address would be taken up very seriously.

Dr. E. Fyleman said he was amused at the extraordinary awe which the bulk of the speakers had of the atmosphere of Burlington House. It seemed to him that Burlington House was similar to most other places, but it certainly lacked the facilities for carrying out experiments. It might be right for the lawyers to have one journal and one society, but one was liable to overlook the comprehensiveness of chemistry and chemical industry. Was it seriously suggested that there should be one comprehensive journal to include such topics as the more abstruse sides of biochemistry, metallurgy, the paint and varnish industry, and so on? It would be quite impossible: it would be necessary to have a bi-weekly journal of the size of the present fortnightly one in order to cope seriously with all the many phases of thought and activity with which chemists were concerned. They might widen the scope of their abstracts, but he thought they would agree with him that the man who contented himself with reading abstracts would not get very far. They were lifeless things and did not help one as much as one would like.

After some remarks by Messrs. Barker and Booth Harris, the chairman proposed a vote of thanks to the President and said that the experience gained that evening would induce the Committee of the London Section always to invite the new President to address the opening meeting of the session. He had been present at a number of such meetings and he had not left one happier or more contented regarding the future welfare of the Society than he would do that evening. Dr. Armstrong, acknowledging the vote of thanks, said that we wanted a close time for chemists just as much as we wanted a close time for the country. We should stop awhile and consolidate the ground; that was the doctrine he had been preaching to them.

GLASGOW

The second meeting of the session was held on November 17 in the Institute of Engineers and Shipbuilders. The chairman, Mr. W. E. Moodie, announced that arrangements had been made for members to visit the works of Messrs. J. G. Jackson, Ltd., of Pollokshaws, on December 9, and inspect various types of "filling" machines. Mr. A. B. Steven then read a paper on "Artificial Silk," in which he summarised the history of this important textile. The first suggestion for producing artificial silk was made by Réaumur in 1734, viz., by drawing out varnish into a fine thread; but no progress was made until 1855, when Audemars nitrated cellulose, dissolved it in a mixture of alcohol and ether and drew out fine threads from the solution. The first workable nitrocellulose process was patented by Chardonnet in 1884; the threads, however, were very inflammable and subsequently the material had to be de-nitrated. In 1897 Pauly patented the use of Schweitzer's reagent, and "viscose" silk was introduced by Cross and Bevan in 1891. The most recent development is that of "acetyl" silk, which is made by treating cellulose with acetic anhydride or acetyl chloride in presence of a catalyst. The product, triacetylcellulose, is practically waterproof. Mr. Steven referred to the many attempts that have been made to produce artificial silk with a non-cellulose basis, and explained several tests to distinguish natural from artificial silks.

SOUTH WALES

A meeting of this Section was held in Cardiff on November 3, at which Prof. W. J. Jones presided and Mr. J. H. Duncan gave a paper on "The Physical Testing of Coal." The paper set out the importance of the scientific control of coal to be used for commercial purposes and emphasised the advantages of simple physical tests over the more tedious academic method of ultimate analysis. South Wales coals are so variable in composition and properties that it is most desirable that they should be blended and the mixture sold on a guarantee, which should state not only the analytical constants, such as ash, calorific power, and volatile matter, but should prescribe how such tests are to be performed. Mr. Duncan gave an account of the manner in which a cube of coal "cauliflowers" when placed in front of a muffle. The character of the "cauliflowering," taken in conjunction with the careful examination of the button of coke left after the determination of the volatile matter, affords to the practised eye most valuable indication of the way such coal will behave in a furnace. By such tests more information is afforded as to the rate of combustion and opening-out of a coal than by most elaborate ultimate analysis and chemical tests which are not desirable for commercial purposes.

In the discussion, Dr. S. Roy Illingworth specially pleaded for the more exact methods of chemical examination of coal, advocating that such tests not only afforded much more reliable information of the value and properties of a coal, but also furthered exact knowledge of its composition.

The first meeting in Swansea of this newly-constituted Section was held on November 10 in the Technical College. Capt. H. Vivian, the vice-chairman of the Section, presided, and Mr. A. Grounds read a paper on "Chemistry in Relation to Boiler-plant Efficiency."

Although the subject is one which has often been discussed before, the lecturer succeeded in putting some new points of view before the audience. Mr. Grounds emphasised that efficiency depended on (1) efficient combustion, (2) efficient transmission of the heat, and (3) retention of the heat, and he showed how different types of fuel have influenced the design of boilers. A very useful device for testing boiler-settings for air leakage was described: it consists of a lath frame one yard square covered with glazed linen, and provided with a small hole in the centre, opposite to which a lighted candle is fixed, supported on a cross-lath. When the frame is held flat against tho brickwork any leaks are at once shown up by the movement of the candle-flame. A large area may be rapidly tested by this means.

In the discussion which followed, Capt. Vivian, Messrs. F. J. Bloomer, G. A. Phillips, and E. K. Regan took part. It was emphasised that records (carbon dioxide, draught, etc.) to be of any value must be as continuous as possible, and that it is the works-chemist's duty to interpret the results obtained; the Chemical Engineering Group might well pay attention to this matter. Some American figures quoted by the lecturer were questioned by Messrs. Phillips and Regan, who agreed that such figures (showing high overload tests) are often misleading when compared with British figures, as American boilers are usually much under-rated.

YORKSHIRE

An address on " Oxidation of Oils " was delivered r Dr. L. L. Lloyd, the chairman, at the meeting ld in the Queen's Hotel, Leeds, on October 30. Oils are classified as non-drying, semi-drying and ying; but these are only relative terms, as all getable oils harden on exposure to the atmohere, the change being most probably caused by idation. The only true non-drying oils are ineral oils that have been subjected to special emical purification. The hardening of oils is not tirely due to oxidation since most oils become rder on exposure to sunlight—this change being robably due to polymerisation. It has been shown at free fatty acids in oils oxidise much more adily than the glycerides; and that when once idation has commenced, it proceeds more rapidly. he oxidation of oils may be partly prevented or duced by means of an antiseptic agent, such as tassium fluoride, such agents possibly preventing ydrolysis of the oils by bacteria or fungi, etc. In me cases oils become sticky on exposure to air, nd in this condition are very difficult to emulsify, nd consequently are deleterious in the textile ade. Many catalysts aid oxidation of oils, parcularly rust, iron, copper oxide, or copper. Oils r their fatty acids, when oxidised, are difficult to move from textile materials because their meltg-points are above the temperature at which ouring is usually carried out, and for the purpose f emulsification fluidity is an essential property.

On November 20 Mr. R. A. Mott and Mr. H. J. Iodsman read a paper on factors which influence e yield of ammonia in the carbonisation of coal, e work being a continuation of that published rlier this year (*cf.* J., 1922, 273 T). The previous aper had described the rôle of oxidation and the fluence of water vapour, but the scope of the vestigation was limited to temperatures below 00° C. This time the dissociation of ammonia in tmospheres of hydrogen, nitrogen, and coal gas as examined, especially the modification caused the presence of small proportions of oxygen and ater vapour. The latter has a very pronounced fect in restraining the decomposition of ammonia, d the remarkable observation was made that this fect was produced, though in a less degree, by ygen itself in the presence of hydrogen, possibly the water vapour formed. Even in the absence water vapour the rate of decomposition varied cording to the nature of the atmosphere. In udying the effect of contact materials it was und that well-used coke-oven brick impregnated th oxide of iron was much more active than new ebrick. This new brick was less active than the mples of coke tried. Fused silica and carbon posited from hydrocarbons were very inert.

Mr. P. Wedgwood and Mr. H. J. Hodsman read note on the determination of the volatile matter fuels. To obtain consistent results in the determation of the volatile matter in coal, it is imtant that the conditions shall be uniform. The tinum crucible is widely used in this determinan, but its cost is an obstacle to its general adopn. An effective substitute should be metallic in racter. Crucibles made from " monel " metal l iron treated with aluminium have been found sonably satisfactory. Results obtained are ally about 0·5 per cent. lower than those obned with platinum, and the crucibles are durable.

LIVERPOOL

On November 22 Mr. William Macnab delivered the Hurter Memorial Lecture in the Chemistry Lecture Theatre of the University. Dr. E. F. Armstrong presided over an audience of about one hundred, which included the Lord Mayor of Liverpool. On the motion of Dr. Armstrong it was resolved to send congratulatory letters to the chairman of the Section, Dr. G. C. Clayton, on his election to Parliament, and to Viscount Leverhulme and Sir Max Muspratt on having received " Dissolution " honours.

The late war produced a demand for enormous amounts of various explosives and chemicals, which led to the Government erecting many factories to supplement the output of private factories. The production of explosives in this country during the war period was:—Picric acid, 68,500 tons; TNT, 238,000 t.; ammonium nitrate, 378,000 t.; and cordite, 139,000 t. Toluene was in great demand for making TNT. A large distillery for handling the Borneo petroleum, which contains toluene and other aromatic hydrocarbons, was transferred from Holland to England, thus providing a valuable source of supply. Large works were erected at Oldbury and Queen's Ferry, the latter being able to produce 100 tons of TNT per day. Considerable quantities of synthetic phenol were produced from benzene, thus increasing the amount of picric acid which could be made. Great improvements were ultimately effected in the manufacture of picric acid. The output of sulphuric acid, as oleum, was increased enormously, the largest amount coming from Grillo plants. Cordite was also produced in large quantities, Gretna alone having a capacity of 1000 tons a week. The use of ammonium nitrate, mixed with TNT, as a filling charge for shells, led to a great development of its production; the largest amount was made by double decomposition of sodium nitrate and ammonium sulphate; a fine instance of the successful application of the phase rule.

In France, working under difficult conditions, owing to so many factories being in the hands of the enemy, remarkable efforts were put forth and splendid results achieved. Picric acid being the explosive most prized for French shells, and the supply of coal-tar phenol being totally inadequate, recourse was had to the manufacture of synthetic phenol from benzene. This manufacture developed until 200 tons a day was produced. The sulphonation of benzene in the form of vapour was carried out on the largest scale and proved a great advance on the old process. The production of propellent powder reached 370 tons per day. About 100 tons a day of nitrogen peroxide was made and used as chief ingredient in the explosive " anilite " employed in aeroplane bombs. Large works were erected for producing nitric acid from atmospheric nitrogen by the arc process; also from cyanamide and by the Kulhmann-Ostwald process. When the submarine menace was at its worst arrangements were made for erecting additional plants to produce 500 tons of nitric acid and 150 tons of ammonium nitrate per day. At the time of the armistice some of these factories had begun to manufacture and the others were nearly completed. In this branch of chemical industry the French got much ahead of us, and still remain far in advance.

Both nations, France and England, may well be proud of their achievements in chemical industry.

In both countries, and also in America, this industry received a great stimulus during the war, and keener competition must now be expected from France and America, as well as from Germany.

We need more men like Hurter in our chemical industry. He may well serve as a splendid ideal for all of us. It is earnestly to be desired that professors and manufacturers who got to know one another better during the war—and others who are interested—will co-operate cordially in developing the best means of educating men who will be able to conduct our chemical industry in the most efficient and progressive manner, and thus enable all competition to be met successfully.

CHEMICAL ENGINEERING GROUP

The first of a series of papers to be given in London was read by Prof. J. W. Hinchley in the Chemical Industry Club on November 10, Mr. J. Arthur Reavell, chairman of the Group, presiding. Prof. Hinchley dealt with "The Dewatering of Peat by Pressure," and showed that much more water could be removed from peat by hot pressing than by applying nearly double the pressure in the cold. Views were shown of presses invented by the author for carrying out the hot pressing of peat, the heating being effected by blowing steam through the peat whilst in the press. By this means the author has found it possible to obtain a peat which on leaving the press contains from 57 to 45 per cent. of water, according to the nature of the peat treated. A further reduction of moisture is obtained by placing this pressed peat in a tunnel which is heated by waste gases from the furnace of the boiler required to generate the steam used in the press. A careful estimate of the cost of the process was submitted in which it was shown that the amount of dried peat consumed in the boiler furnace to generate the steam required for pressing was 25 per cent. of the peat pressed, and that the cost of this method of pressing varied from 17s. 6d. per ton in the case of a one-press plant to slightly less than 4s. 6d. per ton in a ten-press plant, and that it would be possible to sell dried peat at the factory at 15s. per ton.

The paper was followed by a discussion opened by Dr. R. Lessing, who asked what material was used as the filtering medium and if the chemical composition of the extruded water had been investigated. He also mentioned that some interesting work had recently been done in Norway on the composition of peat. Mr. P. Parrish inquired if the type of press described would be suitable for pressing the very friable peat found at Morwell in Australia. Mr. G. Radcliffe mentioned the preserving properties of peat and gave some interesting details of work which he had carried out on Irish peat. The possibility of using this type of press to de-water sewage sludge was raised by another speaker, and Mr. A. J. Broughall asked if vacuum drying was applicable, and if any consideration had been given to the presence of air bubbles on the edge of the cake, since these might retard the flow of water from the interior. The chairman mentioned the difficulty of obtaining equal pressure all over the cake and stated that a press had recently been invented to overcome this difficulty, and that some remarkable results had been obtained. In his reply Prof. Hinchley said that the question of securing a uniform pressure was worth consideration; he had found a pressure of 500 lb. per sq. in. to be the most economical. The sides of the press consisted of tinned steel-wire gauze, which constituted the filtering surface. Most of his experiments had been made with peat from a depth of 3—8 ft., and for several reasons it was not desirable to utilise the lowest layer. He had not experimented with Morwell peat; and he did not think that the application of the centrifuge would afford a solution of the problem.

MEETINGS OF OTHER SOCIETIES

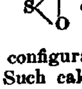
INSTITUTION OF RUBBER INDUSTRY

A meeting was held on November 6 in t Engineers' Club, London, at which Dr. H. Stevens read a paper on "Recent Developments the Plantation Industry." The author dealt wi the methods of tapping, collecting and standard ing the latex, preparing the rubber in sheet crêpe form, drying, milling, packing and transpo

The basic modes of preparing rubber are esse tially the same as those adopted by the pionee 20 years ago. It is now recognised that t severity of tapping affects the composition of t latex, and the intensive system is being replac by tapping on alternate days or even or at le frequent intervals, *e.g.*, every four months. Lat is now collected in glass, glazed earthenware, aluminium cups, instead of in tin cups and cocon shells, and sodium sulphite (1 part to 500 or 10 of latex) is added to prevent coagulation befo the latex is strained. Acetic acid is used coagulant, the latex having been previously bulk and diluted in large tanks (small pans, if crê is to be made) in order to secure a product unifor in appearance and properties; usually the latex diluted to a rubber content of 1·5 to 2 lb. p gallon. The rubber content of the latex is dete mined in the following way: the specific gravity ascertained by means of a special form of hydr meter, and the rubber-content is found by consul ing a graph showing the relation of the averag rubber-content of the latex to the specific gravit inaccurate results are obtained, however, if t latex shows any sign of pre-coagulation or thicke ing. Various improvements have been made in t houses used for smoking sheet rubber, mainly the direction of providing increased accessibilit continuous working, and reducing the time treatment. There has been no change in t method of preparing blanket crêpe, except that Ceylon, hot-air or vacuum driers are frequent employed, drying in ventilated sheds being used the Federated Malay States. For making thi crêpe, hot-air driers are now in use in the Mal States, as air-dried crêpe is hard and cannot milled readily into blanket crêpe. Great care taken to ensure that the rubber is dry befo packing, but sheet rubber often shows traces mould on arrival in Europe, owing to the presen in the rubber of water-soluble organic substance particularly *l*-methylinositol, which is hygroscopi Most of the impurities found in rubber by t manufacturer are due solely to contaminatio during unpacking, sampling and repacking, rubber usually does not contain grit or dirt wh packed.

THE PHYSICAL SOCIETY

At the meeting held on November 9, a paper on "The Structure of the Sulphur Dioxide Molecule" was submitted by Prof. A. O. Rankine and Mr. C. J. Smith. Viscosity data indicate that the actual mean collision area of the sulphur dioxide molecule is $0 \cdot 94 \times 10^{-15}$ sq. cm. Modern atomic theory leads to the conclusion that, in combination, oxygen atoms simulate neon atoms in size and shape, whilst sulphur atoms simulate argon atoms. The values of the mean collision areas of neon and argon are known from viscosity data, and the distances between the centres of atoms in combination are known from the crystal measurements of W. L. Bragg. It is thus possible to calculate the respective values of the mean collision area of the sulphur dioxide molecule, according as the molecular configuration is either



or O=S—O

the latter configuration being suggested by Langmuir. Such calculation decides definitely in favour of the first structural formula, the respective calculated values being $0 \cdot 99 \times 10^{-15}$ sq. cm. and approximately $1 \cdot 08 \times 10^{-15}$ sq. cm.

In a paper on "The Thermal Effect of Vapours on Rubber," Mr. A. S. Houghton described briefly the heating effect produced when rubber is suddenly plunged into the vapours of chloroform, benzene, toluene, ether, water, and gases such as ammonia and carbon dioxide. It is probable that only part of the heat evolved is due to condensation of vapour on the rubber, the remainder originating in the formation of a compound or solid solution of a loose nature between the vapour and rubber.

Mr. J. T. Robin described and demonstrated an apparatus for determining the tensile strength of gas mantles. The method adopted is an application of Archimedes' principle, whereby owing to the gradual fall of level of water in a cylindrical tube in which a float is immersed, a gradually and continuously increasing load is applied to the "burnt-off" fabric of the mantle under test, until fracture of the mantle results. The value of the applied load at the moment of fracture of the mantle is read on a scale approximately calibrated.

THE CHEMICAL SOCIETY

Prof. J. F. Thorpe presided at the ordinary scientific meeting held in Burlington House, W., on November 2. There was a very good attendance, and a large number of papers was scheduled to be read. These were:—

The solubility and volatility of the nitrobenzaldehydes: N. V. Sidgwick and W. M. Dash; Investigations on the dependence of rotatory power on chemical constitution. Part XIII. The spatial configuration of the unbranched aliphatic chain: R. H. Pickard, J. Kenyon, and H. Hunter; Investigations on the dependence of rotatory power on chemical constitution. Part XIV. The normal aliphatic ethers of *d*-*β*-octanol: J. Kenyon and R. A. McNicol; Investigations on the dependence of rotatory power on chemical constitution. Part XV. The normal aliphatic ethers of *d*-methylbenzylcarbinol. Part XVI. A new type of Walden inversion: H. Phillips; Investigations on the dependence of rotatory power on chemical constitution. Part XVII. The di-*d*-*β*-octyl esters of the acids of the general formula $(CH_2)_n(COOH)_2$: L. Hall; Orientation of the 1:4- and 1:5-dimethylglyoxalines. Mode of fission of 5-aminoglyoxalines: F. L. Pyman; Bromo-derivatives of 2-methylglyoxaline: L. Light and F. L. Pyman; 2:5 iminodihydro 1:2:3 triazole. Part I. Constitution of Dimroth's 5-anilidotriazole: P. K. Dutt.

The papers, each of which dealt with particular instances of more general investigations, were presented, respectively, by Dr. Sidgwick, Dr. Pickard, Mr. Phillips, Prof. Pyman, and Mr. P. K. Dutt. An informal meeting was held on Thursday, November 16.

BRITISH ASSOCIATION OF CHEMISTS

The fifth annual meeting was held on October 28, Mr. W. E. Kay presiding in the absence, through illness, of the president, Prof. J. W. Hinchley.

The annual report of the Council refers to a decrease in membership; there are now 1095 members, compared with a nominal roll of 1344 at the commencement of the year. The adverse balance of £43 on the year's working would have been larger but for the response to the Council's appeal for supplementary donations. Accordingly, after considerable discussion, a resolution was carried at the annual meeting to raise the subscription to 30s. The report refers to the effect of the continued depression in trade on the activities of the Association, and particularly on the work of the Appointments Bureau. Nevertheless, the Council has been able to institute an Unemployment Benefit Fund, subscription to which is obligatory on all members holding salaried appointments. The Legal Aid Fund continues to help members in regard to service agreements, etc., and in securing rebate from income-tax for professional expenses. Negotiations have been carried on with the National Union of Scientific Workers with a view to closer co-operation or amalgamation, and two joint council meetings have been held for the discussion of common policy and activities. The Council has also considered the question of terminating the "B" qualification for membership of the Association, legal re-definition of the term "chemist" and other matters affecting the status and professional efficiency of the chemist. The Association is registered under the Trade Union Acts and membership is open to both employers and employees.

Speaking at the annual dinner, Dr. H. Levinstein, the new president, said that, with adequate organisation, the Association could be made to include practically all the chemists in the country, as did the Institute of Chemistry, whose functions were complementary to those of the Association. The chief, but a very great, difference between an ordinary trade union and a trade union of chemists was that the employers of chemists were just as interested in raising the status of chemistry as the chemist himself. Collective bargaining to secure minimum fees or salaries was, he believed, a retrogression rather than an advance, but such questions as the stabilisation of remuneration and rewards for patents could readily be discussed with a body of employers like the Association of British Chemical Manufacturers, and educational matters with university authorities. Dr. E. F. Armstrong also spoke.

NEWS AND NOTES

BRITISH INDIA

Tata Oil Mills

The Times Trade Supplement for November 11, 1922, publishes an abstract from the report of the Tata Oil Co., which shows that for the fifteen months ended March 31, 1922, a loss of Rs. 14 lahks was incurred. A report issued by the company in 1921 disclosed a loss of Rs. 20 lahks. The directors put forward several reasons for these heavy losses, including the collapse of the overseas markets since the mill started work, making it impossible to operate either continuously or at full capacity; the heavy fall in the price of coconut oil from £121 in 1920 to £37 in August, 1922; and particularly, the heavy duties which America has imposed against all foreign oils in favour of similar oils from "its own colonies"—presumably the Philippines—for it was hoped to dispose of much of the output of the mills in America.

The position in which this company finds itself, after less than two years of actual operation, stands out in vivid contrast to the situation in India during the amazing boom period of 1919-1920. In Bombay particularly, the name "Tata" at the head of a new company-prospectus was sufficient in the eyes of the Indian speculator to render ordinary shares—perhaps not unjustifiably—equivalent to gilt-edged securities. In the spring of 1920, before the oil mills had produced a single ounce of coconut oil, the original Rs. 100 shares of the company stood at Rs. 600, and probably no other newly-founded Indian industrial concern attracted so much interest or was launched with greater confidence in its future.

The policy underlying the formation of the Tata Oil Mills Company is characteristic of the Tata group of capitalists, namely, to develop manufactures as far as possible in India itself instead of acting merely as trading concerns engaged in the collection and export of raw material. The Malabar Coast region, which is one of the finest coconut-producing areas in the world, offered a particularly attractive field for new enterprise. Before the war the whole output of copra, apart from the relatively small proportion consumed locally, was exported, chiefly to Europe. In 1914 about 38,000 tons was shipped, and of this amount 75 per cent. was taken by Germany. The only crushing plant in the Malabar country consisted of the primitive native chuck-mills and a few small steam-driven mills constructed on the same principle.

The Tata Mill was erected at Enakulam, on the Cochin Creek, a particularly advantageous site, since it lies in direct communication with the sea and with the long line of backwaters which stretch north and south throughout the coconut area and afford very cheap means of transport for copra and other coconut products. The Government intends to construct a harbour at Cochin which will allow the products of the Mill to be loaded directly on to the ship; at present the Malabar coast possesses no harbour, and the cost of intermediate transport is a considerable disadvantage for traders in that region. Enakulam is also connected by rail with all parts of India.

The mill was equipped entirely with American plant and was erected under the supervision of American engineers who had had experience in the Philippines, where the copra-crushing industry has been developed with marked success. The capacity of the factory is about 100 tons of copra per day. The present writer, in the course of a visit to the Malabar coast during 1920, was particularly struck by the interest shown in the new enterprise on the part of the native population, which certainly looked forward to an era of prosperity as a result of this development of an industry on which it depends almost entirely for a livelihood.

In view of the resources of Malabar in respect of coconut products, the unique combination of advantages which the situation of the mill affords, and the fact that the company is controlled by a group of men who have shown remarkable business acumen and foresight hitherto, it is difficult to believe that the present unfavourable position of the company can be other than temporary.

Crop Forecasts.

Groundnuts and Sesamum.—Reports received from provinces comprising 99 per cent. of the area under groundnuts in British India indicate that the acreage under the crop has increased by 24 per cent. to 1,846,000 acres (first forecast). The second forecast of the sesamum crop sown in provinces containing 99·6 per cent. of the total area under th crop (including Burma, but excluding the "mixed" crop in the United Provinces and the late crop i Bengal and Madras) gives the area sown as 3,432,00 acres; excluding Burma, the estimated area i 2,595,000 acres, or 4 per cent. below the corresponding estimate of last year. The present conditio and prospects of the sesamum crop are reported t be good.

Sugar-cane.—The second forecast of the are under sugar-cane estimates the acreage under th crop at 2,460,000, a decrease of 1 per cent. compared with the estimate at the same time last yea and an increase of 3 per cent. over the final estimat of last year. In general the condition of the cro is good. The forecast relates to provinces contai ing 99 per cent. of the total area under sugar-ca in British India.—(*Ind. Tr. J., Nov.* 2, 1922.)

AUSTRALIA

Beet-Sugar in Victoria

During 1921-22 the State beet-sugar factory Maffra, Gippsland, treated 16,578 tons of sugar-be from 1500 acres, and produced 1872 t. of sugar. T average sugar content was 11·3 per cent., and 8·55 of beet yielded 1 ton of sugar, as compared wi 9·745 t. in 1918-19 and 12·348 t. in 1910-11. F each ton of clean beet 45s. was paid, and after allo ing for interest and depreciation the year's worki showed a profit of £9920. New machinery is to installed in the factory which will more than dou its capacity and ensure more economical worki It is anticipated that the beet crop will also doubled, especially as the Glenmaggie system irrigation renders the growers independent of rainfall to a large extent. Compared with the c sumption of sugar in Victoria—approximat 75,000 t.—the output of the factory is small, but industry offers prospects of extension, as the c of production is about the same as that of ca and the sugar content is gradually improving (*Ind. Austr., Aug.* 31, 1922.)

FRANCE

Industrial Notes

Chemical Industry.—In the *Revue Scientifique* for October 28, Professors Béhal, Haller and Moureu review the present position of the French chemical industry, and especially the organic-chemical industry, in relation to the general economic crisis. Chemical manufacture in France, particularly that of organic products, is declining gradually to the pre-war level owing to the severe German competition made possible by the depre-ciation in value of the mark. For this reason the difference between German and French cost prices is so great that many French factories are con-emplating closure unless assistance is obtained. Apart from the advantage due to depreciated cur-ency, production costs are lower in Germany because almost all the raw materials of chemical -dustry are produced locally, and the factories tside the war-zone are of recent date and magnifi-ntly equipped. In France, however, labour and w materials cost ten times as much; in certain eas the plant has been destroyed or damaged, d the remainder has to be brought up to date. e French industry is protected by a heavy tariff all, but this can be evaded either by false clarations of origin or by having the material ansformed in a foreign country before it is im-orted into France. This state of affairs appears l the more deplorable in view of the great strides ade by France during the war to become self-upporting in respect of supplies of organic hemicals. At present France can not only meet he home demand for pharmaceutical and photo-raphic chemicals, and synthetic perfumes, but is roducing 85 per cent. of the requirements in dyes nd intermediates. In addition, well-equipped search laboratories have been established, and the ourses in the various schools of chemistry have en attended by large numbers of students, but, nhappily, these cannot find employment, and eir distress does not encourage others to follow e profession. The authors appeal to the Govern-ent to act before it is too late by initiating a rict control over imports of organic chemicals. hey emphasise the commanding position held by emical industry in the life of every nation, and oint out the grave error committed in certain arters of seeking a temporary advantage by ading with Germany, instead of supporting the tional industry.

A proposal has been made to establish a Cellulose search Institute, comprising an intelligence partment, provided with all the relevant litera-re, and five research laboratories for investi-ting the preparation of cellulose, bleaching and eing cellulose and artificial silk, production of ificial silk for preparing nitrocellulose, cellulose tates and formates, aeroplane "dope," and the t for research on the manufacture of celluloid. ch an institute would be of value to the French nies, as great interest is now being taken in lising "alfa" from North Africa and similar nial products.

etallurgy.—Production remains good in the ious mining areas, except near the Pyrenees. Normandy and Anjou, manufacturers are find-new markets in England and Germany, and ortant contracts are being considered. Home sumption is progressing, and if supplies of man coke were steadier, more blast furnaces could be blown in. Generally, the metallurgical situation remains unaltered, but with a slight tendency to diminished consumption.

An important meeting has been held by the *Conseil Supérieur* recently formed to co-ordinate all railway transport, and the question of revising railway rates was discussed. A reduction of these rates is held to be long overdue. At present most of the metallurgical firms near the eastern frontier find it cheaper to export their products *viâ* Holland and Belgium. Recently a railway company had a consignment of rails made in Belgium shipped to an Atlantic port, rather than transport it by land over the French Eastern Railway.

UNITED STATES

"Journal of Physical Chemistry"

As previously announced, the above-named journal is to be published under the joint auspices of the American Chemical Society, the Chemical Society of London, and the Faraday Society, and the following chemists have now been appointed to the editorial board:—Professors T. M. Lowry, J. W. McBain, and J. C. Philip (Chemical Society of London); Prof. F. G. Donnan (Faraday Society); Dr. A. L. Day, Prof. G. A. Hulett, Dr. Irving Langmuir, and Prof. W. Lash Miller (American Chemical Society). The board will shortly elect an editor-in-chief.

The Perkin Medal, 1923

Dr. M. C. Whitaker, the next recipient of the Perkin Medal (*cf.* p. 512 R of this issue) was chairman of the New York Section of this Society in 1922, and president of the American Institute of Chemical Engineers from 1914 to 1916. In 1914 he organised the Department of Chemical Engineering at Columbia University and became its head. During his management of the Welsbach Company's factory, from 1903 to 1910, the output of the plant was more than doubled and the cost reduced by more than one-half. In 1916 Dr. Whitaker became manager, and in 1917 president, of the Curtis Bay Chemical Co., now the U.S. Industrial Chemical Co., which at that time made only acetone; now it is the largest producer in the United States of alcohol motor fuel, absolute alcohol, normal and iso-propyl alcohols, isobutyl alcohol, diethyl phthalate and many other fine chemicals. Eight of this company's products are made by new processes which have been worked out and put into operation under Dr. Whitaker's direction.

Chemists in American Public Life

A survey was recently made of the part that chemists play in the public life of their communities in America. On the whole it showed a general tendency among chemists to take interest only in such affairs as concern their personal welfare, and that few chemists are office holders. In one western city, Tacoma, Wash., a chemical club formed a committee to co-operate in civic affairs; but there is one city in Michigan, the seat of a large chemical industry, that is a truly chemical city. Only fifty-five out of its population of 5500, or 1 per cent. are chemists, but in spite of this proportion the chemists have this record: For six years, the mayor and three out of eight aldermen have been chemists; one chemist is on the school board; ten are in the Chamber of Commerce; and sixteen in the Kiwanis

Club, a "better community" organisation. There is one real chemist in the United States Senate, viz., Dr. Edwin F. Ladd, the junior senator from North Dakota. He has been active in the chemical laboratory for thirty-six years and as chief chemist of North Dakota for twenty years he waged a winning fight for pure foods and materials. During this work of law enforcement he learned the ways of legislation and legislatures. He is particularly interested in urging in the Senate such measures as those providing for the adoption of the metric system, the compulsory working of patents, and the setting up of purity standards for paints.

Storage of Portland Cement

The U.S. Bureau of Mines, in studying the storage and transportation of Portland cement, has found that, owing to the smaller area exposed, the cement stored in bulk deteriorates less than when stored in bags, hydration taking place only on the exposed surface. Cement transported in bulk must be shipped in a tightly closed car, and must be protected from moisture during loading, shipping, and unloading. This method of transport dispenses with the use of the costly bags and permits a saving in freight rates in the United States.

Gasoline Consumption by Motor Cars

In the October issue of the *Journal of Industrial and Engineering Chemistry*, Prof. G. G. Brown, of the University of Michigan, asks: "Can we afford the Ford?" He declares that his researches have shown that the Ford automobile touring car, driven under average conditions, runs not more than 17·5 miles per gallon of gasoline and that it should give 24 miles per gallon. One cause for this inefficiency is the present carburetting system, which can be so improved that the average Ford car will give 25 miles per gallon and operate as economically as more expensive cars. Of the 11 million motor vehicles in the United States about 5 million are Fords, which, it is estimated, consume one-fourth of the total gasoline production of the country. If a chemically controlled carburettor, such as that designed by Prof. Brown, were used, 400 million galls. of gasoline, worth $100,000,000, would be saved annually. Mr. Ford could buy a Muscle Shoals every 18 days with the savings made by improving the carburetting system on his cars.

CANADA

Pulp and Paper

President Dodge, of the International Paper Co. of America, stated recently that many of the company's mills in the United States would eventually be converted into power plants. This statement may be regarded as a forecast of the possible disappearance of the U.S. newsprint manufacturing industry in the face of Canadian competition, assisted by the continued rapid depletion of pulpwood supplies in the Eastern United States. The total production of newsprint in the States during 1920 was 1,511,000 tons, whilst 15 mills in Canada have a present capacity of over one million tons. The development of the pulp and paper industry in Canada is exceedingly interesting. In 1891 the exports were valued at $120, and in 1921 at $163,655,344. During the last decade the increase in value of exports has been very marked: in 1912, $8,980,184; 1915, $27,107,697; 1920, $104,[illegible]5,388.

Petroleum

The tar sands of Alberta are occupying much attention, but it is quite clear that many of the proposed methods of utilisation are not economic. The latest method is one developed by the research department of the University of Alberta. The press account of the process, which is all the information available at present, is not sufficiently explicit to justify the expression of any opinion regarding its practicability.

The chief interest in petroleum development in Canada is now concentrated in the Sweetgrass District of Southern Alberta, where, owing to the strikes across the line in Montana, many wells are being drilled. Coutts, a small town south of Lethbridge, is the centre. Many prospectors from Texas, Wyoming, Louisiana, California and other parts of the States are operating in this district, but the latest arrivals include representatives of British financial interests. Many wells are being sunk; the deepest is down 2100 ft., but oil is not expected above 2500 ft. The Imperial Oil Co., Ltd., is drilling six wells in Alberta, but, so far, no useful discovery has been made. The well at Pouce Coupe is down 2612 ft., and there is a flow of 10 million cb. ft. of gas a day. The Fabyan well, at 2600 ft., has also a strong flow of gas. The others are barren of results. Drilling is being continued in the Fort Norman district, on the Mackenzie River.

RUSSIA

Pharmaceutical Chemicals

In June, 1922, eight factories were producing pharmaceutical chemicals, and the intended output was realised. The output included 826 cwt. of medicinal preparations, 514 cwt. of disinfectants, 185 cwt. of soap, and 391 cwt. of various preparations. Production, especially that of ether, is much hindered by the duty levied on alcohol.

Metalliferous Mining in 1922

Ore-mining in Russia is in a bad condition. Even in the Krivoy-Rog, formerly the greatest ore-producing region, only three mines are working, with a monthly output of 11,700 long tons, which is a poor figure compared with pre-war production. Stocks in hand amount to 1,354,000 tons, largely remaining from pre-Bolshevist days. Although production was continued during the first years of Soviet rule in the Tula and Kaluga district, it was stopped last winter and only just recently have steps been taken with a view to resumption. The production achieved has not been large, as this district, like that of Krivoy and also Lipetsk, is in a state of "technical conservation," probably a Bolshevist euphemism for a state of decay. In the Oka district only the Tischinsk mines are at work, the May production being 161 tons.

Production is better in the Ural region, where the Tinchinsk mines have a monthly output of 3609 tons, which is 12 per cent. more than the estimate. The Bakalsk mines have the next largest output with 1873 tons, or 73 per cent. of that anticipated.

The Nikopol manganese mines produced in May 2323 tons of ore, *i.e.*, 57 per cent. of the estimated amount. Stocks of manganese ores amount to 137,000 tons. Copper-mining has been practically at a standstill since 1918, and only recently have fforts been made to revive it; during this year the roduction has been 2705 tons. The most important zinc and lead mines are at Alagir, in the Caucasus, where in 1920 and 1921 about 600 tons f lead and 200 tons of zinc were produced. The iberian zinc and lead works are not yet completed. The winning of asbestos has been carried n by the recently formed trust, "Ural Asbestos." This year's production amounts to 1496 tons, and tocks in hand to 16,000 tons.—(*Prawda* [*Moscow*], *No.* 184, 1922.)

GERMANY

"Reparation" Dyestuffs

The dyestuffs delivered by Germany under the Treaty of Versailles up to May 1, 1921, were valued at 32,476,000 gold marks and from that date to June 30, 1922, at 10,708,000 gold marks. Deliveries were distributed as follows:—

	To May 1, 1921	May 1, 1921—June 30, 1922	Per cent. of total
	1000's of gold marks		
Belgium	2,949	3,221	14·3
British Empire	8,499	1,696	23·6
France	9,251	2,006	26·0
Greece	—	196	0·5
Italy	9,124	3,589	24·9
Japan	2,630	—	6·1
Yugoslavia	23	—	0·1

In addition to the above deliveries, dyestuffs valued at 4 million gold marks were sold to the Textile Alliance of the United States through the Reparation Commission, which also re-sold dyestuffs valued at 3 million gold marks to German buyers.—(*U.S. Com. Rep.*, *Oct.* 23, 1922.)

Denatured Spirit for Medicinal Use

In reply to a petition, presented by representatives of the hospitals, for a reduction in the price of spirit, the Prussian Ministry of Welfare (*Volkswohlfahrt*) stated that the price for use in public hospitals would be reduced by means of a yearly grant not exceeding 40 million marks from the alcohol-monopoly tax, but that the mode of distributing the grant had not been decided. For many purposes, such as disinfecting and dressings, hospitals could economise by substituting a suitably denatured spirit for pure spirit. It was proposed to make available a cheap spirit denatured with diethyl phthalate, which possessed such a bitter taste that it could not be taken internally, although it could be used safely for disinfecting the skin and in preparing alcoholic medicaments for external application.—(*Chem. Ind.*, *Sept.* 25, 1922.)

Acetic Acid and Industrial Alcohol

Official statistics record that in 1920 acetic acid was manufactured in twenty factories, of which eleven utilised acetate of lime as raw material, five calcium carbide, one pyroligneous acid, and three various other raw materials. Industrial alcohol was made in only four factories, the output of 668 metric tons comparing with 8 t. from five factories in 1919 and 109·7 t. from eight factories in 1914. The great increase in 1920 was due to the renewal of demand from industries using alcohol whose production had been restricted during and after the war. The industrial use of undenatured acetic acid has also greatly increased; figures of production have not yet been issued. Prices of acetic acid rose from 90 to 105 marks per quintal for 80 per cent. acid in 1913 to 600—1800 mk. per quintal for 80 to 100 per cent. acid in 1920.—(*Chem. Ind.*, *Oct.* 2, 1922.)

The Production of Gas and Crude Tar from Lignite

In No. 243 of the "Forschungsarbeiten auf dem Gebiete des Ingenieurwesens," Hilliger and Wurm record the results of a number of tests carried out to discover an economical process for the production of gas and tar from lignite. The results show that in the present position of the distillation process and with the present price-ratio for lignite and lignite tar, direct distillation affords an economical method of utilising lignite.

Cement from Blast-furnace Slags

Unsuccessful attempts to convert acid blast-furnace slags into cement by fusing them with lime have been made for some time past. The increasing scarcity of building materials and the production of very large quantities of the slag have once again turned the attention of chemists to the problem of its utilisation, and two processes have been developed which have given promising results. Wennerstrom's method consists in heating by electrical means the slag with lime in a graphite-lined circular furnace, whereas R. Grün first converts the slag into a basic compound by adding alumina to the charge either before, or simultaneously with, the lime. The alumina reduces the melting point of the mixture and enables it to take up more lime. The resulting product when finely ground with clinker makes a good cement.

GENERAL

The British Empire Exhibition, 1924

Active preparations are being made for this Exhibition, which will be held in Wembley Park, London, from April to October, 1924. As the title implies, the function of the Exhibition will be to bring together all parts of the Empire: to bring markets to producers, and goods to buyers. The whole Empire will be represented at Wembley, and the space already booked by Greater Britain is nearly seven times that which it occupied at the exhibition held in the White City in 1908. Wembley Park, it may be remarked, is within 10 minutes ride by railway from Baker Street and Marylebone, and there are 126 railway stations within the London area from which the Exhibition may be reached in an average time of 18 minutes. Exhibits will be arranged in 10 sections, 45 groups, and 150 classes. All raw materials and manufactured goods to be shown must have been produced within the Empire, and applications for floor space must be in the hands of the General Manager (16, Hobart Place, London, S.W. 1) by December 30, 1922. The chemical exhibits will be displayed in Section E, Manufactures: Group XXVI, Chemical Industries, Dyestuffs and Perfumery; other materials of interest to chemists will be shown in the same section under Group XXIII, Metal Industries; Group XXIV, Textiles; Group XXIX, Miscellaneous Industries (including pottery and glass, oilseed products, and rubber). Plant and apparatus used in the chemical industry will be shown in Section D, Machinery and Implements, Group XX. The organisation of the sections covering chemistry, pure and applied, has been entrusted to the Association of British Chemical Manufacturers, with which the Society of Chemical Industry is cooperating actively. Members of the Society are invited to visit Wembley Park to inspect the grounds and the buildings in course of erection, but for this purpose they must first obtain tickets from the General Secretary at Central House.

PERSONALIA

Sir Robert Robertson has been elected president of the Faraday Society.

Mr. D. H. Peacock has been appointed professor of chemistry in the University of Rangoon.

Dr. F. Gianformaggio has been appointed professor of chemistry in the Technical Institute, Syracuse.

Dr. P. Fischer has succeeded Dr. Agde in the chair of chemical technology in the Polytechnic at Cöthen, Germany.

The Perkin Medal of the American Section of this Society has been awarded to Mr. Milton C. Whitaker, vice-president and manager of the U.S. Industrial Alcohol Co., and will be presented to him on January 12, 1923.

Prof. M. Bodenstein has been invited to accept the chair of physical chemistry in the University of Berlin, held formerly by Prof. W. Nernst, who is now president of the Physikalisch-Technisch Reichsanstalt and honorary professor in the University.

Mr. W. B. Wiegand, M.A., of Montreal, chairman of the Rubber Division of the American Chemical Society, has been appointed general manager of Ames-Holden-McCready, Ltd., large manufacturers of tyres and other rubber goods.

Prof. G. T. Morgan, professor of chemistry in the University of Birmingham, has been awarded the Research Medal of the Dyers' Company for his paper on "The Co-ordination Theory of Valency in relation to Adjective Dyeing," which was read last year before the Society of Dyers and Colourists.

The honours bestowed on the occasion of the resignation of the Ministry include a viscounty to Lord Leverhulme, for public services, and a baronetcy to Alderman Max Muspratt, chairman of the United Alkali Co., Lord Mayor of Liverpool, 1916–17, who rendered great service during war in trench warfare.

The following were among those elected members of the House of Commons at the General Election, held on November 15—16:—Major W. A. Bowdler, of Church, Accrington (Holderness, Yorks, East Riding); Dr. G. C. Clayton, a director of the United Alkali Co. (Widnes); Mr. C. S. Garland (South Islington); and Sir Alfred Mond (Swansea West). The unsuccessful candidates included:—Sir John Brunner, Bt.; Major A. G. Church (secretary, National Union of Scientific Workers); Sir William Pearce; and the Rt. Hon. J. W. Wilson. Mr. W. J. U. Woolcock, general manager of the Association of British Chemical Manufacturers, and Col. Sir Edward Brotherton did not seek re-election.

* * *

We regret to note the death, on November 26, of Mr. Harry J. Powell, late of the Whitefriars Glass Works, in his 70th. year.

Dr. H. Larouche, director of the Civic Laboratory and assistant professor of chemistry in the University of Montreal, died suddenly on August 16, aged 33 years.

The death is reported of L. Tschugaeff, professor of inorganic chemistry in the University of Petrograd, from typhus fever, at the age of 50 years. The deceased is, perhaps, best known for his discovery of the method of determining nickel with dimethylglyoxime.

REPORTS

Reports on Cinchona Bark [and Myrobalans]. *Reports of the Indian Trade Inquiry, Imperial Institute. Pp.* 59. *London: John Murray,* 1922. *Price 4s. net.*

Cinchona was introduced into tropical British possessions about 1860, and within twenty-five years Ceylon became the chief source of supply of the bark, yet at the present time Java produces annually about 23 million lb. of bark, or about 90 per cent. of the world's supply, whilst the production in India is only about 2 million lb. (4 million lb. in 1899—1900) and that of other countries about 400,000 lb. Although "druggists' bark" is exported from India, most of the Indian-grown bark is worked up for quinine factories; further, as all of the quinine produced is used in India and both bark and quinine are imported, India cannot be regarded as an immediate source of exports of cinchona bark for quinine manufacture. In fact, to quote the words of the report, "The most striking feature of the trade in cinchona bark is therefore the virtual monopoly held by Java; a monopoly which, moreover, has been secured at the expense of Ceylon and India, and which makes the British Empire ultimately dependent on a foreign country for the raw material from which the essential drug quinine is made."

This position is obviously serious, especially when the hazards of war are taken into account, and when it is realised that the Empire requires an annual supply of about 8 million oz. of quinine, equivalent to about 8¼ million lb. of bark of average Java quality.

The position is complicated further by various agreements made between Java planters and manufacturers of quinine; although full details of these arrangements have, apparently, never been made public, the present agreement—which remains in force until July, 1923—affects only quinine manufacturers in Java and Holland who have agreed to take bark equivalent to 575,000 kg. of quinine sulphate annually, which was the quantity allocated under an earlier agreement to quinine manufacturers throughout the world. Whether quinine manufacturers in other countries will be able to obtain supplies of bark is uncertain, though it is stated that the single quinine factory in this country "has been partially safeguarded by an arrangement made, it is understood, at the suggestion of H.M. Government," under which supplies will be obtained during the next ten years from British-owned plantations in Java which are not now parties to the contract, and which have an estimated output of about 9 per cent. of the total for Java. Certain Dutch plantations in Java are also said to be standing out of the contract and to have arranged to supply bark to Japan, where quinine manufacture was started after the commencement of the war. According to Lt.-Col. A. T. Gage, I.M.S. (*Rept. Extension Cinchona Cultiv. in India*), large extension of cinchona in the areas in India where it is already grown is not possible, but other areas are suitable, *e.g.*, in Northern Tavoy, Burma. In British Malaya also it seems that cinchona might be grown successfully, as the trees on 20 acres planted with *Cinchona succirubra* and *C. Ledgeriana* at Gunong Angsi, Negri Sembilan, in 1914 were making excellent growth three years later. The question of establishing plantations is being considered by the F.M.S. Government, and areas of suitable land have been reserved pending a decision.

Reports on a number of samples of bark from St. Helena, the Cameroons, and the Tanganyika Territory, examined at the Imperial Institute and submitted to brokers and to manufacturers of quinine, show that bark of good quality may be produced, but it is doubtful if these countries will yield commercial supplies of bark in the near future.

The Javan monopoly of cinchona bark is evidently very important to other nations, and it is said that quinine manufacturers in the Allied countries and the United States have formed an Association to watch the position and safeguard their interests, and that a special American mission has investigated the possibilities of Colombia as a source of supply. Experimental plantation of cinchona in Japan and the Philippines is said to have been undertaken and arrangements made for quinine manufacture in Brazil and Peru from locally grown bark.

Provided that supplies of bark can be assured, the manufacture of quinine does not appear to offer difficulties, as the Government factories in India seem to have been financially successful, and a second factory which existed formerly in the United Kingdom was so successful—especially in the quinine export trade—that it was taken over by German manufacturers and subsequently closed.

In 1916 the Bandoeng factory in Java treated about one-fifth of the output of bark and for many years has been most successful. The exports of quinine sulphate from Java rose from 2,556,887 oz., valued at £120,845, in 1913, to 4,572,128 oz., worth £546,621, in 1917.

Appended to the report are useful statistics of production of, and trade in, bark and quinine in the chief producing and consuming countries.

REPORT ON THE ECONOMIC AND COMMERCIAL SITUATION OF AUSTRIA, TO JULY, 1922. *By* O. S. PHILLPOTTS, *H.M. Commercial Secretary, Vienna. Department of Overseas Trade. Pp.* 57. *H.M. Stationery Office*, 1922. *Price* 1s. 6*d.*

The economic plight of Austria is too well known o need description. Failure to restore agricultural production has proved most serious; the country is nable to buy food from abroad, and fertilisers annot be imported because farmers have to sell heir products at less than world prices.

In 1921 production of iron ore improved by 51,036 tons to 679,536 t., and that of pig iron by 16,274 t. to 214,322; the figures for the first uarter of 1922 are 216,868 t. and 60,071 t., respecvely; supplies of coke were obtained from Czechoovakia and England, but lack of labour limited e output. The output of coal was 2,607,000 t. nd importations from Upper Silesia, Czechoovakia, and Poland amounted to 5,928,000 t. ightly more magnesite (120,000 t.) was mined, t the production of salt was only 78,100 t. 60,000 t. in 1913), owing to the cost of coal for aporating the brine. Development of the available water-power has been slow, but 24 works with total capacity of 99,400 h.-p. were under construcn in 1921 and other schemes have been started ce. Most industries working for exportation re very busy during the second half of 1921, but trade fell off greatly when the value of the krone ceased to fall and severe German competition became possible owing to the depreciation of the mark. Although the effect of this slump has been partly overcome, the outlook is unfavourable on account of the shortage of working capital, the fluctuating exchange, foreign (chiefly German) competition, prohibitive tariffs in adjacent countries, high wages, and labour troubles.

The total weight of exports in 1921 was 1,477,402 t. and of imports 8,175,736 t., leaving an unfavourable trade balance of 6,698,334 t., compared with 4,744,000 t. in 1920. The value of the foreign trade is not known exactly, but it is estimated that the exports and imports in 1921 were worth £35,000,000 and £62,800,000, respectively. The share of the United Kingdom in the import and export trade is still very small, under 1 per cent. of the total quantity; skins, fatty oils, coal, wolfram ore, china clay, rubber, tin, caustic soda, varnish and colours were imported from this country in greater quantity. Importations of copra, fats, photographic plates, pig iron, ferro-silicon, etc. and chemicals declined. Among the exports of chemical interest sent to the United Kingdom were magnesite, talc, wood pulp, cement, glassware, and calcium carbide.

REPORT ON THE ECONOMIC AND INDUSTRIAL CONDITIONS IN THE SERB-CROAT-SLOVENE KINGDOM, DATED MAY, 1922. *By* CAPT. E. M. HARVEY, *H.M. Commercial Secretary, Belgrade. Department of Overseas Trade. Pp.* 31. *H.M. Stationery Office*, 1922. *Price* 1*s.*

At the beginning of 1921 conditions in Yugoslavia were promising, but later in the year, when control over the exchange was removed, the currency depreciated rapidly; this, combined with the inadequacy of the railways, greatly hindered trade. Drought seriously affected agriculture, which finds employment for 80 per cent. of the inhabitants. Apart from staple agricultural products, commercial and industrial herbs, such as pyrethrum, rosemary, sage, sumac, belladonna, gentian, etc. are grown in Dalmatia, the opium poppy is grown in Serbian Macedonia, and tobacco in Bosnia, Herzegovina and Macedonia. Progress was made in textiles, but other industries did not prosper, the leather industry in particular suffering from severe competition from Austria and Czechoslovakia. Many new industrial undertakings, mostly on a small scale, are springing up, and development will be rapid when means of communication are improved. German capital is said to be interested in many of these new industries. Development in the mining industry awaits improved transport. A British company has acquired a valuable lead mine in Slovenia, and a coal mine in Croatia is being worked by British enterprise. Oil-boring operations are in progress in Croatia in the district between the rivers Save and Drave; and the Government has shipped to Germany a large quantity of iron ore from the Ljubija mines in Bosnia. In 1921 the production of coal was 63,940 tons, of soft coal 2,651,108 t. and of lignite 103,064 tons.

Imports during the first half of 1921 were valued at 2,093,525,548 dinars; they included chemical and pharmaceutical products, colours, varnish, ethers, alcohols, essential oils, artificial grease, and explosives worth 102,024,271 dinars, glass and glassware 43,141,660 dinars, wax and wax products 34,419,171 dinars, metals and metal products 236,546,955 dinars, and minerals and mineral oils 118,458,462 dinars (dinar=9·5d. at par; av. value during 1921, 0·8d.). The origin of the imports was (per cent.):—Austria 25·45, Italy 21·85, Czechoslovakia 19·75, Greece 7·16, and Great Britain 6·59. Probably a large proportion of the imports from Greece was of British or French origin. During the whole year Great Britain supplied goods valued at £1,045.705. Trading with Great Britain is hampered by the fluctuating exchange, but as German and Austrian firms are beginning to quote in sterling for certain products, *e.g.*, steel, the advantage derived from depreciated currency is apparently disappearing. Exports during the whole year were valued at 2460·7 million dinars, of which 35·86 per cent. went to Austria, 23·43 per cent. to Italy, and only 0·72 per cent. (£759,542) to Great Britain.

LEGAL INTELLIGENCE

THE PHOSPHORIC-ACID CONTENT OF UNGROUND BASIC SLAG. *Le Manufacture d'Engrais et de Produits Industriels v. T. W. Ransom, Ltd.*

In the King's Bench Division on November 9, Mr. Justice Greer heard an appeal by Le Manufacture d'Engrais et de Produits Industriels, Antwerp, against an umpire's decision in favour of T. W. Ransom, Ltd., Manchester. The latter company claimed that a contract to buy unground basic slag from the Belgian company stipulated that the slag should contain from 17 to 20 per cent. of phosphoric acid. Slag containing 11 to 17 per cent. of phosphoric acid was offered, but the English company refused it, contending that the slag should contain approximately 18 per cent.

For the Belgian company it was submitted that at least 11 per cent. of total phosphoric acid would have to be present in the bulk so that the solubility prescribed in the contract could be reached, and that the company was entitled to deliver unground slag containing any percentage of phosphoric acid, provided that the guaranteed solubility of 75 per cent. was not infringed. The umpire found that there was no necessary relation between the contents of total and of soluble phosphoric acid present in the bulk of the slag. In giving judgment Mr. Justice Greer said that the foregoing fact was known to the trade and the umpire was entitled to decide that "18 per cent. basic slag" meant that the content was 18 per cent. or thereabouts. He therefore decided in favour of T. W. Ransom, Ltd., with costs.

GOVERNMENT ORDERS AND NOTICES

"REPARATION" DYESTUFFS.—The Board of Trade announces that a list of the products comprised in the stocks of "reparation" dyestuffs is now available. The list, together with any further information relating to these stocks, may be obtained on application to the British Dyestuffs Corporation, Ltd., Reparation Department, 70, Spring Gardens, Manchester.

COMPANY NEWS

BRITISH SULPHATE OF AMMONIA FEDERATION, LTD.

At the second annual general meeting, held on November 16, Mr. D. Milne Watson, chairman, said that conditions had improved during the past year and that deliveries had not kept pace with the demand. The average price obtained was disappointing, on account of high costs, the price of sulphuric acid alone being more than twice that of pre-war times. There would have to be a great reduction in the price of acid if the cost of producing ammonium sulphate was to be reduced to the level of the selling price of nitrogen, and the Federation was determined to buy acid much more cheaply than at present. No effort was being spared to reduce the cost of production and administration, because, as the output of ammonium sulphate grew, the Chilean nitrate producers would attempt to reduce costs by improving the yield. Their present cost was, roughly, £8 10s. per ton, inclusive of the royalty of £2 10s. paid to the Chilean Government. On May 31 the productive capacity of the firms in the Federation represented over 90 per cent. of the British output, and it was significant that Synthetic Ammonia and Nitrates, Ltd., whose large plant at Bellingham would probably begin to produce within six months or so, had decided to become a member. The use of ammonium sulphate was extending in France, where 25,400 tons of nitrogen as ammonium sulphate was consumed in 1921 (19,400 t. in 1913), compared with 23,600 t. of nitrogen as nitrate of soda (48,700 t. in 1913), and the demand had grown even more in this country. Germany was consuming about 320,000 t. of nitrogen annually, *i.e.*, about 10·3 lb. per acre, as against 2·0 lb. in France and 4·5 lb. in England, and the total consumption of nitrogen in the three countries was 404,300 t. per annum. The prospects of the industry could be judged from the consideration that if these three countries were to consume 12 lb. of nitrogen per acre of arable land the total annual consumption would be 755,500 tons.

STANDARD CHEMICAL CO., LTD., CANADA

The eleventh annual statement, for the year ending March 31, 1921, of this company reflects the extreme depression that has existed in the Canadian chemical industries engaged in the production of acetate of lime, methyl alcohol, etc. from wood. The company has plants at Sault Ste. Marie, Longford, Donald, Parry Sound, South River, Thornbury in Ontario, and Montreal, Fassett, Cookshire, Mont Tremblay, Weedon in Quebec, and the total carbonising capacity is approximately 135,000 cords per annum. During the last financial year, 59,278 cords was retorted, or 44 per cent. of the capacity, which is a decline of 22 per cent. from the total carbonising capacity is approximately compared with $340,327 in 1919–20, and the net loss was $762,368, as against $166,967. The actual deficit shown in the accounts is $624,088. Current assets are estimated at $1,411,659 (1921, $1,942,065); liabilities, $631,185 ($606,223); and stocks, $1,121,622 ($1,616,814). Total assets are $6,733,670, against $6,880,485 last year. The demand for the company's products has increased since the close of the financial year and the company's plants are now working at 60 per cent. capacity.

OFFICIAL TRADE INTELLIGENCE

(From the Board of Trade Journal for November 9 and 16)

OPENINGS FOR BRITISH TRADE

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence), 35, Old Queen Street, London, S.W. 1, from firms, agents or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number.

Locality of firm or agent	Materials	Reference number
Argentina ..	Pottery	561
Australia ..	Fine and heavy chemicals ..	494
" ..	China, glassware, crockery ..	*
Canada ..	Dry zinc white, lithopone, white lead, umber, sienna	496
"	Drugs	497
"	Perfumes	521
" ..	Fire-extinguishing materials ..	†
Egypt	Drugs (tender for)	9409/F.E./C.P.

TARIFF CUSTOMS EXCISE

Belgium.—A Bill to revise the customs tariff is to be presented to Parliament during November.

Germany.—A list of the monopoly taxes on imported spirits is given in the issue for November 16. The duty on imported acetic acid and vinegar has been increased to 135,555 marks per hectolitre of anhydrous acid.

Hungary.—A commercial agreement based on the principle of " the most favoured nation " has been made with Esthonia. Goods recently added to the list of free imports include dégras, coal tar, certain coal-tar oils, oil colours, opium, chemical paper (not photographic), minerals, materials for grinding, cleaning and polishing, firebricks, earthenware, metal sheets, bars and wire.

Italy.—By a recent decree, the duties on synthetic organic dyestuffs and intermediates are increased; the restrictions on the import of these chemicals is withdrawn; and mineral oil-fuel is admitted duty free. Export licences are no longer required for aluminium scrap, calcium cyanamide, ammonium nitrate, and pyrites.

Kenya.—Under the new customs tariff specific duties are levied on imports of butter substitutes, edible fats, cement, kinematograph films, matches, metal wire, methylated spirit, mineral oils, salt, soap, spirits, and sugar. *Ad valorem* duties of 30 per cent. are applied to proprietary medicines, essential and perfumed oils, and of 10 per cent. to asbestos packing, glass and earthenware bottles and jars, tinplate, carbon dioxide, certain metals, fireclay, various oils, colours, varnish, driers, and paper. The duty-free list includes preparations for treating latex, explosives, fuel, creosote, drugs, medicines, disinfectants, rectified spirit for pharmaceutical use, fertilisers and manures, salt, fungicides, insecticides, radium, and vaccines.

Mexico.—The importation of opium, cocaine, morphine, etc. is prohibited save by permission of the Health Department.

Palestine.—From November 1 excise duties are leviable on imported alcoholic liquors, in addition to the customs duties.

Poland.—A commercial convention with Austria has been signed.

Spain.—The full text of the commercial treaty with the United Kingdom is reprinted in the issue for November 9.

TRADE NOTES

BRITISH

Gambia in 1920 and 1921

The chief agricultural product of Gambia is the groundnut crop, and while this continues to be profitable other crops are unlikely to attain importance. The climate is unsuitable for cotton-growing, the production of palm kernels is diminishing, and the export of wild rubber has now ceased. Owing to the prime importance of agriculture to the Colony, the establishment of a Department of Agriculture is being considered. Rhum palms, mahogany and rosewood are utilised locally, but the quantity and quality are insufficient to warrant exportation. The year 1921 was a very bad one for the Colony, and the total foreign trade declined by £3,500,000 to £1,678,021; the export of groundnuts was 59,175 tons and of palm kernels 302 t., as compared with 85,190 t. and 468 t., respectively, in 1920.—(*Col. Rep.-Ann., Nos.* 1020, 1121, 1922.)

FOREIGN

Japanese Imports of Paraffin Wax and Stearin

The paraffin wax imported into Japan comes mainly from Burma and Sumatra, 28 per cent. being derived from the United States. Australia is the chief source of supply of stearin, the United States and Manchuria coming next with 30 and 10 per cent., respectively.

	Paraffin wax (m.p. under 45°C.		Paraffin wax (m.p. over 45°C.)		Stearin	
Year	Long tons	1000 $	Long tons	$	Long tons	1000$
1913 ..	3,715·5	383·6	4,340·3	518·9	324·2	67·2
1916 ..	6,139·7	671·8	8,413·2	1,168·9	234·3	54·5
1918 ..	4,324·4	956·5	10,949·1	2,434·5	110·9	42·0

Japanese Exports of Camphor, Menthol and Peppermint Oil

Exports of these commodities during the first six months of 1920, 1921, and 1922 were as follows:

	January–June 1920	1921 lb.	1922
Camphor	974,522 ..	423,625 ..	1,962,670
Menthol	354,961 ..	137,783 ..	96,976
Peppermint oil	275,713 ..	116,762 ..	107,957

The percentage distribution of the exports of camphor during the first half of 1922 was as follows:—United States 57, Great Britain 14, British India 10, France 9, and Australia 4. The value of the exports of menthol and peppermint oil during the same period of 1922 was 793,634 yen and 219,488 yen, respectively (yen=2s. 0½d. at par).—(*Oil, Paint and Drug Rep.*, *Oct.* 9, 1921.)

Trade Notes from Finland

The manufacture of mineral and other colours is to be undertaken at Nedertornea by a new company, the Kyläjoki Väritehdas O/Y (capital 100,000 Finnish marks). (Finnish mark=9·5d. at par, now about 1·25d.)

A new company, the O.Y. Star A.B. Tammerfors, has been formed with a capital of 2 million Finnish marks, and has taken over the drug factory of the Tammerfors Droghandels A.B. with a view to increasing greatly its operations.

During the first half of 1922 the export of matches from Finland was 1209 metric tons, valued at 18·03 mill. Finnish mk., as compared with 742 t., valued at 6·90 mill. Finnish mk., in the same period of 1921.—(*Chem. Ind.*, *Sept.* 18, 1922.)

Swiss Chemical Trade

The following official figures afford a comparison of the import and export trade of Switzerland in certain chemical products during the first four months of 1913, 1921, and 1922:—

	January—April 1913	 1921	 1922
		Metric tons	
Imports :—			
Turpentine oil	6·85	4·57	5·10
Caustic soda and potash	35·72	9·82	25·39
Chloride of lime	5·44	2·83	1·30
Tar-oil derivatives, etc.	6·21	24·94	4·63
Coal-tar intermediates	12·27	13·08	3·53
Benzine, benzol	58·68	110·09	153·59
Aniline	4·70	0·58	3·90
Aniline compounds	3·84	0·98	1·01
Benzyl chloride, nitrobenzene, etc.	4·79	1·72	1·20
Logwood extract	2·37	1·02	0·69
Coal-tar dyes	2·72	1·57	1·64
Linseed oil	19·72	10·01	17·46
Petroleum	254·75	56·82	70·23
Exports :—			
Soda ash	—	1·56	14·83
Coal-tar dyes	29·90	15·14	16·88
Indigo	7·75	0·45	11·68

Manchurian Trade in Dyes and Paints

During 1920 supplies of dyes in Manchuria were insufficient and prices high, but in 1921 the small demand and the reappearance of German dyes caused a fall in prices which enabled synthetic indigotin again to compete with natural indigo. Numerous brands of German and American dyes are sold in Manchuria, the latter being reputed of first-class quality and selling readily. Imports from Germany were double those of the previous year and many of the well-known German makes reappeared on the market, mostly in limited quantities. All coal-tar dyes are packed in 8 oz. and 20 oz. tins. In the paint market Japanese lead paints have almost a monopoly, but two brands of British red lead are still in fair demand. Only limited quantities of paint and varnish are imported from the United States. Statistics of the imports of dyes and paints during recent years are given below:—

	1913	1920	1921
		lb.	
Natural indigo, paste	4,257,599	2,118,930	1,369,000
Synthetic indigotin, paste	45,900	2,003,200	273,333
		Haikwan taels*	
Coal-tar dyes	288,270	176,348	371,550
Dyes, other	69,302	94,106	53,882
Paint, paint oil	116,135	275,609	248,000

* The average value of the Haikwan tael was 36·5d. in 1913, 73·8d. in 1920, and 41·8d. in 1921.

REVIEWS

Researches on Cellulose, 1910—1921. *By* C. F. Cross *and* C. Dorée. *Vol. IV. of the "Cross and Bevan Series." Pp.* 253. *London: Longmans, Green and Co.*, 1922. *Price* 15*s. net.*

It is gratifying that Mr. Cross has been enabled, with the help of Dr. Dorée, to issue a fourth part of the collected "Researches on Cellulose," the preparation of which was originally undertaken in collaboration with the late Mr. E. J. Bevan. The series dates back to 1895, and the present volume is of special importance as it deals with a period marked by unusual activity in the scientific study of cellulose.

The authors have naturally been confronted with the difficulty of classifying under appropriate headings the researches they have selected for mention. This has been successfully overcome, one section being devoted to the physical properties and relationships of the cellulose complex, and another to the progress made in recent attempts to elucidate the constitution of the molecular unit of celluloses. Thereafter, the physical and chemical problems of modified celluloses are discussed and, in conclusion, a review is given of modern industrial developments.

Following the method adopted in earlier volumes, the authors provide useful summaries of selected researches and, from time to time, add critical notes which the reviewer, although holding somewhat different opinions, has read with genuine appreciation. The question raised in the introduction as to whether a volume of this nature is justified can at once be answered in the affirmative. Not only is it an immense benefit to the student of polysaccharides to have the unwieldy mass of publications on cellulose weeded out on his behalf, but the discussions on the papers themselves will be of service in preventing narrow views being taken by the specialist. The present book will do more than its predecessors to bring together the two different schools of research workers on cellulose. We have one type of inquirer, represented by Mr. Cross and his collaborators, who regards the complex as an organised colloidal structure and finds no help in the molecular constitutional views of the organic chemist. On the other side there is the constitutional chemist inclined to think exclusively in terms of groups and molecules. These schools have to be brought together, and the amalgamation cannot be effected by fair words and compliments.

Mr. Cross who, on his own confession, is an agnostic when it comes to questions of a molecular constitution for cellulose, has the courage of his convictions. There is much to be said for his policy of tilting (with all courtesy) at the academic chemist, or rather at chemists who adopt the lofty attitude implied in the statement that "cellulose is nothing more than a polymerised dextrose-glucoside of dextrose." Such statements seriously damage the position of the scholarly investigator who recognises that a structural formula for the molecular unit of cellulose is but one step in a long journey. To take a simple parallel, he is unlikely to forget that, although the composition of silica is known and the compound has been synthesised, the mechanism of building up the organised structure of a diatom is beyond the chemist's power.

With Dr. Dorée, Mr. Cross adheres to the view that the divergence which starch and cellulose show "from each other and from the anhydro-hexoses is not to be displayed in terms of polymerisation." The theoretical chemist, interested in the celluloses chiefly as aggregates of organic molecules, might reasonably refute some of the arguments used in the present volume and point out that current ideas regarding the constitution of the simple sugars are insufficiently expressed, but a discussion of this nature falls outside the scope of a review.

What has been said will show that the book is more than a reference volume. It is designed for the thinker, and will be appreciated by a wider circle of readers than the earlier issues. Disappointment may be felt in the brevity of the reference to the decomposition of cellulose by bacteria and the possible development of such processes to the production of power alcohol. Otherwise, the subject-matter is well-proportioned, and a fair balance has been maintained between different aspects of studies on cellulose. Special emphasis is laid on volume relationships, and the phenomena of fluorescence, as studied by S. J. Lewis, is accorded a prominent place. Papers published in the less accessible journals are well abstracted, and the essential features of the originals are reproduced with commendable accuracy.

J. C. IRVINE.

(1) COLOUR INDEX. PART I. *Edited by* DR. F. M. ROWE. *Pp.* 24. *Bradford: The Society of Dyers and Colourists,* 1922. *Subscription price of the whole work, in monthly parts,* 84*s.*

(2) THE MANUFACTURE OF DYES. *By* J. C. CAIN. *Pp.* 274. *London: Macmillan and Co., Ltd.,* 1922. *Price* 12*s.* 6*d. net.*

(1) The spirit of enterprise, which was stimulated by the war, pervades industrial chemistry throughout the British Empire, and its manifestation in the projection of a comprehensive Colour Index, of which Part I has just been issued, does credit to the Society of Dyers and Colourists, under whose auspices the work is being undertaken. The special committee of that Society, headed by Mr. Ernest Hickson and supported by very eminent experts, has enabled the editor, Dr. F. M. Rowe, to present an index which in form and arrangement compares favourably with similar publications.

Part I contains the names, constitution and literature references for over 100 dyestuffs, beginning with the nitroso-compounds. The names are so arranged that the firms who produce the colours can be given in alphabetical order, and references to the literature are arranged chronologically. It was obviously impossible to give all the commercial names of the dyes mentioned, because the manufacturing firms frequently change them for various reasons; therefore, it was an excellent idea to reserve a large portion of the Index for notes which the worker in this field is bound to make for himself. The dyes given in Part I are well known to the expert, and it will be interesting to see, as the work progresses, how the committee has solved the problem of the more obscure dyes, such as Benzo Fast Colours which are, without *any* exception, wrongly described in the text-books.

Although the Index is, speaking generally, very accurate, there are a few errors and omissions to be noted. Erio Azurine has not the constitution amidodimethylanilinedioxy-S-acid, but it is the dye mono-ethylamidoaniline chromotropic acid (Friedländer VII, p. 368, A.D.R.P. 8759, June, 1904, Richard), No. 59. Certain brands of the dye called Chrome Printing Yellow G. etc., No. 36, are, it is true, made with salicylic acid, but for wool-dyeing the combination m-nitraniline-*o*-cresotinic acid is much to be preferred, because it is at least 30 per cent. stronger. The treatment of different brands of Meta-Chrome Browns is, in the reviewer's opinion, somewhat inadequate; and many of the Meta-Chrome colours are not combinations with *m*-diamines; F-acid and others are also used, and the most important is the combination picramic acid-chloro-m-diamine.

It would be very unfair to expect absolute accuracy, because this is technically impossible, and it is well known that "Schultz" also makes a number of mistakes which are practically unavoidable. There are, however, two omissions of great importance. First "Friedländer" *must* be noted, because unless the class is given, it is impossible to find the German patents; and every dyeworks' chemist has "Friedländer" at hand. If the committee cannot give references to "Friedländer," it must at once prepare a complete collection of all the dyestuff patents.

The second point relates to absorption-spectra. The small errors mentioned above would not have been made if the absorption-spectra (after Formanec) had been consulted. As only Part I of the work has been issued, one cannot know if the committee intends to insert these missing data, but future parts will be awaited with great interest, not only for their intrinsic value but because they will doubtless bear witness to the great progress which the British dyestuffs industry is making.

(2) It was with a deep sense of loss that this book was opened, as Dr. Cain was very well known to the writer, who was aware of his intention to write a text-book on artificial dyestuffs. An unhappy fate appears to hover around the writers of large text-books on this beautiful subject, and the "torso" left by Cain in his desk shows that he was assembling the necessary material for a work which would probably have become a standard one. His ingenuity in seeking out all the accessible data recalls the memory of Dr. K. Heumann, who also died before his big work was finished.

The arrangement chosen by Dr. Cain does not differ from that of other authors, but it was his intention to give not only the constitution of the dyes but also extracts from the patents and other hints on manufacture. There is no doubt that even the short outlines which the author has left, show that he was a master of his subject, and we must be grateful to Prof. J. F. Thorpe for having published the manuscript, as he states, "practically as he received it."

H. E. FIERZ.

GRUNDLEGENDE OPERATIONEN DER FARBENCHEMIE. *By* H. E. FIERZ-DAVID. *Second edition, revised. Pp. xii+266. Berlin: Julius Springer,* 1922. *Price, bound,* 12*s.*

The second edition of this valuable work differs but slightly from the first edition, which was reviewed in these columns in 1919 (p. 486 R), but certain additions have been made which increase its utility. Thus two methods are given for preparing H-acid as well as for gamma- and J-acids. The amino-anthraquinones are described and the mode of preparing anisoles from the corresponding chloro-derivatives explained. Other changes effected relate only to minor details, but paper and binding have been brought up to peace-standard.

The Properties of Electrically Conducting Systems. *By* **Prof. C. A. Kraus.** *American Chemical Society, Monograph Series. Pp.* 415. *New York: The Chemical Catalog Co., Inc.,* 1922. *Price* $4.50.

Probably more experimental work has been carried out in the field of electrically conducting systems in recent years than in any other, and the literature on the subject has grown so large and is so scattered that it has become practically impossible for anyone who has not actively pursued the subject for some years to obtain a comprehensive view of it. Prof. Kraus has confined himself mainly to pure conductance phenomena and has dealt only briefly with other properties of electrolytes and with the more general problem of electrolytic dissociation. Within the restricted field he has chosen, the author has produced a work of the greatest value. He writes, naturally enough, from the standpoint of the American school of electrochemists, and in his brief treatment of the general theory he perhaps dismisses too lightly those recent theories which attempt to find a solution of the anomalous behaviour of strong electrolytes in the electrostatic attraction between the ions. Whatever may be the shortcomings of the theories of this kind which have been proposed up to the present, these forces do exist and must be taken into account before we can obtain a really comprehensive theory of electrolytes. A very valuable feature of the book is the great prominence given to non-aqueous systems; in fact, they are treated much more fully than are aqueous solutions. Unfortunately there has always been a tendency to neglect non-aqueous systems and to build up theories entirely on results derived from the study of aqueous solutions. The work under review brings the whole subject well into perspective.

The greater part of the book deals, naturally, with electrolytic solutions and the whole subject is treated very fully and in great detail from the standpoint of conductance phenomena. In a work of this kind, covering such a wide field, very careful selection of the available material is imperative, otherwise a false or one-sided impression may be conveyed to the reader. The author has done this very successfully and it would be difficult to find fault with his choice of material. In the same way no complete bibliography is given, but the selection of the more important references provided is sufficient to enable the reader to explore the whole field.

In addition to the main subject of electrolytes, there are three chapters dealing, respectively, with fused salts and solid electrolytes; the properties of metallic conductors; and systems intermediate between electrolytic and metallic conductors, the last being an account of Prof. Kraus's recent important work on solutions of metallic sodium in liquid ammonia. These three chapters, which are of the greatest interest, contain some very striking results which must inevitably lead sooner or later to a clearer understanding of the nature of the structure of metals and solid salts.

Throughout the text great use is made of the application of graphical methods in the interpretation of experimental results. The whole book is very clearly written and the examples and illustrative diagrams are numerous and well chosen. The book makes most interesting and easy reading and Prof. Kraus has rendered a very great service to chemists in writing it.

C. S. Salmon.

REVIEW

Vol. XLI] DECEMBER 15, 1922 [No. 23

WHAT CHEMICAL INDUSTRY OWES TO PASTEUR

LOUIS A. FERNBACH

For the Centenary of Pasteur's Birth, December 27, 1922

OF the most eminent scientists who are universally held to be benefactors of mankind, no one bears a more honoured ne than Louis Pasteur. Public health has ived such immense benefit from his work, l ideas concerning contagious diseases and ir prevention have become so diffused ong the greater mass of the public, that the dical side of Pasteur's discoveries, and the olution which they promoted in medicine and gery, are appreciated almost universally.

But even among educated people who have airly good knowledge of Pasteur's life and coveries, very few realise that this immense gress was the natural outcome of Pasteur's liest researches, and that, before becoming eminent master in pathology, he acquired ne by his biochemical work and its numerous plications in the fermentation industries.

This great chapter of Pasteur's scientific life ll deserves a short re-statement in this *urnal,* exclusively devoted to chemical lustry, especially in view of the celebration the centenary of his birth.

One of the most curious features of Pasteur's liest work is that he first investigated a estion which is apparently very remote from subjects of his subsequent researches. der the guidance of his great master, the nous physicist Biot, he undertook a study crystallography—namely, the crystalline ms of the various tartaric acids and their s; and he was thus led to the discovery of ets which had escaped the notice of previous strious workers, the so-called hemihedric ets, a discovery which was the origin of the ous theory of molecular asymmetry. In a es of papers, Pasteur demonstrated the e relationship subsisting, on the one hand, ween crystalline form and rotatory power, , on the other, between molecular structure the action on polarised light, a subject ch has since been greatly developed and ch forms one of the foundations of modern nic chemistry.

he study of tartaric acid led to the conclusion it and many other optically active substances exist in four different forms :—(*a*) two optically active forms, having equal but opposite rotatory powers, the asymmetric crystals of each being the mirror-image of the other ; (*b*) an equimolecular mixture of the above forms which is optically inactive *by compensation*, and known as the *racemic* form ; (*c*) a form which is inactive *by nature*, its inactivity being due to its crystalline as well as to its molecular symmetry. Unlike the racemic form, this last form cannot be resolved into active compounds ; and this fact leads us to the next period of Pasteur's discoveries—namely, his studies on fermentation.

Among the various methods employed by Pasteur to resolve the racemic form of tartaric acid into its two active constituents, the most striking is certainly the biochemical method, because it represents a most important link in the harmonious sequence of his researches. Having found that a solution of ammonium tartrate ferments easily (through bacterial infection, as we are now able to say), Pasteur transferred some seed from a fermenting solution into a solution of ammonium paratartrate (the racemic form), which fermented equally well ; but the polarimetric observations, made in order to control the progress of fermentation, revealed an unexpected and most important fact—namely, that the dextrorotatory form disappears, and that the final residue of fermentation is the lævorotatory ammonium tartrate. The same effect was obtained with a fungus, which proved later to be *Penicillium glaucum*.

These experiments are of capital importance. Not only do they provide the first instance of the resolution of a racemic body into its active constituents by a biochemical method that has since been applied in many directions, but they also afford evidence of the sensitiveness of micro-organisms to the optical properties and molecular arrangement of organic compounds, of which the processes of *selective fermentation* have since furnished numerous examples. These experiments first brought our great master into contact with micro-organisms, and thus laid the origin of a new science whose importance cannot be overestimated.

The attention which Pasteur was thus led to pay to a particular form of life was considerably favoured by the fact that, at this early period of his career (he was then 32), he was called to act as Dean of the Faculty of Sciences in Lille, in the centre of one of the chief industrial districts of France, where the fermentation industries, especially the manufacture of alcohol and beer, are widespread, and at that time were conducted on purely empirical lines.

In this new field of investigation, Pasteur had to organise the fight against a stubborn prejudice, emanating from one of the greatest chemists of that time, Liebig, who for many years refused to admit the specific action of micro-organisms, holding the opinion that they were merely organic matter in a state of decomposition, which state was communicated to the compounds undergoing fermentation.

One of the most striking instances which appeared to support Liebig's views was lactic fermentation, and the transformation which it promotes of the sugar into lactic acid. To start such a fermentation, it is only necessary to add a small quantity of spoiled meat or old cheese to a solution of sugar, in presence of chalk. Pasteur demonstrated that above the deposit of chalk, which formed at the bottom of the flask, there appeared a thin grayish layer, which consisted of minute rods, and that some of these rods, when introduced into a fresh solution, promoted a new lactic fermentation. The lactic ferment, far from being in a state of decomposition, as claimed by Liebig, multiplied itself vigorously in the course of the fermentation. The existence of numerous varieties of the lactic bacillus was established by the experiments of Lord Lister, whose work on this subject corroborated the results of his great friend, Louis Pasteur.

The part played by yeast in alcoholic fermentation held Pasteur's attention for many years. Through his experiments we have learnt that yeast reproduces during the splitting-up of the sugar molecule, thus confirming the view expressed many years before by Cagniard-Latour, that yeast promotes fermentation by its vital activity. In addition to contributing to our knowledge of the influence of various factors on the development of the yeast cell and on its action as an alcoholic ferment, on its origin and diffusion in nature, on the production of new compounds, *e.g.*, glycerin and succinic acid, on the part played by oxygen in the maturation of wines, on the oxidising functions of the acetic ferments (a subject much developed subsequently by Adrian Brown), Pasteur's researches on alcoholic fermentation have had a most profound influence on industrial practice; above all, they have taught us the importance of pure fermentation, which is one of the fundamental conditions of success in all industrial fermentation processes.

The necessity for securing pure fermentation appeared clearly to Pasteur as a consequence of observations made in his researches on wine and beer, namely, that the alterations which these beverages frequently undergo are due to the presence and development of minute organisms, the so-called disease ferments (*ferments de maladie*). The action of heat, which has since been applied industrially under the name of "pasteurisation," is an effective protection against disease; but a much more rational practice is to obtain a product under conditions which will secure stability. One of the most important of these conditions is *pure fermentation*, a term which signifies that the fermentation is promoted by an organism belonging to a definite single strain, in a liquid which has been previously deprived of all its living germs and which remains protected against all extraneous organisms.

The application of this fundamental principle has been of the greatest service in all fermentation industries. It involves working under conditions of absolute cleanliness, and all thinking wine-producers, brewers, distillers, vinegar manufacturers etc., now realise that the word *cleanliness* means *aseptic conditions of work*, which are the only safeguard against subsequent trouble. It involves also the use of pure cultures, which may be easily obtained by the methods worked out by Pasteur and which have been changed but little since.

However widely Pasteur's marvellous methods and discoveries have been applied, their possibilities are far from being exhausted, and an immense field lies open for their application to new fermentation industries that will benefit mankind.

École de Brasserie,
Institut Pasteur, Paris.

FEDERAL COUNCIL FOR PURE AND APPLIED CHEMISTRY

For many months before his death Lord Moulton was occupied with the elaboration of a scheme for ensuring the closer co-operation of the various interests—academic and technical, pure and applied—which are embraced by our numerous chemical organisations. Lord Moulton was convinced that a serious defect in the organisation of public affairs in our country lies in the lack of solidarity of sentiment and of expression amongst chemists as a body. The culminating task of his life consisted in unifying the scattered chemical talent of the country and teaching it to work for the common cause in unison with the engineer and the manufacturer; as Director of the Department of Explosives Supplies he accomplished this task, but none realised better than he that the extravagant cost of the achievement was largely traceable to the absence of previous organisation among chemists. His insight orn of genius and sharpened by experience, ld Lord Moulton that the conditions of peace e much like those of war: co-operation saves bour and treasure, and leads to that efficiency hich is essential in a modern economic struggle. e saw the necessity of creating for chemistry corporate organisation in which all branches the science and practice should be embraced, hich could put forward its collective view ith the same force as had long been possible other learned professions, such as engineering, edicine, and the law.

With this outlook Lord Moulton threw himlf whole-heartedly into the scheme of the ederal Council for Pure and Applied Chemistry, nd drafted an appeal for funds in order to d British Chemistry of certain obvious disadantages under which it now suffers. He elieved that what is needed in this country is a entral organisation for chemistry, which should ring under one roof our several important hemical societies, an exhaustive library, ample ooms for administrative purposes and for cientific meetings, and, if possible, the social menities of a club. There was no thought of njuring the splendid traditions of the Chemical ociety and the Society of Chemical Industry; oth should retain their autonomy, but if these nd other smaller allied societies are to meet odern requirements there must be that closer o-operation which only comes from physical roximity.

The provision of the needs just above menioned calls for funds, and in the appeal which ord Moulton drew up at the end of 1920 he stimated that £250,000 was required for remises, equipment, etc., and a further £250,000 or literary purposes. This appeal was agreed y the Federal Council and was signed by the residents of the sixteen societies then enraced by the Federal Council; it was being laced before prominent personalities in the hemical and manufacturing world for several onths previous to the sudden death of Lord oulton in March of last year.

We have lost our leader; we realise that e cannot hope, in the present condition of the orld's financial affairs, to raise £250,000 for ur project of placing chemistry in a position imilar to that now enjoyed by engineering, edicine, and the law. Pending the better imes which we all believe are in store for British industry and British enterprise, we can, however, do much to advance our project. We lready have in existence a unifying body. The Federal Council for Chemistry was founded everal years ago with a view to meeting two generally recognised needs: first, the promotion of co-operation and economy of effort between our several large chemical societies, and, secondly, the representation of those interests of chemical science and technology which are too general in character to be the sole province of either of our existing organisations. Following the example set by the creation of our own Federal Council for Chemistry, many other countries have formed a national Council for Chemistry on very similar lines; all these national councils are now combined under the International Council for Chemistry which was inaugurated at the annual meeting of the Society of Chemical Industry in 1919 (J., 1919, 38, 208 T). The International Council now includes the national chemical councils of twenty-four States (J., 1922, 41, 328 R); it has held its three previous annual meetings in Brussels, Rome, and Lyons, and is to meet next year in Cambridge.

Hitherto, the International Union for Chemistry has been largely occupied with the organisation of its numerous international interests, such, for instance, as concern the production of international tables of fundamental constants of the elements and the introduction of a generally agreed system of chemical nomenclature; the "Tables annuelles de constantes et données numériques de chimie, de physique et de technologie," edited with such success by Dr. Charles Marie, are published under its auspices. Now that these and related matters of importance have been dealt with, and organisations created which will rapidly increase its productivity, it is intended to extend the scope of the Union and to include in its annual proceedings the presentation and discussion of reports on the progress and development of large scientific and technical questions. This branch of the Union's activities was indeed inaugurated at the recent meeting at Lyons, and the meeting at Cambridge next year will therefore be one of great interest and importance.

Our own Federal Council has taken an active part in the pioneer work of the International Union, although it should be stated that the bulk of the progress made has been due to the devotion of Professor Charles Moureu, its President for the last three years, and our other French colleagues. The Federal Council, in addition, has been able to do a good deal in securing joint action between our large organisations, such, for example, as promoting the arrangement for some measure of co-operation between the Chemical Society and the Society of Chemical Industry in the weekly publication of the *Journal* of the latter Society. A vast amount remains to be done in this direction, and especially in the establishment of a solid feeling that the chemist should have at heart the interests of his whole subject rather than that merely of the particular chemical society of which he is a member. The promotion of this feeling calls for the united effort of all chemists. It was with this purpose in view that the societies composing the Federal Council were asked to nominate to the Council men who would be active in initiating and carrying into operation measures for the strengthening of the whole chemical organisation of the country.

Hitherto, the principal expenses of the Federal Council have been the annual subscriptions to the International Union, and the revenue has consisted mainly of grants from the Chemical Society and the Society of Chemical Industry. These grants cannot be increased, because both societies have already large calls upon their limited resources for other indispensable purposes; yet money is required to enable the Federal Council to develop its work on an adequate scale. At the meetings of the International Council in Brussels, Rome, and Lyons the foreign organisations corresponding to our Federal Council entertained the delegates to the Union. We shall have to return the compliment at next year's meeting in Cambridge. Further, whilst the prevailing financial stringency makes it impossible to carry out the large scheme outlined by the late Lord Moulton, it is at least necessary that we should make a beginning. We therefore ask for contributions to be devoted towards the scheme, and so convert into a useful form the sympathy of our chemical colleagues with the objects of the Federal Council.

In the present article we have touched on many questions—and therefore, perhaps, in too scanty detail—and have left unmentioned many others which are also of vital importance to the chemical organism. The nudity of our chemical compendia, the paucity of our efforts to cultivate the social side of chemistry, and so develop the excellent work of the Chemical Industry Club—these and many other matters call for attention; they call for a few chemists to lead and for many to collaborate, and above all they call for financial support.

With the above considerations in view the Federal Council has appointed a Benefaction Committee, with the request that they will collect funds. The Committee now consists of Sir William Pope, Dr. E. F. Armstrong, Mr. H. E. Coley, Mr. E. V. Evans, Mr. Emile Mond, Mr. W. J. U. Woolcock, and Dr. S. Miall; other names may be added at a later date. It is intended to issue a preliminary list of subscriptions, and when this has been completed to make a widespread appeal in a more or less public manner. It is requested that contributions be sent to Dr. S. Miall, Society of Chemical Industry, Central House, Finsbury Square, London, E.C.

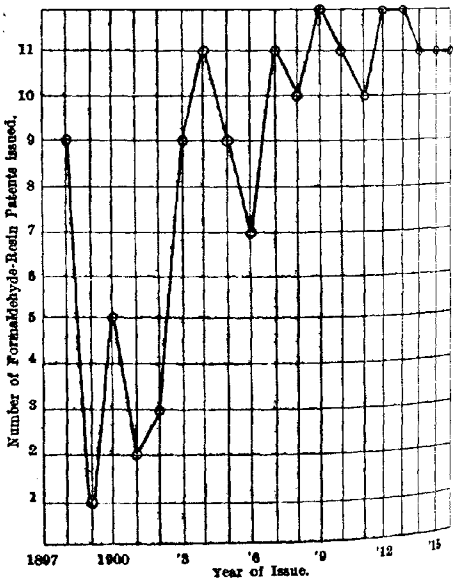
RECENT RESEARCH ON FORMALDEHYDE-RESINS

ALAN A. DRUMMOND

SINCE 1872, when Baeyer first observed that phenol reacts with formaldehyde to give a resinous condensation product, much work has been done with a view to making synthetic resins of this type commercial materials, and as a result, primarily of research by Dr. Baekeland, the technical world has come to realise the possibilities of phenolic condensation products for use in many industries. The object of the earlier workers was merely to produce substitutes for shellac, and it was not until recently that the peculiar properties of these resins, notably their resistance to heat, electricity and chemical action, were appreciated fully. Varnish manufacturers are still actively investigating the possible applications of synthetic resins, but the lack of uniformity in behaviour of different batches, made under supposedly identical conditions, has so far precluded extensive use in this industry.

During the past thirty years many data, more or less empirical, concerning synthetic resins have accumulated, mainly in the patent files. The number of patents taken out year by year in Great Britain since about 1897 up to the beginning of the war, shows clearly that interest in synthetic resins has been increasing steadily.



The graph indicates a general upward tendency in the number of patents, reaching a maximum soon after the publication of Baekeland's lecture in America on Baekelite and its applications (*J. Ind. Eng. Chem.*, 1909, 149). Research in this subject was, naturally, retarded by the war, but it is now receiving renewed attention. The later patents relating to the subject still convey an impression of empiricism, but this may be due to the nature of the record, because systematic scientific method can rarely be deduced from a survey of patent specifications. The fact remains, however, that little or no fundamental work is being published on the exact course of the reaction involved in the production of phenol-formaldehyde resins. It is, perhaps, more along the lines of physico-chemical investigation that new knowledge will come. Up to the present, work has been concentrated mainly on the investigation of the chemical properties of the condensation product, on its behaviour towards various reagents, and on efforts to identify the individual constituents of the resins. As a result of this chemical study, attempts have been made to ascribe a definite constitution to the colloidal resin, but the results have been conflicting. Baekeland deduced an anhydride formula from the results of elementary analysis, starting with an assumption based on work done by Lederer (*J. prakt. Chem.*, 1894, **158,** 223), and Manasse (*Ber.*, 1894, **27,** 2409), who was the first to claim the synthesis of oxybenzyl alcohol by the condensation of phenol and formaldehyde in presence of basic catalysts. Raschig (*Zeit. angew. Chem.*, 1912, 1939) disputed Baekeland's conclusions, but without advancing very clear proof of his own deductions.

Recent work by Coster van Voorhout (*Chem. Weekblad*, 1920, **17,** 2) has supplied more definite information concerning the course of the reaction between phenol and formaldehyde. This worker has investigated the changes in viscosity that occur during condensation, and has successfully isolated chemical individuals from the reaction mixture. He has separated crystalline *o*- and *p*-oxybenzyl alcohols, when an alkaline catalyst was used, and he has shown the presence of dioxydiphenylmethane when the condensation was initiated by acids. His conclusion was that in all probability Bakelite consists of dioxydiphenylmethane (probably polymorphous) in colloidal solution, together with traces of phenol and formaldehyde.

It must appear from the foregoing that, valuable as a knowledge of the chemical constitution, based upon an investigation of the final condensation product, undoubtedly is, further practical advance can more readily be achieved by a synthetic study of the resin, *i.e.*, by investigating it before and during synthesis, rather than analytically after the synthesis has taken place. Such a study involves physical, as well as chemical examination: a study of the changes during condensation in such physical properties as viscosity and density. Coster van Voorhout's paper contains only a brief reference to viscosity determinations; more data of this kind are wanted, and particularly by the manufacturer of formaldehyde-resins.

Air-drying varnishes or lacquers, containing formaldehyde-resins, are readily obtained; they yield films of good elasticity, which can be improved by the addition of such substances as celluloid, collodion, and cellulose acetate, but their durability in use is poor unless they have been stoved. A non-stoving varnish of acid-resisting properties would be of great service even in the chemical industry alone, particularly if it were also highly resistant to heat.

Another difficulty has been the restricted solubility of the finished resins; alcohol has proved to be the best solvent, even for the resins in their more soluble condition, *i.e.*, before the final reaction has been effected by stoving. Spirit as a solvent is not altogether desirable; for one reason, varnishes containing alcohol are liable to leave a track of trapped air-bubbles on the surface that is being covered, and these bubbles or pin-holes are not easily removed. Linseed oil, turpentine and similar oils are more useful varnish media. A process for obtaining oil-soluble synthetic resins has been protected (Albert and Berend, E.P. 15,875, 1914). Such so-called "albertole" resins apparently contain, in addition to the formaldehyde-resins, at least 50 per cent. of natural rosin, and although the process claims to effect a specific reaction between the synthetic and the natural resins so that a durable oil-soluble varnish is obtained, it is difficult not to suspect the durability of a varnish film of such composition. A claim for the production of oil-soluble resins has also been made, whereby advantage is taken of the different reactivities of *m*- and *p*-cresol with formaldehyde; *p*-cresol, with an excess of formaldehyde and an acid catalyst, is stated to give a resin soluble in oils (Robinson-Bindley, Weller, and Dulcken, E.P. 134,563, 1918). The biggest field of application for synthetic resin varnishes, as now made, is as insulators in the electrical industry, where they are used as stoving varnishes, particularly for coating insulating fabrics and tapes, and for impregnating coils.

Following the amalgamation of three of the foremost American manufacturers of insulating materials under the ægis of the General Baekelite Company (*cf.* J., 1922, 320 R), the pooled resources of scientific and technical information should make possible very distinct advances in the methods of manufacture and application of formaldehyde-resins. In view of this strong competition, British manufacturers of electrical insulating material who are beginning to realise the specially advantageous properties of these resins, are likely to be seriously handicapped in their efforts to establish sound commercial processes, unless their methods have a firm scientific basis, founded on the results of systematic research.

THE EXTRACTION OF GASOLINE FROM NATURAL GAS

GEORGE A. BURRELL*

Part I.—Extraction by Compression and by Absorption in Oil

The natural-gas gasoline industry was started about the year 1904 in the oldest fields of the United States, viz., those of northern Pennsylvania, and its development to the commercial stage followed as a consequence of the impossibility of meeting the demand for gasoline by any other means. In 1904 the automobile was still in its infancy, but a demand had already been created for gasoline, hitherto a by-product of little commercial value. Although some gasoline was extracted from natural gas in 1904, the industry did not assume commercial proportions until the year 1910. Table I gives statistics of production in the United States for the years 1916—1920. The total amount of gasoline of all kinds produced in the States in 1920 was about 4·5 billion gallons.

TABLE I

Natural-Gas Gasoline Produced in the United States, 1916—1920

Year	No. of operators	No. of plants	Gasoline produced			Gas used	
			Gallons	Value $	Average price per gall. cents	Volume 1000 cubic feet	Value $
1916	460	596	103,492,689	14,331,148	13·8	208,705,023	14,609,300
1917	750	886	217,884,104	40,188,596	18·4	429,287,797	34,343,000
1918	503	1,004	282,535,550	50,363,535	17·8	449,108,661	40,419,700
1919	611	1,191	351,535,026	64,196,763	18·3	480,403,963	41,314,700
1920	576†	1,154	384,743,962	71,788,122	18·7	496,430,952	41,700,000

† Not comparable with other years because of new classification adopted. (*From statistics of U.S. Geological Survey.*)

At the present time the production of gasoline from natural gas amounts to about 8 per cent. of the total production. This figure appears small, but it is important, because the addition of natural-gas gasoline to refinery gasoline increases the volatility of the latter, and so makes available much larger quantities of less volatile crude-oil distillates for conversion into gasoline. In no other way could the refiner at the present time meet satisfactorily the almost insatiable public demand for motor gasoline. It is probable that if natural-gas gasoline had not been forthcoming for increasing the volatility of motor fuel, the internal-combustion engine for automobiles would have been developed so as to burn less volatile oils, for it is certain that the problem of supplying satisfactory motor-cars would have been solved in some way or other.

OCCURRENCE OF GASOLINE IN NATURAL GAS

Natural gas invariably accompanies petroleum in oil-sand. At times the quantity is almost negligible, usually it is considerable, and frequently it is sufficiently great to turn a well into a "gusher." In the oil-sand the natural gas becomes saturated with the low-boiling constituents of the petroleum and these escape with it from the well.

Natural gas is divided into two great classes: "dry" or "lean," and "wet" or "casing-head" natural gas. By "dry" natural gas is meant gas from natural gas wells, not containing oil, at least not in commercial quantities. In some fields in the United States it is not known until the drill strikes the formation, whether an oil well or a gas well will be found, so close together do the pockets of natural gas and oil lie in the stratum. In such fields it is not uncommon to find both gas and oil in paying quantities in the same well. The term "paying quantities" must be used with reservation, because what would be a paying gas-well in the Eastern States, near extensive pipe-line systems and good markets, would not be a paying proposition in some parts of the West, where the natural gas cannot be conveyed to market except at prohibitive expense. It is different, however, with the oil, which can be stored, and of which a large quantity can be conveyed a long distance by a relatively small pipeline; or it can be transported in tank cars.

"Wet" or "casing-head" gas is found in intimate contact with oil. It emerges from an oil well at the casing-head, finding its way thereto through the annular space in the well between the tubing and the casing.

"Dry" natural gas seldom contains more than 0·5 galls. of gasoline per 1000 cb. ft.; "casing-head" gas contains up to 10—15 galls. per 1000 cb. ft. However, there is no sharp line of demarcation between the two kinds. "Casing-head" natural gas is but rarely found with a lower gasoline-content than "dry" natural gas.

It seems fairly probable that the hydrocarbons of "dry" natural gas were formed by processes analogous to those by which the oil was formed. In some cases, if not many, the natural gas found its way from the main body of the natural hydrocarbons, and lodged finally in the stratum where it was discovered. In its migration it freed itself from most of those hydrocarbons which are liquid at ordinary temperatures, retaining only a relatively small quantity of very volatile gasoline. "Wet" gas, however, being found in contact with crude oil of very high gasoline content, is naturally very rich in this constituent.

COMPOSITION OF NATURAL GAS

The composition of typical samples of "dry" and "wet" gas, as determined by the writer, is given below. The methane was drawn off with a Töpler pump at the temperature of liquid air, and the other hydrocarbons at gradually rising temperatures. Many fractionations were made to extract the several hydrocarbons in a sufficiently pure state. Statements in text-books to the effect that natural gas contains appreciable quantities of oxygen, carbon monoxide, hydrogen, and unsaturated hydrocarbons, have not been confirmed.

A, A'—steam stills ; B—absorbers ; C—cooling-coils under cover.

Analyses of Natural Gas

	A "Dry" gas	B "Wet" gas
Methane	84·7	36·8
Ethane	9·4	32·6
Propane	3·0	21·1
Butanes	1·3*	5·8
Pentanes, hexanes, heptanes, etc.		3·7
Carbon dioxide	Trace	Trace
Nitrogen	1·6	†
Total	100·0	100·0

* Principally butanes.

† Owing to unavoidable experimental error the nitrogen content es not appear; it is probably about 1·0 per cent.

EXTRACTION BY COMPRESSION

Gasoline was first extracted from natural gas by e compression method. The casing-head gas is bjected to pressures up to 300 lb. per sq. in., and oled with water in pipe coils, while under essure. The gasoline produced is condensed and apped in storage tanks. To secure the maximum eld of gasoline from oil wells, the gas is frequently thdrawn at the casing-head of the well under a cuum registering up to 25 in. of mercury. Under ese conditions the well simply becomes a still, and ing to the reduced pressure, it happens, not in-equently, that after the natural gas from an old ll has been exhausted, almost pure gasoline pour distils off from the oil-sand. When some oil lls are connected up with many others to a mmon gasoline plant, they remain profitable rces of gasoline long after they have become nost valueless as oil producers. In methods of -winning only from 20 to perhaps 60 per cent. the oil is recovered; hence the vast bulk of the oil mains underground. Although some gasoline mpression plants are connected to as many as 00 wells, the average number is from 100 to 300 lls. One of the largest compression plants in the ited States, producing a maximum of 9000 galls. gasoline per day, is connected to only 29 oil wells.

A natural-gasoline compression plant, in its usual m, is simplicity itself, and consists of a com-essor or compressors, either belt-driven or directly nected to a gas engine; cooling coils arranged in ders made of 2-in. pipe, on which water ps; and receiving tanks, built to withstand the ssure, where the gasoline is condensed, and out which it is automatically trapped into storage ks. Other machinery comprises water pumps, plying condensing water for cooling purposes; a oline pump to move the gasoline from tank to k and to a loading-rack for shipment; a small erator to supply electric current for lights; and sibly a little machinery, such as a drill press or e, for minor repairs. There is usually also a uum pump connected to several 4- or 6-in. n gathering lines leading to various oil leases. nected to these main gathering lines are 2-in. s leading to the casing-heads of the oil wells n which the gas is withdrawn. Some gasoline pression plants are much more elaborate than simple plant just described, because to many rators the industry has proved a very profitable , and this fact is reflected in the size and iency of their units.

ressures required to condense the gasoline from ng-head natural gas depend upon the gasoline ent. When the desirable condensable con-nents, principally pentane, hexane and heptane, present in large amounts, pressures up to 100 lb. sq. in. are sufficient, but usually pressures of to 250 lb. are employed.

In compressing casing-head natural gas to pressures above 100 lb. per sq. in., two-stage compressors are used. In the first stage the gas is compressed to about 35 to 50 lb.; it is then cooled and given its final compression. For natural gas which gives up practically all its gasoline at pressures up to 100 lb., only single-stage compressors are employed. In two-stage compression but little condensate is collected in the first-stage cooling coils. This condensate is of low gravity, usually of sp. gr. between 0·7368 and 0·7000, and is mixed finally with the bulk of the condensate precipitated by the high-stage compressor. Two-stage compression is economical, because the temperature of compression is reduced, and more gas can be compressed in a given installation.

The output of a natural-gas gasoline plant is largely limited by the handling and transportation of the product, and by the extent to which it can be used. Enough pressure could be applied to condense far more of the paraffin hydrocarbons than are liquefied, but these lighter fractions, principally propane and butane, raise the vapour pressure of the entire mixture to such an extent that railroad regulations forbid its transportation; it becomes dangerous to handle, and loss by evaporation (weathering) becomes serious.

Some of these lighter constituents can be saved and fixed for safe transportation and efficient use by the addition of naphtha, of sp. gr. 0·7778—0·7609 and 450° F. (232·2° C.) end-point, to the hot compressed gases in the condensing coils. By this method any grade of gasoline can be made, and the vapour pressure of the mixture can be lowered sufficiently to make transportation safe and use efficient. This particular method of blending is called "hot blending." Many other expedients are adopted to serve the same purpose, but "hot blending" is the best.

In the Eastern States, where oil products of all kinds command a higher price than in the west, gasoline plants producing as little as 200 galls. per day are profitable under some conditions. It is rare in the eastern fields to find a compression plant producing more than 2000 galls. daily, whilst in the western fields of gaseous oil wells, plants to produce 5000 galls. daily are not uncommon.

A complete compression plant to handle about one million cb. ft. of casing-head natural gas per day, with gathering lines, vacuum pumps, booster stations, compressors, gas engines, buildings, water supply, tanks, loading racks, etc., costs about $150,000. Production costs, including labour, overhead charges, depreciation, depletion, taxes, insurance, sales, supplies, repairs, etc., amount to from 7—13 cents per gall. Natural gasoline in the east now sells for about 18 cts. per gall. at the plant, and in the mid-Continent fields for about 15 cts. per gall.

ABSORPTION PLANTS

The oil-absorption method as applied to natural gas is essentially the same as that applied to shale gas by James Young of Clippens, England, in 1876. It was first applied to natural gas by the Standard Oil Co. of New Jersey in 1906, and a U.S. patent was issued to George M. Saybolt of that company in 1911. This patent has been the subject of litigation for about three years, but a decision is due shortly.

The oil-absorption method has a field of operation distinct from the compression method in that it is applied to natural gas which contains a relatively small amount of gasoline vapour. The compression method is usually applied to casing-head gas containing more than 1 gall. of gasoline per 1000 cb. ft., and the absorption method to so-called "lean" or "dry" natural gas containing less than this quantity. However, the oil method is steadily usurping the field long held by the compression method, as operators are learning by experience that oil plants will work efficiently on rich natural gas and at low pressures.

The great bulk of the natural gas used industrially in the United States is the "dry" gas, which comes from gas wells and supplies light and fuel to cities like Pittsburgh, Pa., Cleveland, Ohio, Cincinnati, Ohio, Louisville, Ky., Tulsa, Okla., Fort Worth, Texas, and thousands of other towns and cities. The compression method cannot be used to extract the gasoline from this gas because the partial pressures of the desirable condensable constituents are so small that a prohibitive pressure would be required to precipitate the gasoline-content. The oil-absorption process is used instead, and by it the gas is brought into contact with an oil of sp. gr. 0·8333—0·8140, and having the following general characteristics:—

Characteristics of Absorbent Oil

Specific gravity	0·8284
Pensky-Marten closed-cup flash-point ..	250°F. (121·1°C.)
Cold test	28°F. (—2·2°C.)
Viscosity (Saybolt)	1,300

Distillation Test

Fractions	Per cent.	Deg. F.	Sp. gr.
1	10	537 (262·2°C.)	0·8159
2	10	543 (261·1°C.)	0·8178
3	10	551 (270·6°C.)	0·8192
4	10	557 (273·9°C.)	0·8202
5	10	565 (278·3°C.)	0·8211
6	10	575 (283·9°C.)	0·8221
7	10	585 (289·4°C.)	0·8245
8	10	595 (295°C.)	0·8269
9	10	618 (307·8°C.)	0·8309
10	8·5	660 (331·1°C.)	0·8373
	1·5	above 660 (331·1°C.)	

The oil containing the absorbed gasoline is pumped to a still in which the gasoline is distilled off, usually by means of live steam. The oil is then pumped back to the absorbers for another charge of gasoline, and so the process is continued, the oil acting simply as a carrier of gasoline from the absorbers to the still.

A complete unit consists of absorbers, weathering or vent tank, heat-exchangers, oil-cooling coils, still and condensors, pumps, boilers, piping, gas engine and compressors.

The absorbers vary in size and number according to the pressure and quantity of the gas and its gasoline-content. From the absorbers the oil passes to a weathering tank where the pressure is released, and gases that are loosely held are withdrawn to the compressor. The oil next passes to a heat-exchanger where it is heated by means of hot oil coming from the still, thereby reducing the fuel requirements of the plant. From the heat-exchangers the oil passes into the still where it meets live steam and where the gasoline is distilled from the oil. A mixture of steam, gasoline vapour and some absorbent oil pass out of the still, first into a so-called "knockout" box, where most of the water vapour and absorbent oil is precipitated under thermostatic control at temperatures of 170°—180° F. (76·7°—82·2° C.), and thence to the gasoline-cooling coils where the gasoline is condensed. The oil, freed of its gasoline, passes out of the still through heat-exchangers into oil-cooling coils, where its temperature is further reduced by means of spraying water on the coils, and thence into the top of the absorbers for another charge of gasoline.

All sorts of apparatus to produce the above effects have been tried, such as horizontal and vertical absorbers, different kinds of filling material for the absorbers, such as wooden baffles, cobble stones, steel turnings, clay forms, etc., tubular and double-pipe heat-exchangers, open and closed types of steam stills, vertical stills, fire-heated stills, electrically and gas-engine operated pumps; and all this experimentation is resulting in standard types of apparatus of good design, to fit whatever conditions are encountered.

The type of plant just described is called an absorption plant, but, as a matter of fact, frequently more than half of the gasoline is produced by a compressor which is always included as part of the equipment. The absorbent oil extracts hydrocarbons from the natural gas which cannot be condensed in the gasoline-cooling coils of the steam-still. Therefore these vapours, along with other light vapours from the vent tank, are compressed up to pressures of 250 lb. per sq. in. and cooled in water-cooled coils while under these pressures. There results a deposit of gasoline lighter in weight and more volatile than the gasoline produced from the still, but which, when mixed with the latter, is transportable and usable. This combined product, known as "absorption gasoline," is more stable and of a lower gravity than ordinary compression gasoline. For this reason it is a preferred product and sells for one to two cents more per gallon. This is one reason why more and more casing-head gas is being treated each year by the absorption method than by the compression method. Another reason is that air enters the pipe-lines which draw natural gas from the wells under reduced pressure. The introduction of air decreases the capacity of the compressors, and, what is far more important, diminishes the partial pressure of the gasoline fractions in the gas so that higher and usually prohibitive pressures have to be employed to condense all the gasoline. The introduction of some air into pipe-lines leading to the absorbers of an absorption plant has but little effect on the efficiency of the plant. Rarely can the air-content of natural gas in compression installations be kept below 12 per cent.

It is also true that if the plant is efficient and if the operators have taken advantage of the best information available, all compression plants have small absorption plants to treat their residual gases, because these contain a certain amount of gasoline. No matter what pressure be used to precipitate it, the gasoline has an appreciable vapour pressure and inevitably finds its way into the outgoing gas; the amount will range up to 0·5 gall. per 1000 cb. ft. The best practice is to absorb this remaining gasoline in naphtha, in a tower, the naphtha remaining in contact with the gas long enough to raise its Beaumé gravity five or six degrees, after which it is diverted to a storage tank and a fresh supply added.

Thus we see that a compression plant is really a combination compression-and-absorption plant and an absorption plant is a combination absorption-and-compression plant. As the former combination is more selective in producing a gasoline free from latile constituents, it is coming into favour as an lround type of plant for treating both "wet" and dry" natural gas.

The colder the absorbent oil, the better does it sorb gasoline; hence in oilfields where water is arce, or hot in the summer time, artificial methods ve been adopted to cool the oil. These methods ually take the form of some kind of refrigeration stem, *e.g.*, ammonia coils. This plan has met ith some success although such installations are ry few.

In compression plants, expansion engines are used a limited extent to cool the hot compressed gas om the compressors. In these engines, compressed s is expanded from the power cylinder of an gine, and thus cooled it is passed through the ter tubes of double pipe coils, inside of which sses the gas to be cooled.

Most of the oil-absorption plants are installed on in lines of natural-gas companies supplying ies with gas for light and heat. Almost invariably the plants are located on the discharge le of compressor stations already installed for rcing natural gas to market These compressor tions are adopted by the gas companies when the essure of the gas from the wells has declined to a int that is insufficient to force the gas to market. is has occurred in all the natural-gas fields in e eastern part of the United States and in most the western fields. The natural-gas industry is declining one and already some gas companies ve had to mix artificial gas with their natural s to supply their customers. This is especially e in the winter time when consumption reaches peak.

The pressure of the natural gas at these stations ies between 25 and 300 lb. per sq. in., and as rule ranges from 100 to 200 lb. At higher ssures less oil is required for extraction than at er pressures, for the same quality of gas. The ntity of oil is the principal determining factor fixing the cost of an absorption plant, because more oil that is required, the larger must be absorbers, pumps, stills, boilers, lines, and er equipment. Therefore natural-gas companies e found in the gas delivered from their comssor stations, conditions almost ideal for the cient working of the oil-absorption process. In ition, they had a water supply already at hand, te, working force, shop equipment, houses, etc., of which only had to be enlarged in building absorption plants.

Depletion of Heating Value

xtensive tests have shown that the heating e of dry natural gas is lowered but little by racting the gasoline. Only 1 to 5 pints of line per million cb. ft. of gas are removed. s is equivalent to 10 to 20 cb. ft. of gas per sand, and corresponds on the average to a ease of 2 per cent. or less in the heating value inary dry natural gas has a calorific value of –1200 B.Th.U. per cb. ft., hence the slight ease still leaves a gas far higher in heating e than artificial gas supplied to consumers. depletion in volume due to the extraction of line from casing-head gas may, however, be er cent. or more, because of the higher gasoline ent of this gas. The heating value is, however, very high; as much as 1500—1800 B.Th.U. cb. ft., owing to the preponderance of the hydrocarbons ethane and propane, with heating values of 1800 and 2500 B.Th.U., respectively.

Natural gas is sold at prices ranging from 30 to 75 cts. per 1000 cb. ft.; but little artificial gas of 500 to 600 B.Th.U. per cb. ft. is sold for less than $1·00 per 1000 cub. ft. in the United States.

The extraction of gasoline from natural gas is a real conservation measure. Most of the casing-head gas thus treated formerly went to waste, after the relatively small requirements of the leases for drilling and pumping wells had been satisfied. The gasoline extracted from dry natural gas sells for much more in that form than in the form of vapour mixed with the gas and supplied for heating and lighting purposes.

Absorption plants remove much water vapour from the natural gas. This is an advantage because in cold weather this water deposits in low places in the mains and freezes, breaking or choking the pipe and thus diminishing the output. The removal of the gasoline vapour also lengthens the life of rubbers in the patent pipe-couplings used on all main gas-lines. Some of these mains are 20 in. in diameter and several hundred miles long, and are connected with hundreds of miles of other pipes with diameters down to 1 in.

CHEMICAL INDUSTRY CLUB

Mr. A. Gordon Craig, Chairman of the Executive Committee of the Chemical Industry Club, presided at the fourth annual dinner, which was held in the Connaught Rooms, London, on November 24. Lord Riddell was the principal guest, and there were also present Sir William Alexander, Sir Max Muspratt, Mr. Roscoe Brunner, Mr. T. R. Duggan, Sir William Pope, Dr. E. F. Armstrong, Mr. A. Chaston Chapman, Prof. F. G. Donnan, Mr. P. A. Ellis Richards, Mr. J. Arthur Reavell, Dr. Herbert Levinstein, Mr. E. V. Evans, Mr. W. J. U. Woolcock, Mr. S. H. Burford, and Mr. J. A. D. Mackay (Master of the Tallow Chandlers Company).

Lord Riddell, in proposing "The Profession and Industry of Chemistry," said that he had no doubt been asked to propose the toast because he knew less about chemistry than anyone present, but during the dinner he had put a few questions to the chemical pundits near him, and he gathered from them two things, first, that the position of the chemical trade now was much superior to what it was before the war, and secondly, that the chemical trade was one of those businesses in which there was very little money. However, he discounted the latter statement because he very often went to trade dinners and he always heard the same story. Therefore, he was not surprised to hear that while the chemical industry was doing well in a way, it was doing badly financially. He knew sufficient of chemistry to know that British chemistry had a glorious tradition. It was the custom here to run our country down and other countries up; but ours was the best and the most glorious country in the world, because almost every great discovery of importance during the past fifty years had been made by a Briton; that applied especially to the chemical industry. Nearly all the great inventions of the world had been made by Britons. There was no man on earth who could be found with a brighter mind than a Briton, and he could not help thinking that it would be a good thing if politicians had to attend trade dinners, as he had to, and come into contact with the wonderful men who were silently doing all the wonderful things in science and industry, and so changing the face of the world. They did not write about it, and the general public knew little of what they were really doing. He was glad to learn that greater unity was now prevailing in the chemical industry and he only hoped that that would lead to greater exports, because the future of our country depended upon our export trade.

Prof. F. G. Donnan made a humorous reply to the toast, and was followed by Mr. Roscoe Brunner, who said that he had that morning presided at a meeting of the Joint Industrial Council for the chemical industry, where they were lectured by one of the labour men upon brains and how to put them into industry. This man said that he had lately met a man who had so successfully put brains into his business that he had not reduced wages but had been able to lower his wages bill by £20,000 during the past year. He recommended that idea of putting brains into business to all who were connected with the chemical trade, but he entirely agreed with Lord Riddell that Britishers were far too apt to belittle themselves, and he had represented, on behalf of the chemical trade as a whole, to that meeting of the Joint Industrial Council that the chemical industry had always put brains into the business and was putting more brains in now than ever before. Some of those in the industry had been looking to the Club to help bring about greater unity, and they had also been looking to the Federal Council for Pure and Applied Chemistry. It was to be hoped that their efforts might be successful in bringing together the warring but friendly societies which represented the chemical profession and the chemical industry. They all looked forward to the Club doing a great deal for those warring elements, which, it was hoped, would become very much more friendly in the future, to the great advantage of the profession and industry.

Brigadier-General Sir William Alexander, proposing "The Chemical Industry Club," said the history of the Club was a short but glorious one; it was doing a great deal of good. Lord Riddell had pointed out how Britons had usually been the initiators of new inventions, but initiation did not mean everything. There was development after the invention, and if we paid more attention in the future to development we should reap the financial benefits which hitherto we had allowed others to take from us. He had recently returned from America, where he had been the guest of the Chemists' Club of New York. That, to him, was a wonderful institution which brought together chemists of all classes. He hoped that in time we should have in this country a club on the same lines, where chemists from all parts of the Empire and America could meet and converse.

Sir William Pope, who replied, said there was a danger of chemists getting into boastful habits, after the very fine speeches that had been heard that evening. He looked to the Chemical Industry Club to play a very great part in pulling together the various chemical interests in this country, and what they really wanted now was the assistance of men like Sir William Alexander and other leaders of chemical industry to come and help the Club, and to assist in launching it on to a much broader basis. Although they had every reason to be proud of what the Club had already done, all associated with the profession should put their heads together and endeavour to raise the status of the Club, and make it a still greater factor in the advancement of chemical industry and chemical science.

Mr. C. S. Garland, M.P., proposed the Guests, and made special reference to the presence of Sir Max Muspratt and Mr. Duggan.

Sir Max Muspratt, replying to the toast, said he was an extraordinary believer in the human touch in industry. A short time ago he was asked to give an inaugural address at the new Widnes Chamber of Commerce and he chose as his subject "The Human Factor in Industry." He ventured to say there at some length what he would now say in a very few words. There was an absolute necessity that we should allow the human element and the human conception to enter into our industry and our science. Many of the things that Lord Riddell had said were absolutely true. We Britons did underestimate ourselves; we had a certain amount of reserve and thought it was bad form to talk about what Britons had done in industry and science; that was because we did not understand and trust one another sufficiently. No body of friends had the slightest objection to one or the other blowing his own trumpet in reason. The other extreme of not blowing one's trumpet because we were not friends, meant that the whole of the British Empire was losing a valuable asset. We wanted, from the smallest laboratory boy to the biggest professor, to learn that we are all members of a great body of scientists and industrialists. We wanted it to be realised from the most humble apprentice in the works to the chairman of the biggest company that we are all one body striving with heart and soul to keep England in its proud position at the head of the chemical industry of the world; and it was because functions like this helped many members of the chemical industry and profession to realise that human touch that he would always be proud to be present, whether as a guest or as the humblest member.

Mr. T. R. Duggan (Chemist's Club, New York) was also called upon to reply. He said it was twelve or fourteen years since he had had the pleasure of speaking to an English audience. He was in the habit of speaking to Americans, and it was very easy to speak to Americans, whereas it was not so easy to speak to Englishmen. They had made very kind references to the Chemist's Club of New York, and he could only repeat that its members would be extremely pleased to welcome any members of the British Chemical Industry Club at any time they should find it possible to visit New York. Already there had been considerable intercourse between the two Clubs, thanks to the efforts of Mr. Coley, the secretary of the Chemical Industry Club. The New York Club was started many years ago, and it might surprise some of them to know that it owed its existence to Dr. Schweitzer, who was an extremely clever man, a German, but a naturalised American citizen. The American Club had good premises, thanks to the generosity of a chemical manufacturer, which were worth £150,000, half of which was mortgaged. The premises consisted of ten floors nd there were thirty rooms, of which twelve were r residential purposes. The New York Club found essential to have resident members; they helped nsiderably in bringing to the Club those who ould not come if they were not sure of meeting meone. He himself had lived at the Club for leven years. In many ways the Club premises in Whitehall were better than those in New York ecause in New York the restaurant did not pay, nd if the London Club moved into larger premises han those at Whitehall Court and started its own estaurant it might have the same experience. The ifficulty in that case was that on certain days of he week there were hardly any members using the lub and yet the staff had to be maintained all the ame. In New York they had a staff behind the estaurant of fifteen which had to be kept up, and ometimes there were two waiters to one diner. It ad been mentioned that he was one of the original members of the Society of Chemical Industry; he was one of the original starters of the Society, not he original that they had in mind, but the original efore that. There was a dispute as to when it was tarted. It was not started in the north of England ut in London by "Tommy" Tyrer one night owards the end of 1880. He himself had to go down o the Institute at Finsbury and there was a party f fifty or so present, which formed the nucleus of he original Society of Chemical Industry. There was another meeting in the following January at which 150 were present, and he was on the committee which was formed at the first meeting. For ome reason he was not on the second committee, ut that was the real history of the start of the Society of Chemical Industry. Unfortunately "Tommy" Tyrer was no longer with us, but his on would probably remember the meeting.

Proposing the toast of "The Chairman," Dr. E. F. Armstrong said Mr. Craig was a chemical merchant, but there were several kinds of chemical merchants. There was the chemical merchant of the very highest class who rubbed off the German abels from the bottles before he placed his own upon them; there was the chemical merchant who glued his own label, a great big one, on top of the German label; and then there was Mr. Gordon Craig. He thought the Club was very fortunate in having him as its chairman.

The Chairman, in reply to the toast, assured those present that if ever he did deal in German goods he informed his customers that they were German. As to the Club, he wished to emphasise the fact that it was a social club. It was a live club and a growing club, and it was intended that the club should grow and outgrow its present premises. As chairman of the Executive he wished o say that they felt they were on the right lines. They now had the support of the most eminent members of the chemical industry and of the Federal Council on the Executive of the Club, which was a great asset. It was also to be emphasised that the Club was intended for recreation and for bringing all classes of chemists together, rom the academic man right down to the humble merchant, such as himself. It might be that they were sometimes not in sufficiently close touch with he manufacturers; well, here was the opportunity o get into close touch with one another and discuss verything from their own points of view. That was what the Chemical Industry Club wanted and aimed at.

SOCIETY OF CHEMICAL INDUSTRY

NEWS FROM THE SECTIONS

EDINBURGH AND EAST OF SCOTLAND

Dr. H. E. Watt presided at the meeting which was held in the Hall of the Pharmaceutical Society, Edinburgh, on November 14. The admission of seven associates was approved.

Prof. G. Barger delivered an address on "Some Recent Advances in Biochemistry." After a short retrospect of the early beginnings of biochemistry, the lecturer dealt with recent work on the proteins by Dakin and others, particularly that relating to partial racemisation. Dakin's explanation of this phenomenon makes clear the possibility of a separate protein for each species; this is known to be the case with the albumin of the egg of the duck and the hen, the difference between the two proteins having been demonstrated by their anaphylactic relationships. It also explains in part the difficulty of synthesising proteins, as the use of alkali in connecting up different amino-acids will bring about partial racemisation. By the use of butyl alcohol and continuous extraction of the amino-acids from solution in water, Dakin found in casein β-hydroxyglutamic acid, an amino-acid which had not hitherto been detected and which constitutes 10 per cent. of the weight of the protein. Perkin and Robinson's work on harmine and harman was then briefly described, and also recent work on hormones and on the extraction of the very active substance thyroxin from the thyroid gland and of insulin from the islets of Langerhaus. An important development in the therapeutic application of chemistry is the production by the Bayer Company of a substance which is a specific remedy for sleeping sickness, and whose efficiency lies in its power of preventing the fission of the trypanosomes. Of considerable interest in connexion with physiological effects and chemical constitution is the *syn*-oxime of perillaldehyde, which has been prepared in Japan from the essential oil of *Perilla nankinensis*, and is claimed to be 2000 times as sweet as sugar, although the *anti*-oxime of the same substance has a bitter taste. In conclusion the lecturer described the production of glycerol from sugar by alcoholic fermentation in alkaline medium.

NOTTINGHAM

At the meeting held on November 22, Mr. S. F. Burford presiding, Mr. S. R. Trotman read two papers, one on "Bleaching Cotton with Hypochlorous Acid," and the other, in conjunction with Mr. D. A. Langsdale, on "The Action of Ozone on Wool and Chlorinated Wool."

In continuation of work already described (*cf.* J., 1922, 219T) the bleaching of cotton by hypochlorous acid was further investigated. Hypochlorous acid itself, and a solution made from bleaching powder and boric acid, showed very similar rates of absorption by the fabric. The absorption from bleaching powder is much more gradual. The hypochlorous bleach gives whiter goods, the percentages of ash and oil are lower, and the copper value (an index of the oxycellulose formed) is much lower than that obtained by the usual process. The use of hypochlorous acid obviates the necessity for a "sour," and hence saves both material and one handling of the goods.

When commercial chlorinated wool was exposed to the action of ozonised air for a week, all the effects of chlorination already described (*loc. cit.*) are accentuated. The proportion of fibres damaged by the loss of their epithelial scales is increased, and the amount of wool dissolved by alkalis is greater, but there is a loss in felting power and elasticity. Very similar effects are produced by other agents, *e.g.*, *Bacillus subtilis*, which are capable of destroying the scales of the wool fibres. All these results give a foundation for the complaints that unshrinkable wool does not wear well.

LIVERPOOL

A special meeting of the Section was held in the University on November 29, under the scheme for co-operation between this Society and the Chemical Society. Mr. A. T. Smith occupied the chair, and about 60 members, Fellows of the Chemical Society and friends, were present. Prof. E. C. C. Baly delivered a lecture on "Photo-catalysis, Part III.: The Photosynthesis of Naturally-occurring Nitrogen Compounds from Carbon Dioxide and Ammonia," in which he summarised the work on this subject done by himself, in collaboration with Prof. I. M. Heilbron and Mr. H. J. Stern. The chairman, Prof. Heilbron, Capt. F. A. Freeth, Mr. A. Morton, Mr. H. M. Langton, Dr. C. H. Clark and Mr. R. Thomas took part in the discussion.

The Annual Dinner of the Section, in conjunction with the Liverpool and North-Western Counties Section of the Institute of Chemistry, was held on December 2 in the Midland Adelphi Hotel, and was attended by over 120 members and friends. The chair was taken by Dr. F. J. Brislee, chairman of the local Section of the Institute of Chemistry, and among the guests were the President of the Society and Mrs. Armstrong, the Lady Mayoress of Liverpool, Sir Max Muspratt, Bt., the Hon. W. and Mrs. Hulme Lever, Mr. John Gray, Dr. G. C. Clayton, M.P., Mr. Horatio Ballantyne, Alderman and Mrs. W. Muirhead, the Town Clerk and Mrs. Moon, Dr. J. P. Longstaff, and Mr. R. B. Pilcher. After a short toast list, the remainder of the evening was devoted to music and dancing.

OTTAWA

The first meeting of the current session was held on November 9, the subject of discussion being "Domestic Fuel Problems." Mr. Hambly occupied the chair; fifty members and friends were present. In introducing the subject the chairman briefly referred to the problems met with in firing both industrial and domestic furnaces.

The characteristics of different types of fuels were dealt with by Messrs. R. E. Gilmore, J. H. H. Nicolls, and H. Kohl under the following heads: (a) the relative value of chemical and physical analysis of coal and other fuels; (b) the classification of the higher types of fuels; and (c) the ignition temperature of different fuels.

Chemical analysis involves the determination of moisture, ash, volatile matter, and fixed carbon. The moisture and ash determination tell what quantity is not real fuel. The volatile matter indicates whether the fuel is smoky or not and the fixed carbon shows how much coke or charcoal a given fuel will yield. Physical analysis includes the handling, storage and burning qualities. The classification of coal into anthracite, semi-anthracite, semi-bituminous, etc. is accomplished by chemical analysis, but this must not be done without taking into account the physical characteristics. If to a chemist's certificate of analysis were attached an interpretation of the results of analysis, the layman or semi-technical man would place more value on chemical analysis than he usually does.

The Welsh coal now sold in some Canadian cities comprises at least four different grades, and the trouble with it is not due to its chemical, but to its physical properties, particularly its hardness. If the best grades of Welsh anthracite were screened and graded before selling to the consumer, they would be equal to, if not better than, the best grades of Pennsylvania anthracite. American anthracite is, however, considered the standard household fuel, and as long as this supply is available it looks as if only the price factor will control its use.

The various methods of determining the ignition temperature of coal were fully described.

Mr. E. S. Malloch outlined the practical operation of a hot-water furnace with each of the different types of fuel, and described the results obtained in each case.

BIRMINGHAM

A joint meeting with the Midland Counties Section of the Institute of Brewing was held in the University of Birmingham on November 23, when Dr. E. B. Maxted presided and Prof. A. R. Ling read a paper on "Starch and its Estimation in Barley and in Wheat."

After discussing the economic importance of starch, Prof. Ling said that in the absence of an accurate method of estimation the practice had arisen of expressing the starch content by difference as "nitrogen-free extract." This, like most of the methods of estimating starch, was inaccurate and attention was therefore devoted to the researches of C. O'Sullivan and Horace T. Brown, which provided a basis for further inquiry. It had been found that the percentage of apparent maltose produced at the end of, say, 1 hr. by hydrolysing starch with malt diastase bore a constant relation to the starch originally present. To apply this method in practice it was necessary to determine how the percentage of apparent maltose produced by hydrolysing starch varied with the diastatic power of the malt employed. This had been done, and extremely pure wheat and barley starches had been found to give identical results on hydrolysis, due allowance being made for variation in the diastatic power of the malt. The method finally evolved may be summarised as follows:—About 5 g. of finely-ground grain is extracted in a Soxhlet extractor with alcohol (sp. gr. 0·920) for 2 hrs., to remove the sugars, fats and certain proteins. The residue of starch is washed into a beaker, gelatinised by boiling for 10 minutes, cooled to 57° C., and hydrolysed with 10 c.c. of malt-extract of diastatic power 70° (Lintner) for 1 hr., with constant stirring. After boiling, the conversion liquid, together with the washings of the residue, is filtered and made up to 200 c.c.; 30 c.c. of this solution is diluted to 100 c.c. and titrated against 10 c.c. of Fehling's solution. A blank experiment, using water and malt extract only, is carried out in the same way as the actual conversion to enable a correction to be made for the reducing bodies present in the malt tract. The percentage of starch is calculated by e formula S=94·73 M′/M, in which S is the per- ntage of starch in the sample, M the percentage of parent maltose produced from dry barley or heat starch from malt of known diastatic power iven in the form of a graph) under definite con- tions, and M′ the percentage of apparent maltose elded by the sample under the same conditions, d with malt of the same diastatic power. The ethod has given accurate results with barleys and heats from the Rothamsted Experiment Station d the Olympia Agricultural and Research ation, Offchurch.

In the discussion Capt. H. J. Page said that the ethod was valuable and gave very concordant sults which accorded with the percentages of arch they expected to find in barleys and wheats. e hoped that the method would be extended to ply to other starches.

A special meeting, to which Fellows of the hemical Society resident in the Midlands were vited, was held on December 5, in the University. Dr. E. B. Maxted presided, and the following ree papers were presented by Prof. G. T. Morgan d his associates:—(1) Researches on Residual ffinity and Co-ordination. Pt. XV. Interactions Acetylpropionylmethane and the Tetrachlorides Selenium and Tellurium (with Mr. H. G. eeves).

(2) The Upper Limit of Diazotisability in the enzene Series: Aminomesitylene-*bis*-diazonium alts (with Mr. G. R. Davies).

(3) Studies in the Normal Butyl Series. Pt. II. he Four Stereo-isomeric $\beta\gamma$-Di-*p*.tolylamino-*n*- utanes.

(1) The tetrachlorides of selenium and tellurium ch induce characteristic tautomeric changes in active β-diketones such as acetylacetone and its mologues. Acetylpropionylmethane (propionyl- etone), preferably in the form of its copper rivative, behaves towards selenium tetrachloride its ordinary mono-enolic modification,

$$C_2H_5.C(OCH_3):CH.CO.CH_3,$$

l yields selenium acetylpropionylmethane,

$$Se_2(C_6H_8O_2)_2.$$

th tellurium tetrachloride, acetylpropionyl- thane reacts in its methylene-enolic form, $I_5.CO.CH_2.C(OH):CH_2$, giving rise to tellurium tylpropionylmethanedichloride, $Te(C_6H_8O_2)Cl_2$. reduction this dichloride furnishes tellurium- tylpropionylmethane, $Te(C_6H_8O_2)$, a substance ing an intense bactericidal action.

2) When treated with three molecular propor- ns of nitrous acid, triaminomesitylene hydro- oride in acid solution is diazotised only in two its amino-groups, yielding aminomesitylene-*bis*- zoniumchloride identified by conversion into inomesitylene-*bis*-azoimide $NH_2.C_9H_9N_6$ and the ichloride hydrochloride,

$$HCl,NH_2.C_9H_9(N_2.AuCl_4)_2.$$

en, however, this diazotisation with excess of ite is effected in presence of hydrazoic acid, formation of the foregoing *bis*triazo-compound ollowed immediately by the diazotisation of the d amino-group, thus leading to the production *tris*triazomesitylene, $C_9H_9N_9$. It is inferred these results that in a monocylic triamine of benzene series, only two of the three amino- ps can be diazotised concurrently. The diazo- bility of the third amino-group is manifested after the two first-formed diazonium complexes have been substituted by other groups, such as the triazo-radicle.

(3) When $\beta\gamma$-dichloro-*n*-butane, or the corresponding dibromo-compound, is condensed with *p*-toluidine, two isomeric diamines are produced having the same graphic formula:

$$p.C_7H_7.NH.CH(CH_3).CH(CH_3)NH.C_7H_7.p.$$

The less fusible isomeride is a racemoid substance resolvable by the aid of d-*o*-bromocamphor-R-sulphonic acid, into two optically active enantiomorphs, *d* and *l* $\beta\gamma$-di-*p*-tolylamino-*n*-butane. The more fusible isomeride, which is non-resolvable, is meso-$\beta\gamma$-di-*p*-tolylamino-*n*-butane. These four stereoisomeric modifications of the same diamine furnish a complete analogy with the four stereo-isomeric tartaric acids, this being the first instance in which a complete set of four basic substances containing two asymmetric carbon atoms has been isolated in definitely crystalline forms. During the condensation between *p*-toluidine and the dihalogenated *n*-butanes a basic by-product is isolated, yielding characteristic bright yellow salts, and identified as 3.5.7-trimethylacridine.

MANCHESTER SECTION AND THE CHEMICAL ENGINEERING GROUP

A joint meeting of these organisations was held in the Textile Institute, Manchester, on December 1, when Mr. W. G. Fraser read a paper on "The Chemical Engineering of Paper Manufacture." In the abridged form of the paper, as circulated, a brief outline is given of the processes and plant used in the manufacture of paper from various raw materials. The digestion and bleaching operations are described, and reference is made to the importance of beater design on the character of the beaten pulp; for example, with a high backfall close up to the roll, hydration takes place rapidly, whilst with a backfall more tangential and further away from the roll, hydration takes place less readily. Some interesting facts are noted regarding the consumption of water and coal in a paper mill; the quantity of water, including that used in steam-raising, varies from 100,000—150,000 galls. per ton for rag papers to 10,000—12,000 galls per ton for newsprint. The amount of coal may vary from 6—7 tons per ton of rag papers to 16—17 cwt. for newsprint. A table is given showing the approximate quantity of coal used for each operation in a mill which consumed 720 tons of coal in the manufacture of 265 tons of paper.

LONDON

On December 4, in the Engineers' Club, Dr. G. Scott Robertson, chemist to the North of Ireland Government, and Mr. F. Dickinson read a paper on "The Valuation of Insoluble Phosphate by means of a Modified Citric-Acid Test." Mr. E. V. Evans presided over a small attendance.

After enumerating the different kinds of insoluble phosphatic fertilisers, the authors draw attention to the insufficiency of the official citric-acid test when applied to low-grade basic slags, particularly fluorspar slags, and rock phosphate. If 1 gram of phosphate be used in the test, instead of 5 g., the analytical results give a much better indication of the fertilising value.

The discussion served to show up the extremely empirical nature of the citric-acid test, and left the impression that it is advisable to work out a new test, based on scientific principles.

THE JOURNAL

On several occasions in the past the Council and the Publications Committee have considered the feasibility of issuing the *Journal*, or a part of it, weekly instead of twice a month; but there were always obstacles which could not be overcome. Now, however, conditions appear to be more favourable, and the Council has decided to publish a weekly Journal from the beginning of next year.

At the October Meeting of Council, it was resolved, on the motion of Sir William Pope, chairman of the Federal Council, to issue the "Review" section as a separate weekly periodical, under a new name, and as the official organ of the Federal Council. To make the necessary arrangements the Council appointed the following to act as an Executive Committee:—Sir W. Pope, Dr. E. F. Armstrong, Mr. E. V. Evans, Dr. S. Miall, Mr. F. H. Carr, Mr. W. J. U. Woolcock, and Mr. C. S. Garland. In its report, presented to the Council in November, the Committee recommended: that the weekly journal should be called "Chemistry and Industry"; that for a period of one year copies of it should be placed at the disposal of the Chemical Society for distribution among those of its Fellows who are not members of the Society of Chemical Industry; and that the editorship should be offered to Dr. Stephen Miall, as the Committee had failed to come to terms with the present "Review" Editor. In accepting these proposals, the Council expressed the wish that, if possible, Abstracts and Transactions should also be issued weekly, under the same cover. The Executive Committee has since decided that this course will be practicable, and, accordingly, arrangements are now being made to issue:—(a) a weekly journal bearing the two titles "Journal of the Society of Chemical Industry" and "Chemistry and Industry," to be sent to members and subscribers at existing subscription rates; and (b) "Chemistry and Industry," under a separate cover, at a charge of 6d. per copy, or 21s. per annum (25s. abroad). The advertisements will appear in both issues.

MEETINGS OF OTHER SOCIETIES

SOCIETY OF GLASS TECHNOLOGY

The meeting held on November 22 in the University of Sheffield opened with the presentation of the Frank Wood medal, established in honour of the Society's first president, to Messrs. G. G. Middleton and H. W. Howes, students in the Department of Glass Technology of the University. In presenting the medal, Mr. Frank Wood expressed appreciation of the honour of having his name associated with it.

Prof. W. E. S. Turner then described his recent visit to investigate the position of the glass industry in Czechoslovakia. After sketching the difficult economic position, he said that the industry was by no means as advanced technically as the British industry, but was living largely on tradition and existing knowledge. Hardly any machinery was used and hand-work predominated. Much money was made during the boom years 1919 and 1920, and but little had been spent on improving the industry, whereas, despite taxation, British manufacturers had invested large sums in improving and extending their works and plant. From a technical point of view this country surpassed the Continent in many respects, and he hoped that the effect of this technical superiority would soon be evident.

A paper on the use of selenium for producing colourless glass was presented by Mr. A. Cousen, who described a large number of experimental melts made to determine the effect of various batch materials on the decolorising power of selenium. Details were also given of a series of melts designed to show the influence of the duration of melting on the colour developed.

SOCIETY OF DYERS AND COLOURISTS

At the meeting of the Manchester Section, held on November 17 in the Chemical Lecture Theatre of the University, a paper on "Ionamines: a New Class of Dyestuffs for Acetate Silk," by Prof. A. G. Green and Mr. K. H. Saunders, was read by Prof. Green.

Earlier work has shown that although the variety of artificial silk known as "acetate silk" possesses little or no affinity for acidic or direct cotton dyestuffs, it exerts a considerable attraction for many basic compounds and for certain azo dyestuffs in which sulphonic groups are absent. In dyeing with a basic dyestuff it is the base itself which is taken up by the fibre, and if the dyestuff is applied in the form of a salt this must be readily dissociated by water. In the attempt to obtain a class of dyestuffs specially suitable to this material the authors were led to investigate the suitability of methyl-ω-sulphonic-acid derivatives of amidoazo-compounds. These derivatives have the general formula

$$Ar'-N_2-Ar''.NR.CH_2.SO_3Na.$$

They are readily soluble in water, and are easily hydrolysed by dilute acids or alkalis with formation of insoluble amidoazo-bases:

$$Ar'-N_2-Ar''.NR.CH_2.SO_3Na+H_2O$$
$$\rightarrow Ar'.N_2.Ar''.NRH+CH_2(OH)SO_3Na.$$

It was therefore to be anticipated that if the hydrolysis were brought about in the dyebath in presence of acetate silk the latter would be dyed by the liberated base.

Experiment confirmed this, and a series of new dyestuffs termed "Ionamines," based upon this discovery, are now being placed upon the market by the British Dyestuffs Corporation.

Ionamines derived from primary amines, or which contain a free primary amino-group, are capable of being diazotised on the fibre and on development give a wide range of shades from orange to scarlet, red, maroon, violet, blue and black. The direct shades are at present limited to yellow, orange, red and violet.

Those Ionamines which have an affinity for cotton are found to have a smaller affinity for acetate silk, whilst the Ionamines possessing the best affinity for acetate silk have none for cotton. The effect on wool is curious. The omega-sulphonic acids dye wool exactly as other acidic dyestuffs and the omega-sulphonic group is thus protected from hydrolysis. With natural silk the dyestuff appears to be partially hydrolysed, but the investigation in this direction is incomplete.

The new dyeing process differs from the ordinary processes of dyeing in that chemical change is involved. There is thus no possibility of "levelling-up" an uneven shade by longer heating in the bath. The material is best entered at a low temperature and the bath raised slowly to 65—75° C. Dyeing is icilitated by the presence of small quantities of ither acids or alkalis. For diazotisation a weak cidified bath of sodium nitrite is employed, re- ction being complete in about five minutes. Only evelopers containing no sulphonic groups can be tilised, the most generally useful being resorcinol neutral), beta-oxynaphthoic acid (slightly acid with cetic) and beta-naphthol (weakly alkaline). The olours obtained with these developers and four ypical Ionamines are the following:—

	Direct	Resorcinol	Beta-naphthol	Beta-oxy-naphthoic acid
onamine A	Yellow	Red-brown	Red-purple	Navy blue to black
onamine B	Orange	Red-orange	Scarlet	Crimson
onamine H	Orange-yellow	Red-brown	Red-purple	Purple
onamine L	Dull yellow	Purple-brown	Purple	Bright blue

Interesting effects are produced on mixtures of otton and acetate silk. By a suitable selection of lirect cotton dyestuff and Ionamine,. the two fibres an be dyed either in different colours or in a solid hade. This can be done either in a single bath or y "cross-dyeing."

The peculiar properties of the Ionamines, which an exert at the same time the functions of both asic and acidic dyestuffs, render it probable that ther uses may be found for them.

INSTITUTE OF CHEMISTRY

At the annual meeting of the Leeds-Area Section, eld in Leeds on November 22, Mr. W. McD. Mackey presided, and Mr. F. W. Richardson read paper on "The Ethics of Expert Evidence."

There is probably some reason for the disrepute n which expert evidence is held, particularly by he legal profession. In wording reports the public nalyst should not allow himself to be led by a bias n order to secure a conviction. Health authorities nd the police are frequently victims of the will o prosecute and magistrates are overwhelmed by he impulse to convict; but the attitude of the uthorities towards violations of the Food and Drugs Act has improved greatly. Several years ago he speaker, in reporting on a sample of butter eficient in fat, suggested that the cows were either bnormal or fed abnormally and asked for samples f the milk. The report was returned with the emark that it was not for the prosecution to uggest a line of defence. In Court the defence roved that the deficiency in fat was due to ex- essive feeding on cottonseed cake. Public analysts re thus to some extent at the mercy of the health ommittee or the medical officer of health, and it suggested that the public analyst should act in a dicial capacity between the health committee and e offender. It is deplorable that even in me clear case of fraud the defendant has no fficulty in obtaining all the expert help required, d however glaring the adulteration, if the firm is ealthy enough, its case is always supported by an ray of leading chemists. Some of these experts, hilst admitting the accuracy of the prosecution's ta, attempt to confuse the issue by raising sub- diary questions. Such jugglery, which at times ludes the magistrate, is to be resented and there need of a special committee appointed by the embers of the Institute of Chemistry to consider es of unprofessional conduct. Members of the me profession should cease all attempts to score one another and to gain professional "kudos" the cost of the opponent's reputation.

THE CERAMIC SOCIETY

At the November meeting of the Ceramic Society Messrs. A. Brittain and C. Elliott read a paper on "The Gypsum Industry." After consideration of the composition and modes of occurrence of gypsum, the authors discussed their investigations on the dehydration of gypsum by heat, as a result of which they concluded that, under technical conditions: (*a*) in the dehydration of lump gypsum by hot gases, the hemihydrate is formed at a much lower temperature than that existing at the surface, there being an inversion point at about 100° C.; (*b*) in the calcination of finely-ground gypsum, the production of hemihydrate occurs within the temperature limits of about 109°—130° C.; (*c*) the hemihydrate$\rightarrow$soluble-anhydrite change occurs within the temperature zone of about 160°—200° C., the product being practically anhydrous before the further rise in temperature occurs.

Processes for the dehydration of gypsum were described, and a general comparison was made in regard to power required for equal output and fuel consumption. Detailed reference was made to certain recent applications of plaster.

Commercial plasters, according to the temperature and time of calcination, may contain (besides the moisture and impurities present in all commercial plasters) varying proportions of: (1) unchanged gypsum; (2) hemihydrate; (3) anhydrous calcium sulphate in the form of (*a*) soluble anhydrite, which readily absorbs water and reverts to the hemihydrate; (*b*) slow-setting anhydrite, which absorbs water slowly and sets with hardening; (*c*) dead-burnt plaster and anhydrite, which do not rehydrate with water. Unchanged gypsum acts as an accelerator to the setting of plaster, whilst slow-setting anhydrite acts as a retarder. The desirability of standardising the various tests for plaster was strongly urged.

THE FARADAY SOCIETY

At the annual meeting, held in the Chemical Society's Rooms, Burlington House, W., on November 20, Prof. A. W. Porter announced that Sir Robert Robertson had been elected president of the Society, and that future annual meetings would be held in May.

Sir Robert Robertson, in the chair, introduced the following papers to the meeting:—(1) "Intra-Molecular Ionisation," by Prof. T. M. Lowry; (2) "The Viscosity and Molecular Dimensions of Hydrogen Selenide," by Mr. C. J. Smith; and (3) "The Hydrogen-ion Concentration of Natural Waters and some Etching Reagents and their Relation to Action on Metals." Two papers by Mr. E. W. J. Mardles on "Viscosity Changes Associated with the Gel to Sol Transition," and "The Scattering of Light by Organosols and Gels of Cellulose Acetate," were postponed.

(1) Dr. Lowry showed that the hypotheses of Co-valency and Electrovalency in conjunction with the octet theory can account for previously supposed cases of variable valency. The familiar cases of intra-molecular ionisation of the organic amino-acids have led the author to suggest electronic formulæ for various organic compounds. The increase in the stability of the oxy-acids of chlorine, sulphur and phosphorus with increase in oxygen-content, can be shown to be due to the positive charge on the central atom of the ion. The effect of the addition of oxygen in modifying the acidity

of certain compounds can also be shown to be due to the positive charge on the central atom of the ion, and apparent discrepancies, *e.g.*, hypochlorous acid, are explicable on the assumption that the oxygen atom occupies the central position in the molecule in place of the chlorine atom. The decrease of acidity in passing along the series perchloric, sulphuric, phosphoric, and silicic acids may be associated with the diminishing positive charge on the central atom of the ion, as well as with the reduction in the mass of the nucleus. In the discussion that followed Dr. Lowry defended the use of the term " ionisation " in opposition to the view expressed by several speakers that the word " polarisation " was preferable.

(2) In continuation of researches with Prof. A. O. Rankine, Mr. C. J. Smith has shown that the results obtained for the viscosity of hydrogen selenide are consistent with those previously obtained for krypton, hydrobromic acid and arsine. The research was rendered difficult by the instability of hydrogen selenide; by comparison with air at 20° C. and assuming the constancy of Sutherland's constant, the mean collision area of the gas was found to be $0{\cdot}86 \times 10^{-15}$ cm. The method of dividing the mercury pellet in the viscometer into two pellets for correction purposes seems capable of wider application.

(3) Dr. Atkins has estimated by means of " buffer " solutions the influence of peat, carbon dioxide, glass, rubber, calcium and magnesium carbonates on the hydrogen-ion concentration of various natural waters, and he suggests the use of acids of relatively low hydrogen-ion concentration and of " buffer " mixtures as etching reagents for metals.

NEWS AND NOTES

CANADA

Pulp and Paper

The Howard Smith Paper Mills, Ltd., is erecting at Cornwall, Ont., a mill with a capacity of about 15,000 tons per annum of bleach soda pulp. Poplar wood will be the chief raw material.

Work is progressing rapidly upon the erection of the large paper mill of the Backus Company at Kenora, Ont. When completed the output of newsprint from this mill will be 1000 tons daily.

Operations have commenced at the new mill of the Temiskaming Pulp and Paper Co., recently erected at a cost of approximately $1,000,000. The plant will have a daily production of 40 tons of ground wood pulp, which will be shipped to Chicago, Kalamazoo, and points in the State of New York.

The large pulp and paper mill which is to be built at Phillips Bridge, nine miles south of Elko, upon the Elk River, B.C., has been promoted mainly by the *Chicago Tribune* and other newspapers. The company will be known as the Wigwam Pulp and Paper Co., Ltd.; the plant is to cost $10,000,000 and employ about 1500 hands.

Engineers of the Armstrong Whitworth Co. have proceeded to Newfoundland to establish a large pulp and paper plant in that colony. The Toronto *Globe* states that the British Government has guaranteed $10,000,000 on the recommendation of the Trades Facilities Board, to assist the enterprise at Humber, Newfoundland, and the Newfoundland Government has guaranteed a like amount.

It is stated that the control of the Belgo Paper Co., which has been organised to take over the Belgo-Canadian Pulp and Paper Co., will rest in Canada, thus ceasing to be in Belgium. The new company has an issued capital of $14,000,000, out of an authorised issue of $20,000,000, and there are also $1,500,000 of bonds. The output will be increased from 200 to 360 tons daily. The head office will be in Montreal.

Mining and Metallurgy

The Cariboo-Gold Platinum Extracting Co., at Quesnel, B.C., is erecting a plant to handle 10 tons of black sands daily; the sands contain the metals of the platinum group.

It is reported that radium has been found in lead deposits on the south branch of the Petawawa River, 18 miles north-west of Pembroke, Ont. Reports from the United States Radium Co. and the Keystone Metal Reduction Co. state that the radio-activity is equal to that of the carnotite ore in Colorado.

The entire matte production of the Mond Nickel Co. has been shipped from Coniston, Ont. There have been forwarded to Wales 140 carloads in September, 137 in October, and 138 in November. It is expected that the Mond nickel refinery at Clydach will be operating on a pre-war scale before the end of the year.

The monthly sales of the International Nickel Co. are now approximately 1·5 million lb. of nickel and 400—500,000 lb. of monel metal. Before the Canadian company can fully provide for expenses the nickel sales must approach 2 million lb. monthly. The monthly output in pre-war times was between 3 and 4 million lb., and during the war it reached 8 million lb. Since the international disarmament ogramme came into existence the company has en endeavouring to find new uses for nickel. The ills at Huntington, W.Va., which cost $3,500,000, ere erected with this end in view. The company s recently resumed operations on a small scale at Creighton mine and at the Copper Cliff reduction orks; the refinery at Port Colborne, Ont., is orking at capacity.

FRANCE

dustrial Notes

Chemical Industry.—Raw materials have risen in rice with the appreciation of the pound sterling and ome buyers have restricted purchases as much as ossible. Practically all contracts now contain a ause providing for cancellation if the exchange alue of sterling rises above a certain level. Prices f turpentine oil have risen by from 10 to 15 fr. per 00 kg., and quotations for copper and lead salts re higher, owing to the firm prices of the corre ponding metals, new or scrap. Consumption of ichromates, sodium sulphide, ferrocyanides and erricyanides is increasing steadily and prices are ising despite Belgian competition, particularly in he north and north-eastern regions. Perfumes are n great demand and stocks are practically de leted. There is little activity in the fertiliser narket, but the production of phosphatic slags as improved and the demand continues to be ery good. Quotations for nitrates are firm; the ffect of the recent earthquake on the Chilean pro luction is not yet known, but it is believed that nly the ports of shipment are affected. Orders re not being placed for British ammonium sulphate n account of its high price, and as a few more coke vens are to be lit in the Nord area the French pro luction of the fertiliser is likely to increase.

Metallurgy.—Exportation of iron ore to Germany is increasing, because Germany is not now buying from Sweden. Production of ore is good in France, except in the Pyrenees. Shortage of metallurgical coke precludes the lighting of more blast furnaces and the purchase of English coke at the present rate of exchange is an expensive method of compensating the short supplies from Germany.

Coal.—The demand for coal, especially for industrial use, is excellent in the Nord and Pas-de-Calais districts, and the winter campaign in the Loire and central coalfields is promising. Exports from the Saar district to Germany have slackened owing to the low exchange value of the mark, but Switzerland and Austria are still placing important orders. Imports from Great Britain have increased slightly, but are held back by the exchange. During October France imported 1,768,000 metric tons of coal and 441,000 t. of coke, compared with 1,692,000 t. and 421,000 t., respectively, in September. Exports during October were:—coal 400,000 t., coke 46,000 t., briquettes 11,400 t.

General.—Next year the Lyons Fair will be held in the spring, from March 5 to 17, instead or in the autumn. Russia and the new States in the Near East are interested in the Fair and arrangements are being made to induce visits from potential buyers in Switzerland, Spain and South America, with the object of making the Fair as international as possible.

A Canadian exhibition-train is to visit all the chief industrial centres in France next spring to exhibit products of Canadian manufacture that are unlikely to compete with French manufactures. The scheme, supported by the State and the railway companies, is similar to that under which a French exhibition-train covered 13,000 kilometres and stopped at 82 towns in Canada last year.

UNITED STATES

Tantalum a Commercial Article

As the result of research extending over six years, a Chicago firm has developed a process for producing metallic tantalum. The metal combines the properties of softness and workability with extreme resistance to wet corrosion and therefore should become a valuable material in industry. It is manufactured *in vacuo* because it must be free from oxygen, hydrogen, nitrogen and other common gases; large-scale production is not expected and the price will prohibit its use for ordinary purposes. Tantalum is not attacked by *aqua regia* or by any acid or alkaline solution, except hydrofluoric acid. Like aluminium it acts as a valve in electric cells, and although a dielectric oxide is readily formed on its surface, thus making it useless as an anode in electrolysis, this property permits its use in electrolytic rectifiers for alternating current. Tantalum melts at 2850° C., but it combines with gases at high temperatures, forming stable compounds that do not readily dissociate at temperatures below the melting-point of the metal. Since 1914, when the German source was cut off, the metal has not been available in the United States, but the possibilities for its use have greatly increased owing to the development of the electrical arts. Dr. C. W. Balke, director of research to the Fansteel Products Co., is investigating the properties of tantalum and also working on the commercial production and utilisation of its sister metal, columbium.

Factors in the Spontaneous Combustion of Coal

In Technical Paper No. 311 of the Bureau of Mines, Washington (price 5 cents), Mr. O. P. Hood reviews briefly the factors concerned in the spontaneous combustion of stored coal. Among such factors are included, superficial area and freshness of the surface of the coal stored, temperature at time of storage, and ventilation of the pile. Spontaneous combustion originates most frequently in fine coal, below 1·25 inch or nut size. The rate of heat generation at a freshly broken surface of coal appears to depend upon the oxygen content of the coal. A freshly broken surface is initially very much more active than after a few weeks, and this factor is of consequence in considering the question of crushing coal prior to storage. Spontaneous fires rarely occur after the coal surfaces have been exposed for three months, and are more liable to occur in coal put into storage during the summer. Should the temperature of the pile reach 140°—150° F., and continue to rise, spontaneous ignition is probable within a few days or weeks. Removal of the pile is necessary if the temperature reaches 160°—180° F. The natural ventilation of a coal pile due to variations in temperature and barometric pressure is considerable and serves to dissipate the heat generated in the pile. Segregation according to size, the larger pieces of coal collecting at the bottom of the pile, with the smaller coal above, is a factor suggesting that spontaneous combustion is initiated somewhere between the two extremes of the central core of fine coal and the large-piece region, where the ventilating current is just sufficient to supply oxygen for a maximum rise of temperature, and insufficient to remove the heat generated. Some observers state that, in general, fires in large coal piles occur from 5 to 8 feet below the surface, on the flanks of the pile. Factors such as the sulphur and volatile-matter content of coal are regarded as of relatively minor importance in the initiation of spontaneous combustion.

"Anthracoal"

This substitute for coal is made by coking a mixture of culm or waste anthracite coal and coal-tar pitch or other bitumens. Tests indicate that it is denser, harder, tougher, and stronger than coke, and that when struck with a hammer or passed through crushing rolls, it breaks with an irregular fracture, similarly to anthracite, but leaves very little fine material. Anthracoal can be made in a coke oven upon the same large scale as bituminous coke, and as it can be produced at little greater cost, it should prove a valuable means of utilising the anthracite culm now going to waste. Its commercial development is the outcome of experiments made in 1914 in the chemistry laboratory at Lehigh University. It is stated that only mechanical difficulties of a nature that can be remedied stand between the trial runs and the actual utilisation of anthracoal as a domestic fuel; consumers are satisfied with it and it commands the same price as the best anthracite.

AUSTRALIA

The Possibilities of Alkali Manufacture

The committee appointed in 1917 to consider the possibility of manufacturing alkali in Australia has reported that conditions are unfavourable, as the necessary raw materials are lacking. Accompanying this statement is a report by Brunner, Mond and Co., which states that as rock salt or saturated brine is not known to occur in Australia, the suggestion to manufacture alkali by the ammonia-soda process must be abandoned. Manufacture by the electrolytic process is ruled out, owing to the small consumption of chlorine products; if this difficulty were removed the process would be the best suited to Australia. In the meantime the company has decided to form an Australian company to represent it locally. According to Mr. P. J. Blackburn, the report is premature, because the results of boring at Calegero, near Bairnsdale, commenced originally for Messrs. Brunner, Mond and Co., and continued since for the Calegero Salt Mines Co., are promising. The Mount Lyell Chemical Co. manufactures about 500 t. per annum of alkali equal in quality to imported material, but cannot attempt to supply the entire home demand, as the market for caustic soda is so limited. About 7000 t. of lump (double strength) alkali is consumed annually in the Commonwealth.—(*Ind. Austr., Sept.* 28, 1922.)

SOUTH AFRICA

Alcohol from Prickly Pear

The *South African Journal of Industries* (November issue) states that a new company, the South African Motor Fuel Development Co., Ltd., has been registered at Bloemfontein, with a capital of £100,000. The object of the company is to carry on, in South Africa or elsewhere, the business of manufacturers of and dealers in industrial alcohol, motor fuel, and fuel for lighting and heating purposes, and by-products arising from such manufactures (vinegar, sugar, syrup, yeast, oil, and fruit jellies). The raw material will be the prickly pear. It is stated that the motor-spirit will be retailed at two shillings per gallon.

There are said to be about 2 million acres of land in South Africa infested with the prickly pear. Nothing is stated with regard to the cost of collection or the means of transport.

GERMANY

Metallurgical Research in 1922

The present condition of the metallurgical industry in Germany renders necessary the most rigid economies in material and labour. To this end an intensive research campaign to investigate the basic principles on which the various processes of smelting and working metals depend has been organised by the Deutsche Gesellschaft für Metallkunde. At the third general meeting of this society, held at Essen from October 14 to 17, a comprehensive programme of economic and practical questions dealing with the metallurgy of non-ferrous metals was discussed. The tendency of German metallurgical development at the present time is to produce suitable alloys of metals derived from domestic ores to replace those made entirely or partly from imported ores, and thus to render the country independent of foreign supplies in case of need. Most attention is being given to the production of aluminium alloys, but increasing interest is being taken in the possibilities of the use of magnesium, calcium, barium, sodium, and silicon alloys.

The Potash Industry

In his report, read to a meeting of the Potash Syndicate on November 19, the managing director (Forthmann) said that sales up to the end of September, 1922, had been very satisfactory, viz., about one million metric tons of pure potash (K_2O), compared with 621,400 t. in the corresponding period of 1921. Home demand was still good, and were it not for the scarcity of railway trucks, the last quarter of the year would also furnish good results. Sales to foreign buyers had also been very good; they were estimated at 1,250,000 m.t. of K_2O, and thus for the first time since the outbreak of war would exceed the foreign sales in 1913 (1,100,000 t.). By a very large majority the meeting approved a new method of fixing net sale prices in order to avoid selling 40 per cent. manure salts, for which there is a large home demand, at prices lower than those of crude salts, which cost considerably less to produce, are much in demand abroad, and therefore bring in much greater net profits.

The Industrial Situation in October

H.M. Commercial Secretary at Berlin states that, despite the further depreciation of the mark, the economic situation changed but little during October, and only a few industries were forced to restrict production or to work for stock. Orders have decreased, deliveries of raw materials have improved, and labour is more plentiful, but the long-feared slump is not yet within sight. The export trade, however, has not revived to the extent anticipated, owing to tariff restrictions in importing countries, strong competition from France and Belgium, and the fact that the cost of production many industries exceeds the world's market ices. In the chemical industry, the coal-tar dye arket is very uncertain, few home orders are being aced and foreign orders have decreased. Producon is still hampered by shortage of raw materials, articularly soda, salt, and coal, and by transport eficiencies. Many of the smaller and mediumzed factories may have to close down on account lack of inland orders and scarcity of capital. Berlin chemical industry experiences difficulty purchasing foreign raw materials and coal with e mark at its present value, but there is an ctive demand, both home and foreign, and the actories are fully employed on current orders. The emand for fine ceramic products is good, and reign trade is satisfactory. The plate-glass ndustry is more dependent than ever on foreign oal, the situation in the sheet-glass industry emains unchanged, and exports of hollow glass ave increased, despite the shortage of soda.

GENERAL

nsulin, The Hormone of the Pancreas

It has long been known that extirpation of the ancreas in animals leads to a fatal diabetic-like ondition in which the blood-sugar rises above its ormal threshold value, sugar appears in the urine, nd glycogen ceases to be stored in the liver. These acts suggest that the condition of diabetes is due o the lack of an internal secretion necessary for he metabolism of sugar. The pancreas contains, in ddition to its main cells, which secrete the panreatic juice through ducts, a number of tiny islets alled the islets of Langerhans, which apparently secrete the anti-diabetic hormone, insulin, into the blood-vessels surrounding them. Numerous attempts have been made from time to time to obtain proof of the existence of this endocrine substance, but until quite recently all extracts have had little effect on the blood-sugar when injected into normal animals.

To two young Canadian workers, F. G. Banting and C. H. Best, of Toronto, must be accorded the credit of having first prepared an extract which alleviates the symptoms of diabetes, both in animals and in man, in an exceptionally striking manner. With the aid of J. B. Collip, a process was worked out whereby a potent preparation of insulin could be obtained suitable for clinical trials without undue risk to the patients. It consists briefly in mixing minced ox-pancreas with an equal volume of 95 per cent. alcohol and straining. Two volumes of 95 per cent. alcohol are added to the extract, and the protein precipitated is removed. The solution is concentrated at 18—30° C. and extracted with ether, re-concentrated to a paste, and treated with 80 per cent. alcohol. The supernatant layer when poured into a large excess of absolute alcohol deposits the active principle mixed with other substances. It is water-soluble, contains but a trace of protein but no lipoid, is salt-free, and free from alcohol-soluble matter. Its physiological action has been worked out in some directions, but chemically next to nothing is known of its nature. Studies are, however, under way to isolate the active principle, and when this is done it will be identified chemically and synthesised artificially, just as has been done for adrenaline, the hormone of the suprarenal glands.

As yet it is too early to state whether insulin is a cure for diabetes, but what is certain is that it alleviates the symptoms, enabling patients to partake of a relatively hearty meal, to put on weight, and to recover their mental and physical vigour. Its method of administration is not devoid of complications, the only effective way at present being hypodermic injections twice daily.

Fertilisers—A " Key " Industry

Under the heading " Fertilisers before and after the War " (reprinted from the Transactions of the Highland and Agricultural Society of Scotland, 1922) Prof. James Hendrick, of the University of Aberdeen, gives an interesting review of the present fertiliser position as compared with that obtaining before the war. The enormous growth in the production and consumption of the most important nitrogenous, potassic and phosphatic fertilisers during the years immediately preceding hostilities is illustrated by selected statistics, after which the radical alterations in the fertiliser position which were brought about owing to war conditions are briefly explained. The author rightly points out that the fertiliser industry is of just as much, if not more, importance to the country in time of war as the dyestuff and fine chemical industry, although it is almost exclusively the latter that has attracted attention in this connexion. Whereas the dyestuff industry can be adapted in time of war to the actual manufacture of munitions, it is the fertiliser industry which is the mainstay of the country for the production of the sulphuric acid, nitrates and ammonia, without which the munitions cannot be manufactured. The present position with regard to the production and the agricultural value of the three great classes of artificials is then dealt with in some detail, the relative value of the newer fertilisers of each class in comparison with the older ones being illustrated by the results of manurial trials carried out at the Craibstone Experimental Farm of the University of Aberdeen, and in other parts of N.-E. Scotland.

Propyl Alcohol as a Disinfectant

The best disinfectant for use on the skin is propyl alcohol because it is a strong germicide and harmless to the skin, even after extended use. Solutions of 35 to 50 per cent. strength have given good results with facial acne and various diseases of the hair, whilst poultices containing 10 to 20 per cent. solutions have often proved useful in treating bacterial eczema.—(*Pharm. Zentralh., No.* 31, 1922.)

Fusel Oil and Acetone in Czechoslovakia

The annual output of fusel oil in Czechoslovakia is about 150 metric tons, of which 5 per cent. is consumed locally and the remainder exported, mainly to Germany, the United States, Holland, Austria, Hungary, and Switzerland. The whole output of fusel oil in the Succession States of Austria-Hungary in refined in one factory in Bohemia. Butyl alcohol, which competes with fusel oil in the United States, is not used in Czechoslovakia. Acetone, obtained from the dry distillation of beech wood, is produced by five factories, and of the total annual output of 600 t., about four-fifths is exported. About 3000 workpeople find employment in the acetone industry and the question of fiscal protection is being considered. Acetone is used chiefly in making paints and related products, artificial and patent leathers, and celluloid articles. In Czechoslovakia the manufacture of photographic films is negligible and that of artificial silk and cellulose acetate in its infancy.—(*U.S. Com. Rep., Sept.* 11, 1922.)

New Deposit of Talc in Austria

Work has been commenced on the talc deposit recently discovered near Mautern, in Steiermark, Austria. The deposits are from 1 to 1·8 metres thick and about 2000 m. long.

The World's Production of Electric Iron and Steel

Prior to 1913 electric steel was produced almost exclusively in the United States and, especially, in Germany and France; although production began in 1908–9, it did not attain importance until 1913. Under the stimulus of war conditions, however, the world's production increased rapidly, reaching a maximum in 1918, as is shown by the following statistics:—

I.—*Output of Electric Steel Ingots and Castings*

	1913	1915	1916	1917	1918	1919	1920	1921
				Metric tons				
United States	30,663	70,523	171,621	309,416	519,546	390,603	510,186	172,211
Germany	88,881	131,579	190,036	219,700	240,037	55,382	—	—
Great Britain	—	22,352	47,456	100,169	117,295	78,232	90,526	27,534
Canada	—	5,715	17,813	45,774	108,051	14,060	25,669	17,114
Austria-Hungary	26,837	23,895	47,247	47,152	41,163	—	—	—
France	21,124	21,000	44,429	54,031	58,222	42,559	58,080	24,457
Italy	—	26,946	32,677	47,744	71,964	88,824	119,378	140,000*
Sweden	2,276	2,187	6,648	10,664	13,089	11,818	12,356	—

* Estimated.

After 1918, despite a temporary revival in 1920, production fell rapidly, except in Italy, reaching a low level in 1921, a year in which the German output was probably about 45,000 tons. Especially noteworthy was the increased production of electric steel castings and cast alloy steels in the United States, the respective figures being 9354 t. and 450 t. in 1913, and 86,457 t. and 10,245 t. in 1921. The Italian industry has developed continuously, and at the end of 1921 there were about 50 works possessing 180 electric furnaces with a total capacity of about 800 tons. Most of the furnaces are of the Stassano type, and although Héroult and Girod furnaces are in use, they are gradually being replaced by Fiat and other Italian makes. The number of electric furnaces in Great Britain has increased from 21 (owned by 16 companies) with capacities ranging from 1 to 3·25 t. in 1914 to 150 with capacities varying from 0·25 t. to 20 t. in 1922. In 1921 the first electric furnace was installed in Ireland. An indication of the growing importance of electric furnaces in the steel industry is given by the increased output of electric steel castings in Great Britain, viz., from 3032 t. in 1915 to 16,967 t. in 1921. Similarly, in Canada the proportion of steel castings to total output of electric steel has risen from 43·6 per cent. in 1919 to 83·2 per cent. in 1921. Recent statistics for Germany are not available, but, owing to the loss of large areas under the Peace Treaty, it will be long before the country recovers its former importance as a producer.

Electric pig iron is made by reducing iron ores with coke or charcoal, and by preparing "synthetic" iron or re-melting steel scrap with cast iron; the former method is used in Sweden and Norway, the latter in France, Canada, and Italy.

II.—*Output of Electric Pig Iron*

	1913	1915	1916	1917	1918	1919	1920
				Metric tons			
France	28,753	29,760	46,208	90,309	83,959	55,422	59,656
Sweden	31,966	35,075	44,782	67,059	75,684	64,470	82,575
Italy	4,160	3,800	16,911	56,524	61,888	29,057	—
Norway	—	8,742	6,233	6,295	9,007	2,032	2,862
Canada	—	—	—	12,418	29,052	6,985	8,013

The future of this branch of the iron and steel industry appears to be promising despite the reduced production in 1919; the production from five countries in 1921 is reported to be more than twice that of six countries in 1913. At the end of 1920 there were 15 completed blast furnaces (14 in Sweden, 1 in Japan); 15 were being built (4 in Sweden, 6 in Italy, 2 in Brazil, 3 in Norway); and all of them, except those in Italy and Japan, were designed for utilising charcoal as fuel. In 1920, out of a total production in Sweden of 82,575 t. of electric pig iron, 15,793 t. was made in low-shaft furnaces, which resemble those used in making iron alloys and carbide. These furnaces were used because of the shortage of pig iron; they have a small capacity and much of the heat and all the valuable gases evolved are lost, so that their use is only profitable in special circumstances. During the war many furnaces of this type were used for making "synthetic" iron in countries possessing hydro-electric power.—(*Stahl u. Eisen*, Oct., 1922.)

The Olive-Oil Industry in Italy and Tunis

Although Italy has a larger area planted to olive trees than any other country in the world, it only takes second rank as a producer, the output being about 26 per cent. of that of the world, compared with 37 per cent. from Spain. Production and exportation have recently been as follows:—

	Area Acres	Production	Exportation
		Metric tons.	
1913	4,315,584	156,780	22,340
1919	4,248,400	103,590	1,090
1920	4,226,170	171,000	1,236

The large domestic consumption is the cause of the disproportion between production and exportation; thus, in 1913, when 22,340 t. was exported, 2086 t. of (crude) foreign olive oil and 13,462 t. of cottonseed oil had to be imported. Exports in 1921 were only 3199 t., and this failure to regain the pre-war level of exportation is due to decreased production, prohibition on imports of cottonseed oil, and the tendency of other countries to refine their own oil. Exports of sulphur oil, mainly to the United States and France, have risen from 8878 t. in 1913 to 10,821 t. in 1921.

Tunis takes fourth rank among producers of olive oil, and although the area under olive trees decreased from 889,560 acres in 1910 to 579,820 acres in 1918, the output of oil increased from an average of 22,217 t. during the period 1910–15 to 37,489 t. during the period 1916–20. War conditions stimulated the industry and exports rose from 13,067 t. in 1913 to 21,415 t. in 1919 and 23,287 t. in 1921, in which year the production was 70,000 tons. Tunisian oil is of little interest to the world's trade as the output is sold to France and Italy a year or more before it is produced.—(*U.S. Com. Rep., Sept.* 25, 1922.)

n Italian Forerunner of Solvay

The process of making sodium carbonate by the nteraction of salt and ammonium carbonate bears he name of Solvay, because, although not the first o discover the process, he was the first to apply it uccessfully on an industrial scale. The October ssue of the *Giornale di Chimica Industriale ed pplicata* contains an article by Signor V. Ravizza n a predecessor of Solvay named A. G. Forni, who resented a project for manufacturing soda by the mmonia-soda process to the Austrian Viceregent 1 1836, two years before Dyer and Hemming took ut their patents and 25 years before the patent of . Solvay. The project comprised a description of e plant required to produce 250 metric tons of nhydrous sodium carbonate per annum, and the rection of a small experimental plant in Milan was uthorised by the Austrian Government. Nothing me of the trial, owing to the illness and financial oubles of the inventor, and after a commission of emists had, on erroneous grounds, reported gainst the process, Government support was withrawn. Efforts to obtain private assistance were so unsuccessful, and the only record now remaing is a descriptive pamphlet written by Forni in 341.

REPORTS

EPORT ON THE COMMERCIAL, INDUSTRIAL AND FINANCIAL SITUATION IN JAPAN IN 1921 AND UP TO JUNE 30, 1922. *By* SIR E. T. F. CROWE, *H.M. Commercial Counsellor, and* G. B. SANSOM, *Acting H.M. Commercial Secretary, Tokyo. Department of Overseas Trade. Pp.* 59. *H.M. Stationery Office,* 1922. *Price* 1*s*. 6*d*.

The hope entertained early in 1921 that pan was on the way to economic recovery was t realised; although production and stocks minished, and the home demand was active, the neral situation remained unfavourable. The lue of the exports in 1921 fell from 1948 million n to 1253 mill. yen, and that of the imports from 36 mill. yen to 1614 mill. yen, so that the adverse ade balance decreased by 27 mill. yen to 361 mill. n (average value of yen in 1921 = 2s. 2d.). though the value of the exports in 1921 was arly three times the annual average for the riod 1909–1913, this increase was due almost tirely to progress in the silk industry, whose osperity depends on "fashion" in the United ates. Exports of porcelain, glassware, sugar, d matches declined, but a considerable trade was ne in bottles and tumblers. Negotiations took ace between the chief Japanese match manucturers and the Diamond Match Co., U.S.A., with e object of forming a ring to control the eastern arkets for matches. The fall in prices was the ain cause of the smaller value of the imports, and rge increases were shown only by cotton (30 per nt. of the total imports), woollen textiles, achinery, rubber, photographic materials, and ientific instruments. Great Britain is still far om having recovered her pre-eminence in the etal trade, the imports of iron and steel and tinate originating as follows (per cent.):—United ates 45, United Kingdom 17, Germany 15, China , Belgium 8, and India 5. Attempts to manucture tinplate in Japan have failed, and the onworks are said to be unable to work at a profit. Of fertilisers, only 18,000 t. of nitrate was imported from Chile (121,000 t. in 1921), and phosphate was in small demand. The United Kingdom supplied only 12 per cent. of the imported ammonium sulphate, the bulk coming from the United States, and a small proportion from Germany. In the heavy chemical trade, the chief features were keen competition in soda ash and large imports of rosin. Caustic soda is now manufactured in Japan from soda ash. Germany has regained dominance in the dye market and supplied 4 mill. lb. in 1921, the United States coming next with 877,000 lb.; in this industry the Japanese cannot compete with Germany, and many of the companies floated during the boom have ceased operations. Owing to the Government being compelled to cut prices, there was a marked revival of demand for camphor. The Japanese spend large sums on photographic materials, and of the importations, plates are purchased mainly in Great Britain, and paper and films in the United States. Statistics of the import and export trade are appended:—

Imports:—	Long tons
Sugar	300,629
Salt..	190,004
Leather	2,914
Paraffin wax ..	15,284
Rosin	7,982
Caustic soda, soda ash	44,710
Coal-tar dyes ..	2,491
Sodium nitrate ..	17,896
Ammonium sulphate	77,962
Paper pulp ..	38,727
Phosphorus ores ..	208,963
Coal	777,255
Iron ore	568,785
Iron, pig	223,551
Lead	33,158
Tin	3,307
Nickel	2,244
Rubber, crude ..	21,323
Kerosene (galls.) ..	27,073,000
Glass (£)	692,220*

Exports:—	
Starch	2,699
Sugar, refined ..	43,641
Oils, vegetable and fish	5,849
Camphor	851
Menthol	136
Cement	167,684
Rubber tyres ..	1,314
Matches (1000 gross)	23,154
Coal	2,387,709
Soap (£)	224,547*
Pottery, glass, etc. (£)	3,084,424*

* Value; yen = 2s. 2d.

The output of minerals and metals in 1921 was as follows:—

Gold ..	oz. troy	236,969
Platinum ..	„	231
Silver ..	„	4,185,502
Copper	Long tons	53,238
Lead ..	„	3,089
Bismuth ..	„	0·7
Tin	„	289
Mercury ..	„	6
Zinc ..	„	10,211
Iron, pig ..	„	88,540
Iron-sulphide ore ..	„	92,404
Chromite ore	Long tons	3,309
Manganese ore	„	3,811
Arsenic ..	„	1,374
Arsenic ores	„	1,481
Phosphorus ores	„	29,348
Graphite ..	„	856
Lignite ..	„	24,035,550
Asphalt ..	„	6,823
Sulphur ..	„	33,539
Sulphur ores	„	24,777
Petroleum, crude ..	galls.	77,854,400

Compared with 1920, nearly every item shows a big decrease.

THE TRADE IN INDIAN MYROBALANS. *Imperial Institute. Indian Trade Inquiry. Reports on Cinchona Bark and Myrobalans. London: John Murray,* 1922. *Price* 4*s*. *net.*

Myrobalans, the dried fruits of species of *Terminalia*, mostly *Terminalia Chebula*, Retz, are one of the chief tanning materials produced and used in India and are also exported in large quantities. The collection of the fruits affords a valuable minor source of revenue and is so largely in the hands of a combination of Indian dealers that it is considered unlikely that European firms would be able to compete successfully. Usually the season's crop is sold by tender on the trees, but contracts over a period of several years are sometimes made, the buyers undertaking to collect and dry the nuts, which are then sent to the warehouses where they are sorted and cleaned before being packed for shipment.

Five varieties of myrobalans are recognised in commerce, named according to the district of origin, as follows:—"Bimlies," or "B's," from Bimlipatam, Madras; "Jubbelpores," or "J's," from Jubbulpore, in the Central Provinces; "Rajpores," "R's," from Kohlapur State; "Vingorlas," "V's," from Bombay forests; and "Coast Madras"; each variety being separated as a rule into No. 1 and No. 2 grades.* The grading of nuts is usually done carelessly and gives rise to complaint among buyers in the United Kingdom, but as a rise in the price of No. 1's reduces the demand and stimulates that for No. 2's, there is not much inducement to improve grading. It is recommended that all unsound nuts be removed before shipment. At the present time myrobalans are bought by tanners in this country largely on appearance, and although it would be preferable to sell on a basis of tannin content, and colour determination, it must be remembered that the value of myrobalans to the tanner depends not only on the high tannin content, but also on other properties, such as deposition of "bloom" on the leather, and fermentation with the production of acid necessary to swell the hide.

It has been largely supposed that the immature nuts are richest in tannin, but analyses of fruits of different stages of maturity made at the Imperial Institute and also by Puran Singh (*Indian Forester*, 1915, 41, 15) show that fully ripe fruit contains most tannin. Myrobalans alone do not form a satisfactory tanning material, but are most useful when blended with other materials; in sole-leather tannage quebracho with 25—30 per cent., mimosa bark with 15—20 per cent., or mangrove bark with up to 50 per cent. of myrobalans, are generally used.

Myrobalans are usually shipped to Europe as whole nuts, but recently increased quantities of crushed nuts (freed from stones) have been exported, and if improvements in crushing were introduced it is considered that the bulk of the demand would be for the crushed material. It appears that the crushed material is often packed wet, so that it becomes sticky and forms lumps which cannot be extracted, whilst many of the crushed fragments are also too large for easy extraction. The preparation in India of liquid or solid extracts for export does not appear to offer any advantages, as in neither case would the extract contain more tannin than the nuts. Considerable amounts of liquid extract are prepared in the United Kingdom.

Myrobalans, either in the form of fine powder or as extract, are also used in the dyeing industry, chiefly in the "heavy woollen district" of Yorkshire, where the cloth consists of "shoddy" with 50—70 per cent. of cotton. Myrobalans are used in conjunction with iron for dyeing the cotton black, but as the colour is not fast to acid, this method has been replaced to some extent by the use of Cotton Milling Black. In the Bradford trade the use of myrobalans for the production of black on cotton is declining owing to the superiority of Direct Dyeing Blacks, which permit the subsequent dyeing of the wool by acid colours. A small demand also exists for myrobalans in the indigo-dyeing industry, where it is employed to remove surplus dye from the fabric. The demand for myrobalans in dyeing is not likely to increase, but may be maintained, as they are cheaper than sumach (the only other available pyrogallol tanning material).

The importance of the trade in myrobalans is considerable. Prior to the war Indian exports amounted to about 1,400,000 cwt. annually, valued at nearly £400,000; of the 40—50 per cent. shipped to parts of the British Empire, almost all went to the United Kingdom; the remainder was taken chiefly by Germany (one-fifth of the total export), the United States (one-sixth), Belgium (one-ninth), and smaller quantities to France, Italy, Russia and Japan.

It is proposed to investigate, in India, the different varieties of *Terminalia*, and to carry out analyses and tanning trials in the Imperial Institute with fruits of the different varieties; and the Committee suggests that an inquiry be made into the methods of collection, drying, grading and storing myrobalans in India.

OFFICIAL TRADE INTELLIGENCE

(From the Board of Trade Journal for November 23 and 30)

OPENINGS FOR BRITISH TRADE

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence, 35, Old Queen Street, London, S.W. 1, from firms, agents or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number.

Locality of firm or agent	Materials	Reference number
Argentina ..	Metals, tinplate	619
Australia ..	Pottery, glassware	567
Belgium ..	Pharmaceutical and industrial chemicals	573
„ ..	Special steel, aniline oil, cresylic acid, potassium and sodium bichromates, boric, carbolic and citric acids, benzine, benzol, bleaching powder, dyeing and tanning extracts, formaldehyde, nicotine, sulphites, bisulphites, petroleum jelly, pitch, potassium cyanide, soda	575
„ ..	Rubber goods	597
Brazil ..	Paint, varnish, oils	591
British India	Metals, cement, soap, perfumery, paper, glassware	568
Canada ..	Pottery, perfumery	†
„ ..	Insulating porcelain and glassware..	9998/E.D./E.C.
China ..	Asbestos roofing	617
Egypt ..	Drugs, medical stores (tender for) ..	9409/F.E./C.C.
„ ..	Paper (tender for)	9483/F.E./M.P.
Latvia ..	Kerosene, asbestos sheet, varnish, chalk, ozokerite, pigments, tin (tender for)..	6610/F.B.
Morocco ..	Leather, rubber	9357/F.E./G.C.
Norway ..	Oils, fats	606
Peru ..	Earthenware, lead sheets and pipes	593
South Africa	Disinfectant fluid (tender for) ..	10040/E.D./C.C.
Sweden ..	Chemicals used in tanneries and rubber factories	584
Switzerland..	Technical and pharmaceutical chemicals	613
„ ..	Leather	615
„ ..	Oils, fats, chemicals, metals, alloys, tin, fertilisers	616
United States	Leather scrap..	17639/F.W./M.P.

† Canadian Government Trade Commissioner, 73, Basinghall Street, London, E.C. 2.

TARIFF CUSTOMS EXCISE

Austria.—Increased consumption taxes are payable on spirits, wine, sugar, matches, various beverages, acetic acid, and artificial sweetening substances. Export duties are leviable on raw hides and skins, horn, wood, ores, magnesite, rosin, turpentine, paper pulp, and rubber waste.

British Guiana.—Surtaxes of 10 per cent. of the specific duties are applied to goods included in the first schedule of the Customs Duties Ordinance, 1922, and of 20 per cent. to goods specified in the second schedule.

British India.—Regulations have been issued controlling the importation of preparations of morphia, opium and cocaine.

Canada.—Under a recent customs ruling silica, magnesia, and chrome firebricks are entitled to entry free of duty.

Denmark.—A modified scale of import duties has been applied to alcoholic beverages, ethers, perfumery and perfumed articles. Denatured spirit or spirit for medicinal use are exempted from the additional duty now payable on spirit of 50 per cent. strength.

Federated Malay States.—Draft rules have been issued providing for restrictions on the export of rubber.

France.—The commercial arrangement with Italy which was signed on November 13 came into force on November 28.

French Togoland.—New import tariffs have been fixed for spirits, alcoholic dyestuffs and perfumery, sugar, salt, and denatured alcohol; and new export tariffs for palm oil and kernels, copra, cotton and sisal. The duty-free list includes fertilisers, coal, bottles, and scientific products.

New Hebrides.—A recent regulation prohibits the import of pure alcohol, crude spirit, or any alcoholic liquids, but not of pure alcohol for industrial, pharmaceutical or medical use.

Nigeria.—Fuel oil for power purposes may be imported duty-free.

Poland.—Surtaxes have been applied to the customs duties on certain goods, as follows:—900 per cent.: certain fertilisers, graphite, antimony, nitric acid, certain edible oils, metals, cellulose and paper; 4900 per cent.: superphosphates, olein, asbestos, electrical carbons, silica and magnesite bricks, various wares of glass, certain coal-tar products, sulphur, rare-earth products, sodium bicarbonate, carbon bisulphide; 14,900 per cent.: ammonium nitrate, chloride of lime, sodium sulphite and hydrosulphite, acetate of lime, sulphuric ether, tanning extracts, etc.

Rumania.—Opium and its derivatives may be imported only by special authorisation.

San Thomé and Principe.—By a recent decree the export duties are doubled, as are also the import duties, except those on sugar, calcium carbide, olive oil, medicines, quinine salts, matches, and paraffin.

Sweden.—Export prohibitions have been withdrawn from gold, silver, and platinum.

Uganda.—The customs tariff now in force in Kenya has been applied to Uganda.

United States.—The rules of procedure under the "flexible-tariff" provisions of the new customs tariff are published in the issue for November 30.

PARLIAMENTARY NEWS

HOUSE OF COMMONS

Merchandise Marks Bill

Sir P. Lloyd-Greame, President of the Board of Trade, informed Mr. Hannon that this Bill could not be re-introduced before Christmas, and he was unable to state when such legislation would be considered.—(Nov. 27.)

Guarantees under the Trade Facilities Act

Answering Mr. Briggs, Mr. Baldwin, Chancellor of the Exchequer, said that the total amount guaranteed under the Trade Facilities Act up to September 30 was £23,563,645. The guarantees given since that date included £2,000,000 to the Newfoundland Products Corporation, Ltd., £50,000 to the Dolcoath Mine, Ltd., and £850,000 to the Tata Power Company.—(Nov. 27.)

Coal Output in Great Britain and the United States

In reply to Commander Bellairs, Mr. Lane-Fox stated that the output of coal per man in Great Britain was 257 tons in 1910, 144 t. in 1921 (when all pits were idle for 3 months), and 216 t. in the year ending September, 1922. In the United States the output per man (including that of anthracite) was 618 t. in 1910 and 549 t. in 1921. These figures were not strictly comparable as coal-mining was much easier in the United States than in this country.—(Nov. 27.)

Surplus Government Chemicals

Mr. Baldwin, in a written answer to Mr. Hancock, said that the Disposals Board had held sales of chemicals on other dates than September, 1920, but the preparation of statistics showing the results of such sales would be too expensive.—(Nov. 28.)

Charges for Town Gas

In answer to Mr. Jephcott, Sir P. Lloyd-Greame said he had received requests for an inquiry into the present method of charging for town gas on a thermal basis, and had appointed a Departmental Committee of Inquiry consisting of Sir C. Hyde, Mr. A. Balfour, Sir J. Martin, Mr. A. A. Pugh, and Mr. W. J. U. Woolcock.—(Nov. 30.)

Petroleum Production

In reply to Mr. Hancock, Sir P. Lloyd-Greame said that the production of crude petroleum in 1921 in Great Britain, Trinidad, Egypt, and Mexico was 140,000 tons (estimate), 334,000 t., 190,000 t., and 28,000,000 t., respectively. The cost of production could not be stated.—(Dec. 4.)

"Reparation" Dyestuffs

Sir P. Lloyd-Greame, answering various questions, said that the appointment of the British Dyestuffs Corporation as distributing agent for "reparation" dyes had been approved by the Colour Users' Association and dye manufacturers other than the Corporation. The agreement was terminable at three months' notice on either side, and the commission payable to the Corporation was 6·5 per cent. on gross turnover, plus 1 per cent. for guaranteeing accounts. The commission was to cover charges for importation, packing, storage, etc., but the Board had agreed to make a maximum annual grant of £30,000 towards the cost of these charges. He was not aware that any information obtained by the

Corporation in the conduct of the agency was being utilised improperly.—(Dec. 4.)

Blast Furnaces

In a written answer to Major Kelley, Sir P. Lloyd-Greame stated that, at the end of October, 151 out of 487 furnaces were in blast in the United Kingdom, 109 out of 221 in France, and 33 out of 54 in Germany. Particulars for Germany could not be given.—(Dec. 4.)

Disposal Board

Mr. Baldwin informed Sir A. Hunter-Weston that the expenditure of the Disposal Board during the past year was £2,600,000, of which a large proportion was incurred in the destruction of poison-gas shell, breaking down ammunition, etc. The cost of maintenance of Gretna factory during the last year was £27,000, but revenue amounting to £20,000 had been received, and sales of plant since January 1 had realised £250,000, the sale expenses being 5 per cent. of the prices realised.—(Dec. 5.)

Feeding Stuffs and Fertilisers

In reply to Mr. Dixon, who asked whether the proposed departmental committee on the cost of agricultural produce to the consumer would also inquire into the cost of feeding stuffs and fertilisers, Sir R. Sanders, Minister of Agriculture, said that the terms of reference would be limited to questions relating to agricultural, horticultural and dairy produce and that the committee would have to decide what articles were included within the scope of the terms of reference.—(Dec. 5.).

British Empire Exhibition

In a written answer to Sir H. Holbrook, Sir W. Joynson-Hicks said that the President of the Board of Trade had invited him to investigate the use of materials and supplies of Empire origin in the British Empire Exhibition.—(Dec. 6.)

Home-Grown Sugar-Beet

Replying to Mr. A. Bennet, Sir R. Sanders wrote that an area of 3776 acres at Kelham and 4180 acres at Cantley, *i.e.*, a total of 7956 acres, was planted with sugar-beet. Both crops were to be worked this season at the Cantley factory, which employs 600 men; the average weekly wage is about £2 14s. 8d. —(Dec. 6.)

Pasteurisation of Milk

Major Boyd-Carpenter, replying to Sir J. Leigh, said that there was some distrust of pasteurisation as now practised, partly on account of the high temperatures frequently employed commercially. There was no evidence that pasteurisation properly conducted would destroy the essential qualities or constituents of milk. It was hoped that the steps now being taken by the Ministry of Health would conduce to the provision of wholesome milk at reasonable prices.—(Dec. 7.)

Safeguarding of Industries Act

The following are summaries of answers given by the President of the Board of Trade to questions relating to the operation of the Act:—

Key Industries.—The Act has enabled the industries covered by Part I to continue, and to extend the range of production considerably. Returns are to be supplied showing the state of employment in these industries.—(Nov. 27.)

Receipts from Duty.—The amounts of duty collected under Part II, up to November 24, are as follows:—Fabric gloves, £50,695; glassware, domestic, £995; glassware, illuminating, £3599; hollow-ware, domestic, £8370; incandescent gas mantles, £35. The date of the Order respecting gas mantles was October 9, and of that respecting the other goods August 8. The cost of collection has been less than the receipts.—(Nov. 27.)

Sodium Hyposulphite of photographic quality is well known to the trade, but there is no fixed standard to which it must conform; hyposulphite of this quality is dutiable.—(Dec. 4.)

Potassium Permanganate is not dutiable unless of "R" quality. If a claim for duty is disputed on the ground that the consignment is not of dutiable quality, the importer can apply to have the matter referred to a referee under Part II. of the Act.—(Dec. 4.)

Sulphocyanides.—The sulphocyanides of aluminium, barium, and copper were removed from the lists because the Referee's observations in the cream-of-tartar case indicated that he would probably regard these compounds as heavy chemicals. These observations do not apply to sodium and potassium sulphocyanide, and they were therefore left in the lists.—(Dec. 4.)

Scientific Instruments.—The report of the committee which investigated the application for a duty of 33⅓ per cent. on scientific instruments is being considered and an announcement will be made shortly.—(Dec. 4.)

Vulcanised Fibre.—The report of the committee appointed to consider the complaint regarding the dumping of vulcanised fibre from the United States is unfavourable to the complainants and will be published and presented to Parliament at an early date.—(Dec. 4.)

Duties.—The total amount collected in duties under the Act, up to and including December 1, 1922, is £432,575.—(Dec. 7.)

During the debate on the motion for an Address in reply to the King's Speech, Sir J. Simon moved an amendment, regretting that no mention was made in the Speech of the repeal of the Safeguarding of Industries Act and other protective measures which were raising prices, hampering trade and limiting employment. Sir J. Simon discussed the administration of the Dyestuffs Act and observed that this and similar measures tended to restrict the free rights of British merchants to purchase in the best market. The licensing system under the Dyestuffs Act implied selection and therefore favouritism, and exporters were unable to know whether they could safely accept repeat orders. It was right to protect a "munitions industry," but the worst way to do so was to enable selected manufacturers to make additional profits out of their fellow-subjects. The duties under the Safeguarding of Industries Act had been imposed on 6300 chemicals instead of on a few directly connected with military preparedness. Imported chemicals were being detained at the ports to ascertain whether their purity made them dutiable. It was claimed that, as a result of the Act, 2000 fine chemicals were now being made in this country, but the highest chemical authority stated that the list consisted very largely of impure German chemicals that had been purified in this country.

In reply, Sir P. Lloyd-Greame observed that when the war began we lacked optical glass, drugs, and chemicals of every kind, and Lord Balfour of Bur-eigh's Committee had recommended that those key ndustries should be protected, as an essential assurance against war. To-day, optical-glass factories were being steadily developed, many new chemical factories were being started, the range of production was growing, and so excellent were our scientific nstruments that scientific institutions in France, Belgium and Italy bought them in preference to cheaper foreign products. Prices of optical glass had fallen by from 20 to 50 per cent. and of chemicals by from 20 to 30 per cent., and if the consumer did not always benefit, that was the fault, not of the Act, but of the middleman. It had been arranged that the Board of Trade and the Department of Scientific and Industrial Research should investigate the key industries to ascertain what progress had been, and was being, made. The legislation against dumping and unfair competition was promised during the war, and it would be unwise to repeal it just when the United States had set up a prohibitive tariff that would probably lead to dumping in this country. The principle upon which the Act and the duty levied under it were based had been accepted by each successive Government, and he asked the House not to reject it.

Sir A. Mond said that the disappearance of key industries might put the country in a serious position, but it was never anticipated that the Schedules to the Act should be extended or applied in the way they had been, and he believed the administration of the Act required revision. The attempt was being made to establish the dyestuffs industry—one of the most difficult in the world—in face of able competitors who had 40 or 50 years' experience, and free competition would make the task almost impossible. The progress made was disappointing and should be investigated. Mr. G. C. Clayton, in opposing the motion, recalled the history of tungsten manufacture in this country and of the German monopoly of supply prior to the war. Without the present Act, manufacture of tungsten at Widnes would now have to cease. Mr. Asquith remarked that the Act was a farce; there was no evidence of any dumping now; and the remedy was worse than the disease. Lt.-Com. Astbury gave instances to show how German makers reduced the prices of certain dyes when British makers began to produce them, and pointed out that if the Dyestuffs Act were repealed, Germany would force every British maker to close within six months. British dye-makers had produced 500 new colours, 516 colours equivalent to German colours, 28 vat colours (made for the first time in this country), and 82 research chemicals. It was pointed out by Mr. H. Spencer that the price of the commonest Swiss dye was one-half that of the British equivalent, and that British dyers still refused to guarantee the fastness or wearing qualities of their products. It was true that the cost of dye represented a small fraction of the total cost of the textile, but that small fraction was sufficient to make competition with foreign makers impossible. Sir R. Horne said that the duty of 33⅓ per cent. applied under Part II. was intended, not to stabilise the exchange, but to give at least some help in adjusting the difference between the internal and the external purchasing value of the foreign currency. The amendment was defeated by 269 votes to 207.—(Dec. 4.)

REVIEWS

Theories of Organic Chemistry. *By* Dr. F. Henrich. *Translated and revised from the 4th German edition by* Prof. T. B. Johnson *and* Prof. Dorothy A. Hahn. *Pp. xvi+603. New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd.*, 1922. *Price 30s. net.*

Many English readers who are familiar with the German edition of this work will probably agree with the reviewer that its chief defect is the tendency to omit reference to work carried on outside Germany. The translators of the book appear to have been aware of this defect, and they are quite frank concerning the treatment of it, for in the preface it is stated that "in presenting the work to an American public it has seemed desirable to stress wherever possible the contributions of American investigators." In pursuing this plan the translators have improved the original work. Thus the section on electronic conception of valency has been rewritten and now includes a new chapter containing an account of the theories of Falk and Nelson, Lewis, and Fry; but this account will hardly attract the full interest of British readers, since the work of Langmuir has been omitted with the notable developments made by Lapworth, Robinson and other English research workers. Another welcome addition is the chapter dealing with Nef's theories, and in the reviewer's opinion the translators have done wisely in reproducing the original paper in which these were summarised. The account of intramolecular rearrangement has been greatly improved by revision and by the addition of the researches of Stieglitz and of Wheeler and Johnson, which received very brief notice in the original. These are the chief additions, but other changes have been made in the order of treatment, with the result that the logical sequence of the subject is improved; for example, an account of pseudo-acids and bases is now given immediately following that of tautomerism.

These alterations have undoubtedly enhanced the value of the book, but it is unfortunate that the translators did not carry out their revision on a broader basis. The reader will notice that no reference is made to the work of Thorpe and his collaborators on the glutaconic acids, ring-chain tautomerism and the stability of spirane systems. In the chapter dealing with rotatory power and constitution the researches of Pickard and Kenyon, Lowry and others are omitted, and the work of English investigators on the relation of absorption of light to constitution is hardly noticed. An account of recent research in stereochemistry is wanting, and in the reviewer's opinion a few pages devoted to the work on molecular asymmetry would have been a useful addition. In further criticism it may be added that some subjects seem to be unduly stressed, particularly the description of Stark's hypotheses and the work of Hantzsch on chromoisomerism. Beyond these remarks there appears to the reviewer little to be said by way of criticism, whilst in praise of the book much could be said; it will undoubtedly receive a wide welcome.

The work of translation has been well done; the style is clear and in a book of this kind, which contains so many complex formulæ, it is surprising to meet with so few errors in the text. One of the chief purposes of the translators is to increase the research worker's knowledge of the history of the science and his appreciation of the work of its founders. These valuable advantages, together with a more correct perspective of modern work, are, in the reviewer's experience, to be gained by reading some book such as Graebe's History of Organic Chemistry before the study of the present volume is undertaken.

SAMUEL SMILES.

CRITICAL SURVEY OF QUESTIONS AFFECTING THE COKE-OVEN INDUSTRY. *By* DR. CARL STILL. *Translated from the German by Coke and Gas Ovens, Ltd., Salisbury House, London Wall, E.C. 2, and published by permission of Glückauf. Pp.* 137—300.

The survey is an excellent translation of various articles from *Glückauf* by Dr. Carl Still, now published in a convenient and compact form. The work is divided into three sections dealing with (1) Benzol Recovery, (2) Design of Coke-Oven Flues, and (3) Manufacture of Sulphate of Ammonia, respectively. Each branch is treated exhaustively from a purely theoretical standpoint and the author has gone to considerable pains in a praiseworthy effort to apply the laws underlying physical phenomena to the numerous problems met with in the designing and practical operation of modern coke-oven plants. The work abounds in formulæ and equations, some of which are of a complicated nature and demand a mathematical knowledge beyond the powers of many associated with the routine of a coke plant. This, however, does not detract from the value of the work, as the necessary data, having been collected from well-known authorities, have the merit of authenticity. Moreover, and (in the mind of the writer) of supreme importance, the conclusions arrived at are in the majority of cases in remarkably close accord with the result of the writer's practical experience. To quote an example: the author condemns the common practice of endeavouring to obtain from a benzolised wash oil a crude product rich in benzol, giving, say, 65 per cent. distillate at 120° C., instead of aiming at the recovery of the whole of the absorbable hydrocarbons, whatever their nature may be, even if by so doing the distillation test be reduced considerably. In the case of a "rich" crude benzol, the author's theories point to a loss in absorption efficiency and an actual loss of benzol. During the war period the writer had occasion to investigate this point, and has now ample proof from tests on a commercial scale that at the plant under observation the manufacture of a "straight" 65 per cent. product entailed a serious loss of hydrocarbons, including toluol, and only by effectively stripping the wash oil with a consequent product of less than 50 per cent. was the toluol recovered efficiently. The concordance of practice with theory in this case gives one confidence in the theories expounded, and on the whole, where the details of the equations are obscure they may be safely "taken as read" and the mind concentrated on the summaries and conclusions arrived at.

In section (1) the author discusses the determination of vapour tension, general rules for benzol absorption, internal conditions in scrubbers, benzol yields, effect of re-circulation of wash oil, etc., terminating this section with a *résumé* of the highest possible significance to workers in this particular branch. In the second section the author deals with the design of coke-oven flues, going very fully into the question of the relative areas and sections of individual flues in ovens of the vertical-flue type, sizes of gas-nozzles, effect of varying widths of ovens, taper of ovens, etc. The points raised should be of great value in plants where the general construction allows of reasonable adjustment of the details of control. In section (3) the manufacture of sulphate of ammonia is discussed from the point of view of the more recent hot and cold, or, as commonly described, the direct and semi-direct, processes for the recovery of ammonia. The thermal aspect under varying conditions is treated fully and useful tables and charts are included. The writer has been highly interested in the work and can wholeheartedly recommend it as worthy of very serious consideration by all workers in the coke-oven industry.

J. E. CHRISTOPHER.

AMERICAN FUELS. *By* R. F. BACON *and* W. A. HAMOR. *Vol. I, pp. ix+628; Vol. II, pp. vi+629. London: McGraw-Hill Publishing Co., Ltd.,* 1922. *Price* 60*s. net.*

These two volumes are inscribed as being of the Mellon Institute Technochemical Series. They consist of a series of twenty-six essays, by various authors, on different problems of fuel technology. As is perhaps inevitable with such a compilation the arrangement of the material is not always happy; for example, some of the problems relating to power production are described under "coal preparation," and those relating to coal-washing under "finely-divided fuel."

Whilst the work no doubt makes a fairly complete survey of modern American practice, there appears to be a bias in favour of untried processes, which may or may not be still in the early experimental stage; and it is often difficult to judge whether the essayists describing these processes take them seriously or regard them as means of brightening their narratives. Some of the novelties described, with such details as are available, or the imagination of their inventors has anticipated, are such methods of cleaning coal as the Trent amalgam process, the Chanco sand-flotation process, and electrostatic separation; a rotary gas-producer employing a pulverised fuel; the Dayton process for making producer gas from liquid fuel; and a mercury-vapour turbine, destined to rival the Diesel engine as a prime-mover; such things make interesting light reading.

Undoubtedly the most important article in the volumes is that dealing with the preparation and uses of pulverised coal; it is a long article (242 pages), and presents what is probably the best coherent account that has yet been published of this rapidly developing branch of fuel technology. Another commendable chapter is that on surface combustion, which as an industrial heating process seems to have had better luck in America than in this country. The remaining chapters are, as a whole, devoid of interest, though there are occasionally to be found, amongst the welter of commonplace, items of information regarding American thought and practice which have not been impressed hitherto upon British readers; it is, however, somewhat surprising, in view of the rapid development of fuel technology in America, often to find adherence to antiquated and incorrect views of the phenomena involved in the preparation and use of the various fuels. No chemist can feel satisfied with the present extent of the application of scientific knowledge to fuel problems as exemplified in writings of this character.

The work is furnished with one inadequate index, annoyingly placed at the end of the second volume.

R. V. Wheeler.

Electricity. By S. G. Starling. *Science in the Service of Man Series. Pp.* 245. *London: Longmans, Green and Co.,* 1922. *Price* 10*s.* 6*d. net.*

Within the limited compass of about 240 pages the author of this book has endeavoured to cover the whole range of electrical engineering and the modern theory of electricity, and the result is that everything has had to be severely clipped, mathematics is entirely omitted, explanations are somewhat vague, and certain essential details are absent.

The first nine chapters are treated in the conventional way, and it is not until Chapter X is reached that real interest is stimulated; from here onward the author has done real service in putting modern theory in a simple and understandable form to those who have an elementary knowledge of the subject. Such defects as occur in this part of the book are due more to the author's desire to seek a simple and concise explanation of a difficult point without the aid of mathematics, than to a want of familiarity with the subject; had these chapters been expanded and made to cover the whole range of the preceding ones, even at the expense of eliminating such old friends as rubbed amber, loadstones, etc., which are to be found in scores of similar books, a real advance would have been made. As it is, we fear that the average chemist will find very little to interest him in the first part of the book, whilst those parts dealing with the strictly electrical-engineering problems are decidedly weak.

The treatment of the direct-current dynamo and motor and the description of the three-wire system of distribution are unsatisfactory. For the measurement of power the Kelvin watt-balance is described rather than the more simple and generally employed dynamometer-wattmeter of the two-coil type, and the Thomson energy-meter is the only type described, no reference being made to ampère-hour meters either of the magneto-motor or electrolytic type, although these are now almost universal on DC supply. The chapter on alternating currents is still more unsatisfactory. The author studiously avoids dealing with the effect of inductance and capacity in the AC circuit, with the result that from the outset he is in difficulty. The reader is left with the impression that resistance is the controlling factor in transformer windings, that single-phase generation is the rule rather than the exception, and that the single-phase induction motor is n most general use. How the latter machine is onstructed, and how the split-phase necessary for starting is derived are left to imagination.

Polyphase currents are considered outside the cope of the book, and are therefore dismissed in a ew words. We wonder what the power engineer will think of the statement on page 67:—"For hese reasons the synchronous motor is no use for pplying power, and is only employed in certain maller pieces of apparatus where constancy of peed is of the greatest importance."

In the chapter on electric lighting undue prominence has been given to subjects which have been written up so many times before. The carbon-filament lamp and the open carbon-arc occupy a large amount of the space which might well have been devoted to the more modern developments of electric illuminants. More on the processes of producing wire-filaments, the process of "dark or chemical" exhaust with the employment of "getters and fillers," metallic arcs, mixed electrode arcs, and vacuum-tube lighting would have been welcome.

The treatment of electrolysis and batteries is very elementary, and to the general reader will probably be of interest, but to the chemist a much fuller treatment would be more welcome. A brief description is given of the Nodon valve, now practically obsolete, but no mention is made of the more efficient mercury-arc-rectifier.

The chapters on Electromagnetic Theory and Wireless Telegraphy, Gases and X-rays, and Radioactivity are well done so far as they go, but they might have been expanded. The book concludes with a glossary of electrical terms, and here again we experience disappointment. The definitions of the ampère, ohm, and volt will not prove very helpful to the general reader, and the same applies to several of the other definitions.

In conclusion, it may be said that where the author has to deal with the purely physical problem the book is useful, but those parts dealing with the technical and engineering side of the subject require considerable revision; and the value of the work would be greatly enhanced by the inclusion of such subjects as the modern theory of magnetism, magnetic alloys, arc welding, electric furnaces, thermo-electricity and the electrical methods of measuring high temperatures, and the more recent developments in electric lighting.

CORRESPONDENCE

THE NEW COLOUR INDEX

Sir,—I appreciated greatly the review and constructive criticism of the Colour Index by Prof. H. E. Fierz in the last issue of the *Journal*, and am indebted to him for drawing attention to some errors and omissions. The fact that the Colour Index is published in parts affords the opportunity of incorporating such information in the list of corrections and additions in the final part.

The nucleus of the Colour Index represents mainly a collection of information on dyestuffs which has been published up to the present. This is then submitted to colour manufacturers and to members of the Revision Committee, and, as a result, numerous corrections have been made and additional facts have been included in the Colour Index as published. Unfortunately colour manufacturers are not always prepared to correct an inaccurate statement, as is shown in the case of Erio Azurine B (No. 59) quoted by Prof. Fierz, for Messrs. Geigy and Co. had an opportunity to make the correction but did not do so.

As Prof. Fierz states, absolute accuracy in a work of this kind is impossible for numerous reasons; the Colour Index represents an attempt to make the best use of the information at my disposal.

The desirability of including references to "Friedländer" was considered, and these references were omitted because almost every German Patent quoted is contained in "Friedländer" and, consequently, can be found readily. It is intended to index, not only all the commercial names of dyes in the Colour Index, but also all the patent numbers quoted. The inclusion of a column in this patent index giving references to "Friedländer" is under consideration and, if decided upon, will meet Prof. Fierz's point.

Parts I, II and III of the Colour Index have now been published, and it is anticipated that the remaining parts will appear at monthly intervals until completion.—I am, Sir, etc.,

F. M. Rowe,
Editor, Colour Index.

Manchester,
Dec. 2, 1922.

OBITUARY

H. J. POWELL

The death of Mr. Harry James Powell, C.B.E., B.A., removes from the glass industry a prominent and well-known figure, and one who did much, over a long period of years, to maintain contact between science and industry.

The glassworks at Whitefriars are the oldest and most famous in London, the business having been commenced about 1680, coming to the Powell family in 1834. Mr. Harry Powell, after a training at Rugby and Trinity College, Cambridge, where he took a second class in Classical Moderations, entered the business in 1873, and throughout the long period of his control showed himself in sympathy with progressive ideas in the industry. Thus, in 1875, de la Bastie carried out experiments at the works on glass-toughening, whilst in that same year glasses were melted at the works containing salts of didymium and erbium for experiments to be conducted at Oxford.

This service to science was but the forerunner of many. Thus, Mr. Powell had vacuum vessels made for Prof. Sir James Dewar's low-temperature work in 1895; in 1897, special glasses for Lord Berkeley's experiments on electrolysis, and glasses for Professors Gray and Dobbie for use in investigations on the relation between the dielectric constant and the composition of glass. Commencing in 1911 a series of glasses was made to assist Sir William Crookes in his researches on glasses affording protection from heat and ultraviolet radiations. Under Mr. Powell's managership of the works there were also produced, at various dates during the period of 25 years before the war, X-ray bulbs, glasses for artificial eyes, and special glasses for thermometers of very small depression constant. Technical investigations of special interest to the glass manufacturer were also carried out and were briefly summarised by Mr. Powell in a paper to the Society of Glass Technology in 1918. Because of his wide experience, as well as the ability of the factory to make a variety of scientific glass, Mr. Powell's services were of great value during the war period.

Mr. Powell was Juror for glass at the Paris Exhibition in 1889, one of the first vice-presidents of the Society of Glass Technology, chief contributor to the article "Glass" in the Encyclopædia Britannica, joint author with Messrs. Chance and Harris in 1882 of "Principles of Glassmaking," and the author of a number of papers on glass technology. He also took an interest in public work before the war, representing Dulwich in the first and second London County Councils, was a governor of Dulwich College from 1898, a co-opted member of the London Technical Education Board, and a member of the Board of Education Committee for Advice on Art Education.

W. E. S. Turner.

REVIEW

Vol. XLI] DECEMBER 30, 1922 [No. 24

THE ARTIFICIAL SEASONING OF WOOD BY THE OZONE PROCESS

ALEX. RULE

M. OTTO, the inventor of the well-known Otto process for the sterilisation of water by means of ozonised air has ntroduced a process which makes use of the ame agent for the artificial seasoning of wood n an industrial scale (British patents 125,846 nd 133,263).

The object of this process is to obtain a material possessing all the characteristics of wood which has been dried and seasoned by the natural method. Natural seasoning proceeds very slowly and, in extreme cases, must be allowed to extend over several years, whereas the Otto process produces similar results within a few weeks. In freshly cut wood the cells are filled with sap consisting chiefly of water, which constitutes about 40 per cent. of the total weight of the wood; but, in addition, the sap contains a large number of complex substances, which may be classified into two main groups:—(1) Amylaceous substances, closely resembling starch in composition. (2) Resinifiable substances. In natural seasoning the wood gradually loses water, the starchy substances are converted into sugars and the resinifiable substances undergo oxidation to form solids. Only the ligneous tissue of the wood remains unaltered. These changes are accompanied by gradual alteration in external orm; the wood shrinks, and, if the seasoning rocess is irregular, distortion may also occur—or example, a flat surface may gradually ecome curved.

The disadvantages of using incompletely easoned wood in the various arts are too well nown to need recapitulation; if these disdvantages are to be avoided care must be aken only to employ wood which has reached condition of stability as a result of the comlete oxidation of certain components of the ll-sap. This condition can only be attained ith extreme slowness, as illustrated by the ct that wood, which has been exposed to the ction of air for three years, still contains nchanged starch and unoxidised resinous atter. In certain industries, for example, the manufacture of pianos, it is not at all unusual to leave the wood to season in the air for at least ten years before use. Wood left to season in this manner naturally represents capital lying idle and entails charges for storage-space, etc., most of which may be avoided by adopting a suitable process of artificial seasoning. At the present time the question of increasing the rate of seasoning is particularly important owing to the fact that, during the war, the existing stocks of seasoned wood were consumed almost completely: well-seasoned timber is therefore scarce and in many cases shortage of capital renders it practically impossible to continue to rely on the natural method in building up new stocks.

Several processes of artificial seasoning exist already, but according to M. Otto, none of these produces a material which possesses the same characteristics as naturally-seasoned wood. To reduce the moisture-content of wood to 10 per cent. by treating it with hot air, is a comparatively simple process; at the same time very few of the plants used for this purpose are really efficient. Wood, after treatment in this way, is certainly dry, but if the temperature in the drying plant does not exceed 60°C., all the above-mentioned components of the sap remain in the cells unchanged; subsequently certain of these components undergo slow oxidation, which is accompanied by contraction in the contents of the cells; as a result the wood gradually shrinks, just as it would have done if it had been employed in the green state. The starch, which still remains unaltered in the cells, attracts parasites and gives rise to the formation of mould; moreover, these unchanged components of the cell-sap are distinctly hygroscopic, consequently the wood absorbs moisture again from the air. If the temperature of drying is raised with the object of decomposing these substances the results are not very greatly superior. It is true that in these conditions the organic components of the sap are destroyed and disappear, but the general effect is to leave the cells empty, thus rendering the wood brittle and lifeless.

Other processes consist in removing the sap, previous to drying, by treating the wood with hot water or steam. In this way it is, indeed, possible to eliminate the organic components of the sap and to ensure that after the wood has once been dried it will remain so, but again, the cells are left empty and the wood possesses the same defects as arise from drying at a high temperature.

As a matter of fact no process is capable of producing the same results as natural seasoning unless it provides for the oxidation, without elimination, of the organic components of the cell-sap. If an artificial oxidising agent is employed for this purpose it must act rapidly, it must penetrate to the innermost portions of the wood without affecting the ligneous tissue, diluting the sap, or discolouring the wood, and it must leave no residue. These conditions prohibit the use of the majority of oxidising agents ordinarily employed in chemical industry; ozone, on the other hand, fulfils all these conditions and, as employed in the Otto process, is capable of reproducing exactly the phenomena and results of seasoning by exposure to air, but at a rate about three hundred times more rapid.

After a long course of experimental work on the subject M. Otto has now established his process on an industrial scale. It consists essentially in submitting the wood to the combined action of gentle heat and ozone, which brings about simultaneous evaporation of water and oxidation of the organic components of the call sap. Two forms of apparatus, namely, compartment kilns and progressive kilns are employed. The latter form is illustrated by Figs. 1, 2, and 3.

Fig. 1.

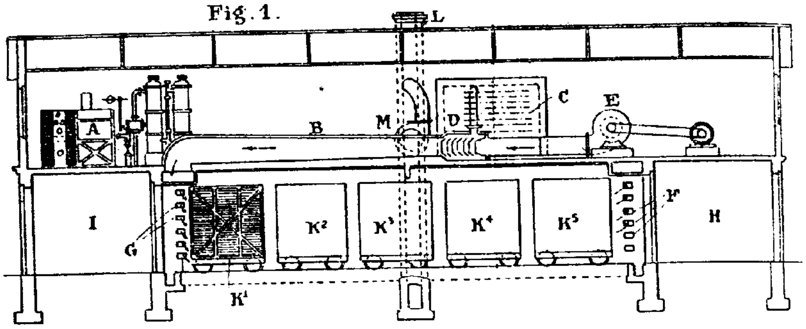

Fig. 2.

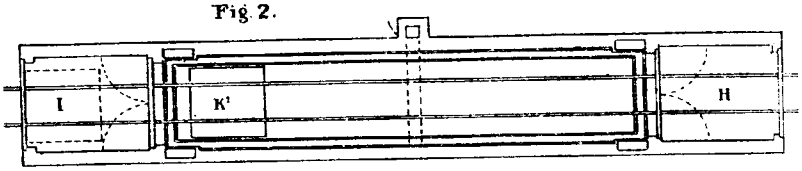

Fig 3.

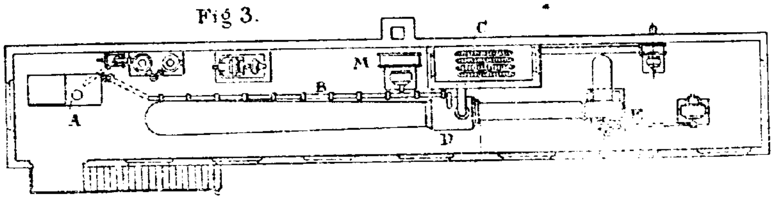

A is an ozone generator of the type employed in the Otto process for sterilising water. The electrodes consist of cast-iron plates, which are cooled by a current of air and are separated by glass di-electrics. The air entering the ozoniser is dried beforehand in earthenware columns containing calcium chloride. B is a duct for circulating the ozonised air, C a heat generator, D an emulsifying mixer, which intermixes hot air and ozone and consists of a series of conical nozzles suitably arranged (Fig. 1). E is a fan for producing circulation of the air. F, G are distributing ports, H and I hot-air locks at the entrance and exit respectively of the kiln, and K¹, K², K³, K⁴, K⁵ are the wagons for containing the wood.

After normal operation has been established the wood is submitted successively to the action of hot air, of ozonised air alone, and of a mixture of ozonised air and hot air. The duration of eatment varies from ten to fifteen days, cording to the nature of the wood. In that riod green wood can be converted into asoned wood possessing all the characteristics wood which has been exposed to the action of r for ten years; the physical properties are entical, and no differences are detectable by e mechanical, chemical or microscopical sts usually employed to distinguish between turally-seasoned and stove-dried wood.

The Otto process has undergone a thorough ries of trials extending over two years, at the perimental factory in Paris, with perfectly tisfactory results. The "Conservatoire ational des Arts et Métiers" has examined the ocess in its experimental laboratory and fully nfirms the results claimed by the inventor.

In France the process is exploited by "La mpagnie Française des Bois," which possesses factory at Paris containing two compartmentlns, each with a capacity of 240 cubic metres. new factory is being erected at St. Denis to erate the process in progressive kilns similar that illustrated above.

HE EXTRACTION OF GASOLINE FROM NATURAL GAS

GEORGE A. BURRELL

Part II.—Extraction with Charcoal, and Plant Design

The third method used for extracting gasoline om natural gas is based upon the adsorptive wer of "activated" charcoal. This process was rfected within the last four years by the writer d his associates.

A very porous charcoal was developed during the r for use in gas-masks. It was introduced by nglish chemists and first appeared on the battleld in the form of the well-known box respirator the English armies. Its method of preparation d mode of action have been widely discussed ewhere, so that it must suffice here to say that best activated charcoal for absorbing gasoline, d probably for most other absorption purposes, made by first charring coconut shells at a derate temperature, grinding the charcoal thus duced, and activating it (freeing it from residual rocarbons and other substances) by heating it a high temperature in the presence of an diser, usually steam.

n gasoline practice the activated charcoal, of 14 mesh, is placed in three absorbers, which, for lant producing 1000 galls. of gasoline per day, about 6 ft. high and 5 ft. in diameter. The ural gas is passed through one of the absorbers, when the charcoal in it has become saturated h gasoline up to about 15 per cent. of its weight, gas is passed into the second absorber; and then the third. In the meantime saturated steam urned directly into the first absorber to drive gasoline out of the charcoal. The gasoline our and steam pass out of the absorber and ugh water-cooled coils, where they areconed and separated. At any given moment one rber is absorbing gasoline, one is being treated with steam, and one is cooling. The residual gas is passed through the absorber being cooled in order to hasten this operation.

One advantage which the charcoal process has over other processes is that at very low pressures, 2—5 lb. per sq. in., the absorbent action of the charcoal is very efficient. At these pressures an oil plant requires very much more oil than is needed to treat the same quantity of gas at high pressures.

Five charcoal plants are now in operation and two more are being built.

Designing Gasoline Plants

In constructing a gasoline plant it is necessary that the quantity and quality of the natural gas be carefully determined. This is simple in the case of absorption plants built to treat natural gas at one of the main lines of a natural-gas company. Tests are usually made by means of a small portable absorber filled with absorbent oil. The gas is measured, and at the end of the absorption the gasoline is distilled from the oil with steam and measured again. Varying types of small absorbers are used. One built of pipe and coils on the principle of a Friedrich wash-bottle gives good results owing to the long contact between the gas and oil, and the best results are obtained with two or three of these absorbers placed in series. The gasoline content of natural gas may be deduced roughly from its density, and also by shaking a measured volume of it with the absorbent oil in a Hempel or similar pipette.

Casing-head natural gas is frequently tested by actually compressing and cooling the gas, as it comes from the well, in a small portable compressor, frequently mounted on a motor car and belted to its engine. Tests have also been made by passing the gas through a small coil embedded in a mixture of solid carbon-dioxide and acetone. Another method is to pass the gas through tubes containing charcoal, and to distil the gasoline from the charcoal by heating it in a distillation-flask about one-half filled with glycerin. There is a host of different testing methods, but those whereby the gasoline-content is directly determined with a small oil-absorber, a portable compressor, charcoal, or a freezing mixture, are the more reliable.

Compression Plant Design

In fixing the size of a compression plant based on small-scale tests, one has to make allowance for a future decrease in the quantity of the gas resulting from the action of vacuum pumps which sooner or later partially exhaust the gas; as this occurs the gas becomes richer in gasoline, and sometimes the net yield of gasoline increases considerably. However, the quantity of gas invariably declines.

Four- to six-inch main gathering lines are used for connecting groups of wells to the plant, and two-inch lines are laid from the main lines to the individual wells. Vacuum pumps are placed preferably at the plant, but at times the distance from the wells may be so great as to necessitate placing the pumps in the field, and using booster pumps to take the gas from the discharge-side to the vacuum pumps and force it, at 0—10 lb. pressure, to the suction side of the compressors at the plant. Compressors of different type are on the market.

Cooling-coils are preferably of the atmospheric type, consisting of 2-inch coils in headers on which

ater drips, frequently from sprays in a cooling ower. The radiating area of the coils is usually 6—0·7 sq. ft. per 1000 cb. ft. of plant capacity.

Run tanks, which collect the condensate direct rom the coils, are equipped with automatic traps discharge the condensate into storage tanks. he discharge gas should be passed through an bsorption tower, preferably in contact with aphtha to extract the last portions of gasoline.

The plant, if possible, should be located close to railroad so as to provide for inexpensive shipment f the product; but many small plants ship their roduct in steel drums, of 50 gallons capacity, by eans of auto-trucks.

There follow data covering four compression asoline plants located in different parts of the nited States.

less fuel. The industry principally uses steam because the fire hazard is thus reduced.

Oil cooling-coils are best made of 2-inch pipe arranged in headers, and with about 1·0 sq. ft. of surface per gallon of oil circulated per hour. Those of the atmospheric cooling type are best.

Fuel Consumption.—In many absorption plants fuel is the largest item of cost. To reduce it as much as possible, gas-engine power should be employed to run the pumps, compressor, generator, and small items of tool machinery, with the exception that if steam is employed for distillation, enough is used in two or three of the pumps to provide exhaust steam for the stills, otherwise steam would have to be generated for this purpose alone. In most compression plants fuel is not an item, because gas otherwise wasted is used; hence no special economy is practised at the power station of a compression gasoline plant.

Data Relating to Compression Plants

Plant No.	Low-stage compression												High-stage compression			
	Intake			Discharge		Cooling coils				Compressor discharge			Cooling coils

a Plant produces daily 700 galls. gasoline of sp. gr. 0·6731—0·6667 from 450,000 cb. ft. of gas.
b Plant produces daily 7,500 galls. gasoline of sp. gr. 0·7000 from 7,500,000 cb. ft. of gas.
c Plant produces daily 1,590 galls. gasoline of sp. gr. 0·6195 from 350,000 cb. ft. of gas.

(From Bulletin 151, U.S. Bureau of Mines.)

DESIGN OF OIL-ABSORPTION PLANT

The design of oil-absorption gasoline plant requires more skill than the design of compression plants. The nature of an oil plant lends itself to the design of a multitude of apparatus for performing the work, and many fantastic kinds of absorbers, stills, heat-exchangers, vent-tanks, etc. were built in the early days of the industry. At the present time, however, designs are fairly well standardised, and different plants now being built are fairly uniform in construction.

Absorbers should be of the vertical type and up to 60 ft. high. Their diameter is limited by the pressure they have to withstand. Twelve feet for low- and 3 ft. for high-pressure absorbers are the customary maxima.

Heat-exchangers are preferably of the double pipe type, because when properly welded they do not leak so readily as those of the built-up tubular types; but the latter are more efficient. They should be designed to give about 0·25 to 0·30 sq. ft. of exchange-surface per gallon of oil circulated per hour.

Steam stills will vary from 4 ft. in diameter and 15 ft. long for heating about 2800 galls. of oil per hour to 12 ft. in diameter and 35 ft. long to treat 20,000 galls. of oil. Pan-type stills heated with free steam, are best when steam is used as the distilling medium, but direct fire-heated stills consume

QUANTITY OF OIL REQUIRED

The quantity of oil necessary to circulate through an absorption plant will vary with the gasoline-content of the gas and with its pressure. More oil is required at low pressures. This follows from well-known laws. The quantity actually required has been found by much experience to vary from about 4 galls. for 1000 cb. ft. of gas at pressures of 150 lb. or more, and containing about one-eighth gall. of gasoline per 1000 cb. ft. of gas, to 150 galls. per 1000 cb. ft. for gas treated at 5 lb. pressure and containing eight galls. of gasoline per 1000 cb. ft.

The cost of constructing an absorption plant depends upon the richness of the gas, the amount of gas, and the pressure under which the gas is treated. A plant handling 20 million cb. ft. of gas at 150 lb. pressure, and containing 200 galls. of gasoline per million cb. ft., will cost about $150,000·00, completely erected.

CALCULATIONS FOR DESIGN

The steam, water, heat-exchange cooling area of coils, fuel requirements, etc. can all be fairly closely calculated after preliminary tests have been made of the gasoline-content of the gas and its pressure and quantity.

Steam requirements can be based on the following average data:—

Temperature of oil entering still ..	135°F. (57·2°C.)
Temperature of vapours from still ..	210°F. (98·9°C.)
Temperature change	75°F. (23·9°C.)
Specific heat of absorption oil	0·50
Weight of absorption oil	7 lb. per gall.
Heat required to raise 1 gall. absorbent oil from 135°F. (57·2°C.) to 210°F. (98·9°C.) = 75 × 0·50 × 7 = 262·5 B.Th.U. per gall.	
Specific heat of gasoline	0·58
Latent heat of gasoline	100 B.Th.U. per lb.
Weight of gasoline	5·5 lb. per gall.

The water requirements for the gasoline cooling-coils can be calculated from the temperature of the gasoline vapour leaving the knock-out box, which will be about 180° F. (82·2° C.), its final temperature, which can be assumed to be about 60° F. (15·6° C.), and the specific heat and latent heat of the gasoline. The last is about 100 B.Th.U.

The water for the oil cooling-coils can be calculated from the temperature of the oil leaving the heat-exchangers, which will be about 160° F. (71·1° C.) in open steam-stills, its final water-cooled temperature before entering the absorbers, about 70° F. (21·1° C.), the temperature of the water before and after it is used to cool the oil, approximately 60° F. (15·6° C.) and 100° F. (37·8° C.), respectively, and the specific heat and weight in pounds per gallon of the absorbent oil.

The capacity of the absorbers in terms of cubic feet of gas per 24 hours can be approximately determined from the formula:—

$$Q = 314{\cdot}16d^2\sqrt{\frac{P}{G}}$$

where P = absolute gas pressure.
G = density of gas.
Q = capacity in cb. ft. per 24 hours.
d = diameter in inches.

The diameter of the absorbers is determined by the gas pressure which they have to withstand. The spreading or absorbent surface of the filler used

Fig. 3.—General Lay-out of Oil-Absorption Plant.

(From Technical Paper 263, U.S. Bureau of Mines.)

inside the absorbers decreases their capacity, and allowance has to be made for this. Their diameter also should be such that the velocity of the gas through them does not exceed 150 feet per minute, otherwise absorbent oil will be carried out of them and into the gas lines by the gas, despite oil-traps placed to catch the oil.

The amount of piping required in constructing the heat-exchangers and oil cooling-coils can be calculated from the constants already given.

General

The industry is now firmly established. Its future growth will not be so rapid as its growth in the past because a tremendous amount of gas, long wasting its gasoline, was "caught up with" and treated, as operators learned of possibilities in extracting the gasoline. Every oil and gas well is, however, a potential gasoline producer, and just as the natural gas and petroleum industry thrives, so will its by-product industry, the natural-gas gasoline industry.

More natural-gas gasoline will be required each year for mixing with heavy refinery distillates to make them suitable for motor use, thus providing the low-boiling constituents needed to make motor-engines start and to accelerate them when running.

Users of gasoline in Europe demand a much higher grade of gasoline for their motor cars than do consumers in the United States. Hence a very large amount of natural-gas gasoline is added to gasoline destined for exportation.

Different grades of natural-gas gasoline are sold at the present time. The most desirable and the highest priced gasoline in the country is so-called "straight absorption gasoline" of sp. gr. about 0·6667. This grade suffers less loss by evaporation than others, in its handling and utilisation. Other grades consist of "straight compression gasoline" of different distillation-ranges and end-points, and a host of blends ranging from specific gravity 0·667 upwards.

Refiners, of course, prefer to buy the crude natural-gas gasoline product and mix it with their efinery "cuts." On the other hand natural-gasoine operators prefer to do this blending themselves t their plants because they save thereby much 'wild" gasoline which they could not otherwise etain. The refiner has the upper hand in the rgument because he has better access to the retail narkets and can better dispose of blends than the natural-gas gasoline operator. The ideal combination is that of a company possessing both refineries nd natural-gas gasoline plants; all the large oil ompanies are in this position.

Natural-gas Gasoline: Distillation Data

Per cent.	A Typical compression product Sp. gr. 0·6114 Deg. F.	B Typical absorption product Sp. gr. 0·667 Deg. F.
Initial	54 (12·2°C.)	75 (23·9°C.)
10	68 (20·0°C.)	98 (36·7°C.)
20	78 (25·6°C.)	114 (45·6°C.)
30	87 (30·6°C.)	127 (52·8°C.)
40	98 (36·7°C.)	141 (60·6°C.)
50	112 (44·4°C.)	155 (68·3°C.)
60	134 (56·7°C.)	172 (77·8°C.)
65	160 (71·1°C.)	—
68	190 (87·8°C.)	—
70	—	190 (87·8°C.)
80	—	218 (103·3°C.)
90	—	276 (135·6°C.)
92	—	302 (150°C.)
	Loss 32 per cent.	Loss 8 per cent.

Both these compression and absorption products were withdrawn as made without blending or allowing them to "weather." In actual plant practice, the compression product is both blended and weathered in order to save as much of the "wild" parts as possible and to reduce the vapour pressure to conform with shipping regulations.

SAFEGUARDING OF INDUSTRIES ACT

SODIUM PHOSPHATE

A complaint to remove "sodium phosphate" from the list of dutiable articles was preferred by the Chemical Merchants' and Users' National Vigilance Committee (represented by Mr. K. Swan and Mr. R. L. Parry), and opposed by the Board of Trade (Mr. Whitehead) and Thomas Tyrer and Co., Ltd. (Sir A. Colefax, K.C., and the Hon. S. Cripps). The one and only sitting, held on November 25, was devoted to a consideration of the form of the complaint. For the complainants Mr. Swan contested that the term "sodium phosphate" was often used by the trade in a generic sense, *i.e.*, as including the three sodium salts of orthophosphoric acid and sodium pyrophosphate; these substances were all heavy chemicals. The opponents held that to chemists, the trade, and the public "sodium phosphate" meant di-sodium hydrogen phosphate and none other; as this substance was included in the Board's list with the prefix "R" and not otherwise, they contended that the Referee had no power to hear or adjudicate on any complaints in respect of other substances. Without prejudice to this objection, the Board asserted that sodium phosphate, mono-, sodium phosphate, di-, "R.," sodium phosphate, tri-, and sodium pyrophosphate were each of them fine chemicals, and that sodium phosphate, di-, "R.," was also extensively used as an analytical reagent. Sir A. Colefax urged that the notice of the complaint was bad because it did not specify any particular phosphate. After much legal argument, the Referee said he would take evidence as to whether "sodium phosphate" had a specific meaning or not. Mr. Swan then handed in a "family tree" showing the relationships between the three sodium salts of orthophosphoric acid, the sodium salts of pyrophosphoric acid and sodium metaphosphate, contending that the term "sodium phosphate" covered all these substances.

Mr. E. J. Parry, in his evidence, referred to a number of text-books and chemical dictionaries of somewhat ancient date in which the term "sodium phosphate" was used rather loosely, but in reply to the Referee said he could not show any reference to "sodium phosphate" being used to connote any substance other than disodium hydrogen phosphate. Speaking as a chemist, the expression "sodium phosphate" was used generically in all the text-books, but when he saw the words "sodium phosphate" alone and without qualification, he understood them to mean the disodium orthophosphate. Cross-examined by Sir A. Colefax, Mr. Parry repeated a previous assertion to the effect that although ortho-, pyro-, and metaphosphoric acids were distinct chemical individuals, they were always treated as separate varieties of phosphoric acid; they were modifications of one original substance. Sir A. Colefax contended that they were not modifications of any single substance, and asked witness for its formula. Mr. Parry replied that there were three formulæ.

The Referee's award, dated December 4, is as follows:—

In this case the complaint referred to me is that sodium phosphate has been wrongly included in the list of dutiable substances. The complainants claim that under this complaint they are entitled to ask me to consider the propriety of the inclusion in the list of: Monobasic phosphate of sodium; dibasic phosphate of sodium; tribasic phosphate of sodium; and pyrophosphate of sodium, both in the neutral and acid varieties. The words "sodium phosphate" do not occur in the list without some further word of description. It is therefore necessary to determine which article or articles in the list is or are referred to by these words.

It is the duty of a complainant to indicate with at least reasonable certainty which article is the subject of his complaint. There is no difficulty about using the exact description appearing in the list. Departure from such a course must lead to ambiguity. The evidence called by the complainants established quite clearly, and I find as a fact, that both in the trade and among chemists "sodium phosphate" is the substance described in the list as sodium phosphate, di-.

The evidence does not suggest that the words "sodium phosphate" have been used or are used to describe any other substance. Yet I am asked to treat the words as co-extensive with the words "phosphates of sodium." I do not think I should be justified in so doing. I cannot see how I can give the words "sodium phosphate" any meaning other than that which they in fact have. The result is that the only article which I have jurisdiction to consider is that described in the list as sodium phosphate, di-. The letter "R" appears against it in the list, and it is conceded that so qualified the inclusion is not open to objection. The complaint therefore fails. No costs.

I understand that there are other complaints referring specifically to sodium phosphate, mono- and tri-. Nothing I have said prejudices in any way the further prosecution of these complaints.

OXALIC ACID

A complaint, lodged by the Chemical Merchants' and Users' National Vigilance Committee, that oxalic acid had been improperly included by the Board of Trade in the list of articles subject to duty under Part I of the Act, was heard by Mr. Cyril Atkinson, K.C., on November 11, 17, 18, and 20. The complaint was opposed by the Board of Trade (represented by Mr. Whitehead) and by certain other interests, and by J. D. Pritchard and Co., Ltd., of Swansea, formerly manufacturers of oxalic acid by the potash-fusion process. This firm was represented by Sir Arthur Colefax, K.C., and the Hon. S. Cripps, and the complainants by Mr. K. Swan and Mr. R. Lambert Parry.

Early in the proceedings Sir A. Colefax stated he would mainly rely upon the contention that oxalic acid was a synthetic organic chemical, and to a less extent he would claim that it was an analytical reagent when in a very high state of purity. The Board of Trade maintained that oxalic acid was not only a fine chemical by reason of its method of manufacture, but a synthetic organic chemical and an analytical reagent.

Mr. Swan's case was that oxalic acid is a heavy chemical; if that were proved it would follow from the wording in the schedule that oxalic acid was not a synthetic organic chemical, or an analytical reagent, or any other fine chemical. [The relevant words of the Schedule are: "Synthetic organic chemicals (other than synthetic organic dyestuffs, colours and colouring matters imported for use as such, and organic intermediate products imported for their manufacture), analytical reagents, all other fine chemicals (except sulphate of quinine of vegetable origin) and chemicals manufactured by fermentation processes."] According to the trade a synthetic organic chemical was a fine chemical; the process of manufacture of oxalic acid through sodium formate was not truly synthetic; and oxalic acid was only used in minute amounts as an analytical reagent.

The Referee stated that he would adopt the definition of "synthetic" that he laid down in the camphor case:—

"The word 'synthetic,' as used in the Act, means a building-up of carbon compounds either from their constituent elements or from groups of differently constituted molecules by orderly steps, the result of which can be followed, and from which the constitution of the structure can be deduced or inferred" (*cf.* J., 1922, 239 R).

Mr. A. F. Butler, of R. W. Greeff and Co., Ltd., said that the trade had always regarded oxalic acid as a heavy chemical: in lists issued by his firm in 1914 and 1922 it was classified as a technical chemical, and (in answer to Sir A. Colefax) it appeared in one recent list under the heading "Fine Chemicals and Pharmaceutical Products." He had never heard it described in the trade either as a synthetic organic chemical or as an analytical reagent. Before the war commercial oxalic acid was of 99—100 per cent. purity, but to day from 98 to 100 per cent. Prior to hostilities his firm was agent for a German combine of manufacturers and he dealt with the agency known as the Verkaufs-stelle für Oxalsäure. Nearly all the acid he had imported in 1921 came from Holland, where it was manufactured, he believed, by the formate process.

Mr. W. G. Wilson, a director of Charles Page and Co., Ltd., gave similar evidence. In addition to trading with Germany and Holland, his firm imported a little oxalic acid from Norway and from the United States, representing in this country the Victor Chemical Works, of Chicago, where the output, by the formate process, was over 1000 tons per annum. American oxalic acid could not compete in Europe. His firm dealt in quantities ranging from one cask (up to 5—8 cwt.) to 10-ton lots, and sold it mainly to the textile and leather industries and for bleaching straw.

Mr. John Brown, of Brown and Forth, Ltd., said that he always associated the term "fine chemical" with a B.P. standard of purity. He imported oxalic acid in 5—10-ton lots from Holland, Germany, and Norway, and he also bought from Pritchards, but this firm could not compete with the foreign suppliers. America, however, was "down and out." He was not importing oxalic acid at the present time, preferring to wait to see which way the cat jumped. (The Referee: "Am I the cat?")

Mr. E. J. Parry stated that he had searched trade literature and found that oxalic acid was always classed as a heavy chemical except in two places, in this *Journal* and in the price list of Greef already mentioned. He did not regard the process of manufacture through sodium formate as a synthetic process in the sense laid down by the Referee (*cf. s.*). The first stage of that process, viz., the reaction (a) $NaOH+CO=H.COONa$, was exactly analogous to the reaction between caustic soda and carbon dioxide, and if the formate was called "synthetic," so also must be sodium carbonate. No organic radicles took part in this reaction, and there was no increase in the number of carbon atoms. The reaction *per se* gave no clue to the constitution of sodium formate. The next stage: (b) $2H.COONa=H_2+(COONa)_2$ was a mere decomposition at a very high temperature and lacked every characteristic of synthesis ("a temperature of 400° C. is totally antagonistic to any idea of synthesis"); the course of the reaction was entirely unpredictable. Only if the word "synthetic" were used in the sense of "artificial" could oxalic acid made by this process be called a synthetic organic chemical; and if this broad sense of the word were used, a great number of admittedly heavy chemicals would have to be included. On the point that oxalic acid was claimed to be an analytical agent, Mr. Parry said that its use for this purpose had become discredited; personally, he had not used it for ten years, sodium or ammonium oxalate was now always used instead.

Cross-examined by Sir A. Colefax, who asked if the synthesis of urea from ammonium cyanate was not everywhere admitted to be a true synthesis, although it involved no building up of carbon atoms, Mr. Parry said he would prefer to call it a "preparation"; and he admitted that the analogy between reaction (a) and the action of carbon dioxide on caustic soda was not complete in that in the latter case there was a simultaneous production of water. Reaction (b) was not a synthesis because, for one reason, it was not possible to follow the intermediate steps; probably a considerable number of subsidiary reactions took place and the yield of oxalic acid was only about 45—55 per cent.; but in the first stages of all the classical syntheses the intermediate steps were generally not known. Further, one could not deduce the constitution of the acid from this reaction. He did not regard the polymerisation of acetylene into benzene as a true scientific synthesis, but only a synthesis if that word were used as synonymous with "artificial," in which sense it was often used by chemists. Asked why he did not regard reaction (a) as synthesis, he replied that, except in a few cases, the word "synthetic" was not applied to inorganic chemicals; if it were, nearly every inorganic heavy chemical would be synthetic.

Dr. J. Gordon Parker, the sole witness for J. D. Pritchard and Co., said that if he had been asked five years ago, he would certainly have replied that oxalic acid was a fine chemical, because he had always associated heavy chemicals with productions of hundreds of thousands of tons and with comparative ease of manufacture. He had never heard the mode of preparation through sodium formate referred to otherwise than as a synthetic process, and it was so designated by a large number of authoritative text-books (Ullmann, Perkin and Kipping, Richter, Roscoe and Schorlemmer, Molinari, etc.). He disagreed with Mr. Parry that the final product of a reaction was not synthetic, (a) if its constitution could not be inferred from the method of preparation; (b) if there were subsidiary reactions involving destruction of intermediate products and formation of by-products; and (c) if a high temperature played a part in the process. It was customary for tanners to keep oxalic acid in the same store as reagents, the finer dyes, and fine chemicals. The process of manufacture necessitated very careful control.

In cross-examination by Mr. Swan, Dr. Parker said that in his view "synthesis" did not imply any necessity to be able to deduce the constitution from the reaction or reactions; and in the Referee's definition (*cf. s.*) he would prefer the word "likely," *i.e.*, not haphazard, to "orderly" (steps). Reaction (a) was a synthetic reaction and sodium formate a synthetic organic product. Organic synthesis did not only mean addition of carbon but of hydroxyl and other groups. In the technical process of manufacture the yield was much higher than 65 per cent. Examined by Sir A. Colefax, witness gave as an instance of an organic synthesis taking place at a higher temperature, the conversion of acetylene into benzene; from this reaction alone, the constitution of benzene could not be inferred. An important difference between the reactions of caustic soda with carbon dioxide and carbon monoxide was that the dioxide was the anhydride of an acid, whereas the monoxide was not. He did not regard the manufacture from sawdust as a synthetic process.

Dr. L. A. Jordan, who is the manager of a syndicate about to promote the manufacture of oxalic acid in this country by a new process, said he had specialised in the manufacture of synthetic organic compounds, and he held the view that oxalic acid was a fine chemical; it was of a high degree of purity, and was made neither in very big quantities nor in large batches, by a process which needed careful supervision and skilled labour. Beyond applying the usual tests for a fine chemical he was a chemist and knew by instinct what was a fine chemical and what was not (Referee: "I wish I did"). Oxalic acid was a synthetic organic chemical; he could not imagine any chemist doubting it; it was built up by a series of operations which were individually and collectively synthetic, and which involved the commonest ideas on synthesis such as linking of carbon atoms and a progressive increase in molecular weight, although these points were not absolutely essential to synthesis (*e.g.*, the synthesis of urea, and of aniline from nitrobenzene). The most important points in a synthesis were knowledge of the initial substance and of the final product; knowledge of the intermediate steps might assist in deducing the constitution of the product, but to this end other data, derived from analysis and determination of molecular weight and basicity, had also to be obtained. The Referee alluded to the definition of synthesis used in the camphor case and asked the witness if he could adduce examples of synthesis in which the reacting molecules were not dissimilar. Dr. Jordan instanced the formation of diphenyl from benzene, of the hexoses, $C_6H_{12}O_6$, from formaldehyde, and the condensation of benzaldehyde to form benzoin. In reply to the further question "if as the result of experimentation you arrive at a substance B but want A, is B a synthetic product?" the witness related a number of classic instances in which discoveries now recognised as syntheses had resulted from reactions following unforeseen courses. Finally, Dr. Jordan stated that he took a very wide view of the term "synthesis"; practically all artificially prepared carbon compounds were synthetic, but, of course, there were organic compounds, *e.g.*, certain alkaloids, which had not yet been synthesised.

In his final speech, Sir A. Colefax dealt with certain of Mr. Swan's fallacies, as he termed them. The interpretation that if oxalic acid is not a fine chemical, it cannot be a synthetic compound, was untenable. No one on his side had maintained that every step in a synthesis must itself be synthetic; or that it was essential to be able to deduce constitution from any one reaction involved in a synthesis. The question of high temperature was irrelevant. Although the bulk of the trade evidence was in favour of the view that oxalic acid was a heavy chemical, he would rely upon the abundant evidence to the contrary, supplied by the text-books and Drs. Parker and Jordan.

Mr. Whitehead said that the production of phenol from benzene was a clear case of synthesis not involving an increase in the number of carbon atoms. Mr. Swan's construction, that if oxalic acid was not a fine chemical, it could not be a synthetic organic chemical, was quite wrong; in law, they did not use general terms to define particular terms, but *vice versâ*. On the question of inferring constitution, he submitted that synthesis depended entirely upon the possibility of inferring and not upon the intention of the chemist when he started work or upon the accomplishment.

Mr. Swan, in his address, recalled the evidence as to trade usage which was to be found in the catalogues, price lists, Kelly's Directory, and trade journals; and he contended that this view applied equally well to oxalic acid made by the formate method as by the sawdust process. He reiterated his view of the interpretation to be put upon the wording of the Act, submitting that all synthetic organic chemicals were fine chemicals, and even if that view were wrong the inclusion of a heavy chemical, *i.e.*, oxalic acid, among them would be anomalous and unique. On the question of synthesis he took his stand upon the definition given in the camphor case; Sir A. Colefax had shifted his ground in that respect. Nothing could be gained from a text-book definition unless the author stated what he meant by "synthetic," and he urged that a reaction could not be called synthetic if it were unintelligible or obscure. In the present case the evidence was conclusive that the reaction involving the transition from formate to oxalate was not known with certainty; if it were understood with certainty to-morrow, it would become synthetic. The acetylene→benzene reaction involved the artificial production of benzene; it was not a synthesis within the meaning of the Act.

The Referee's award was issued on December 18, as follows:—

The question in this case is whether oxalic acid is properly included in the list of dutiable articles. The inclusion in the list is justified on three grounds:—1. That oxalic acid is a synthetic organic chemical. 2. That oxalic acid is a fine chemical. 3. That oxalic acid is an analytical reagent. I am not satisfied that oxalic acid is a fine chemical. Indeed, I think it is not. I am quite satisfied that its inclusion cannot be justified on the ground that it is an analytical reagent. But I have come to the conclusion that it is a synthetic organic chemical, and as such rightly included in the schedule.

The question whether oxalic acid is a synthetic organic chemical is one of considerable difficulty. It is, I think, entirely a matter of opinion, depending upon the particular view held as to the precise limitations of the meaning of the word synthetic. In the synthetic camphor case I accepted the following definition of synthesis: "A building-up of carbon compounds either from their constituent elements or from groups of differently constituted molecules by orderly steps the result of which can be followed and from which the constitution of the structure can be deduced or inferred." It may be that on some future occasion it will be necessary to reconsider this definition, but I do not understand that this definition is challenged by either side in this case. The difference of view has reference to the question whether the steps in the building up of oxalic acid from caustic soda and carbon monoxide come within it. There is no doubt that oxalic acid is an organic body which can be built up from its elements. The process begins with the use of carbon, the number of carbon atoms in the molecule is increased and the molecule becomes heavier. The molecular construction contains two atoms of carbon linked together. Although in practice the first step in building up is the combining of carbon monoxide and caustic soda, both these substances can be obtained from their elements.

The real dispute is as to whether the steps taken in the building up are orderly steps and steps from which the structure of the resulting molecule can be deduced or inferred.

The decision seems to turn upon the view taken of the main step—the heating of the sodium formate causing the hydrogen to be liberated and the two unsaturated links to combine, forming sodium oxalate. The temperature necessary to produce this reaction is no haphazard temperature. A temperature of 440° C. or thereabouts is necessary except in the presence of sodium carbonate or certain other substances when a lower temperature will suffice, viz., 300° to 350° C. In this sense it is a controlled temperature. It seems to me quite impossible to rule out a reaction depending upon a controlled degree of heat from those steps regarded as synthetic. But it is said that it is impossible to draw any inference as to the structure of sodium oxalate from the reaction in question. If the molecular structure of a substance is known before it is synthesised, and that knowledge is capable of suggesting, and does suggest, steps which may possibly bring about that result and then by experiment it is found that these steps do in fact produce that result, it seems to me that such steps are entitled to be considered as synthetic. I think that one might well have reasoned that if by heat the hydrogen could be expelled from the molecule H.COONa leaving the unsaturated link COONa it was at least possible that two or more of these links might combine and give the structure desired. The reasoning back from a known structure seems to me to be just as much a basis of synthesis as the reasoning forward towards an unknown structure. Further, I do not think that the definition demands that the hypothetical operator should know exactly what is going on during the experimental reaction.

The view I take after a very careful review of the evidence both in this and the camphor case is that oxalic acid obtained by the formate process is synthetic. There is one other matter with which I must deal, namely, Mr. Swann's argument that the expression "synthetic organic chemicals" is limited to fine chemicals. He relies on the words "all other fine chemicals" as indicating that this part of the schedule is only intended to cover chemicals that are fine. There seem to me to be insuperable difficulties about this view. It would give no independent effect to the words "all synthetic organic chemicals" or "analytical reagents." I quite agree that the word "other" creates a difficulty, but I adhere to the view I expressed in the sodium phosphate case that the particular description "all synthetic organic chemicals" cannot be cut down or defined by the more general words "all other fine chemicals." I therefore decide that oxalic acid manufactured by the formate process is properly within the schedule. It is conceded that the acid imported into this country is all manufactured by this process. I therefore award that the complaint fails.

CHEMICAL INDUSTRIES IN CANADA

The Dominion Bureau of Statistics has recently published a report on the production of chemicals and allied products in Canada for the calendar years 1919 and 1920. The statistics cover the following groups: Coal tar and its products; acids, alkalis, salts and compressed gases; explosives, ammunition, fireworks and matches; fertilisers; medicinal and pharmaceutical preparations; pigments, paints and varnishes; soaps, perfumery, cosmetics and other toilet preparations; inks, dyes and colour compounds; wood distillates and extracts; miscellaneous chemical industries. The report is disappointing in so far as the number of industries treated is limited; the paper and pulp, alcohol, glucose and other well-known industries, involving the application of chemical methods and generally associated with chemistry, are, unfortunately, not included, and the reason for these exclusions is not quite clear. Technologists and others having occasion to consult the Canadian report may conclude that many substances which are classed as chemicals are not made in Canada, and there would be good ground for such opinion, because of the detailed information regarding such industries as the manufacture of baking powder, cosmetics, and shoe blacking, which are treated fully in the report.

The report, although somewhat circumscribed in the industries treated, and also belated in making its appearance, is instructive and will prove a source of valuable information; the statistics are more authoritative, fuller, better arranged, and more free from anomalies than any issued in previous bulletins upon these industries. In some instances the textual comment is of such a character that it may induce the manufacturer to think and investigate his methods with a view to ultimately increasing production and lowering cost of manufacture.

The returns for the year 1919 practically cover the transition period arising from the abnormal conditions of war to those of peace, and is particularly marked by the falling-off in the output of the chemical industries employed in the manufacture of war materials.

	1919	1920
Total plants operated	429	456
Par value of stocks and bonds held in—	$	$
Canada	31,905,063	38,930,012
Great Britain	21,869,469	23,417,928
U.S.A.	121,622,220	129,161,069
Other countries	583,091	1,221,247
Total	$175,979,843	$192,730,256

From the foregoing it will be observed that in 1919 nearly 70 per cent. of the par value of stocks and bonds was held by residents of the United States, and that in 1920 this figure had fallen to about 66 per cent.

The total capital, including fixed assets—as lands, buildings, machinery, etc.—and liquid assets—as stocks and materials on hand—was $111,760,019 in 1919, and $118,840,897 in 1920, the capital being almost equally divided between the fixed and liquid assets. The average number of employees and amount of wages paid for the respective years were as follows:—

	1919	1920
	No.	No.
Males, salaried	2,539	2,790
Females, salaried	834	890
Male wage-earners	9,190	10.623
Female wage-earners	3,040	2,980
	$	$
Salaries	5,674,203	7,115,734
Wages	10,710,226	14,580,398
Salaries and wages (total)	16,384,429	21,736,132

The average salary for 1919 was, approximately, $1680, and for 1920 about $1940; the approximate wage rate for the respective years was $875 and $1070. The percentage ratio of the numbers of salaried and wage earners in the two years was almost constant.

The following financial statistics cover the costs of fuel, materials, miscellaneous expenses, total expenditure (including wages and salaries), and selling value of product:

	1919.	1920
	$	$
Fuel	2,009,526	3,298,117
Materials	48,303,812	60,082,027
Miscellaneous	17,667,486	21,053,223
Total expenditure	84,365,253	106,877,136
Selling value of products	96,463,988	121,789,336

The total power equipment in 1919 was as follows:—Total rated horse-power of prime movers (exclusive of boilers), 77,171; alternating current, 5896 kv.a., and direct current, 5746 kw. In the year 1920 the total rated horse-power of prime movers employed (exclusive of boilers) was 293,380.

The difference between the selling value of the products in 1919 and the total expenditure was $12,098,735, being about 14·4 per cent. in favour of the former; in 1920 these figures were $15,619,837 and 15 per cent. respectively. Calculating these differences in relation to capital—fixed and liquid assets—they represent in 1919, 10·8 per cent. and in 1920, 13·1 per cent. upon total invested capital.

An examination of some of the expenditure charges is interesting in view of the fact that the excess profit tax and income tax were practically *post bellum* enactments. An industry in which a large portion of the capital is invested in land and in buildings and machinery, which should not call for expensive repair, in 1919, charged 4 per cent. upon the fixed capital to repairs of buildings and machinery, and 13·8 per cent. in 1920; these and wages paid for the respective years, represent the cost of repairs as 32·2 and 64·4 per cent. The buildings and machinery, although in active use in 1918, must have suddenly developed marked signs of post-war weakness, which undoubtedly brought pleasure and relief in the preparation of the taxation schedule.

The values of the imports of chemicals, under the classes enumerated in the report, have been as follows: 1919, total $34,282,647, of which $3,397,095 came from the United Kingdom, $28,719,765 from the United States; in 1920 the total was $29,886,102, derived as follows: U.K. $4,154,345; U.S.A. $23,854,300. In 1921, total $36,334,612; U.K. $6,048,717; U.S.A. $26,766,364. In 1922, total $24,041,885: U.K. $3,238,465; U.S.A. $17,688,482.

The exports were as follows: 1919, total $56,799,799: $20,176,855 to U.K., $30,671,606 to U.S.A.; 1920, $22,581,049: $3,595,936 U.K.; $13,803,067 U.S.A.; 1921, $19,582,057: $3,225,947 U.K., $11,694,858 U.S.A.; 1922, $9,271,027: $939,529 U.K., $5,937,114 U.S.A.

The above customs returns are for the fiscal years ending March 31 of each of the above years.

The imports were at a maximum in the year 1921, in which period the output of Canadian industries was the greatest in value since the termination of the war. The exports in 1919 were the highest ever attained, owing to the shipment of military stores; since that year there has been a steady and heavy decline.

The calendar year 1921 exhibits a marked decrease in value of chemicals produced ($77,748,000), plants employed (444), capital $109,225,000), employees (12,289), salaries and wages ($15,853,000), and cost of material ($36,203,000). Notwithstanding the decline in the chemical industry during the past year, the statisticians are of the opinion that the worst is past, and that Canadian chemical trade will advance to a higher position than it ever held in pre-war times.

THE COAL INDUSTRY

The Dominion Bureau of Statistics has issued a comprehensive report reviewing the coal industry and trade of Canada in the years 1919—20—21. This is one of the best trade returns published by the Bureau; it contains in detail the output of collieries, imports of coal by ports of entry, exports, information regarding capital invested, plant equipment, men employed, time worked and lost tonnage, and statistics of the production from each province. The apparent coal consumption of Canada is estimated at between 30 and 35 million tons annually, half of which is imported from the United States. In 1921 there were 396 coalmines in operation, covering an area of 713,000 acres. Total capital invested, at the close of the year 1921, was $176,991,495, of which $77,000,000 was in British Columbia, over $3,000,000 in Saskatchewan, and $1,000,000 in New Brunswick. The coalmining industry gives employment to about 30,000 men, and in 1921 wages amounted to $42,758,471, and salaries aggregating $3,717,238 were paid to about 1600 officials.

The two reports referred to are entitled "Chemicals and Allied Products in 1919 and 1920" and "Coal Statistics for the Years 1919, 1920, 1921," respectively, and are published by the Mining, Metallurgical and Chemical Branch of the Dominion Bureau of Statistics, Ottawa.

SOCIETY OF CHEMICAL INDUSTRY

NEWS FROM THE SECTIONS

SOUTH WALES

A meeting of this Section was held in the Technical College, Cardiff, on December 1, Prof. C. M. Thompson presiding. Mr. H. W. Webb read a paper on the Oxidation of Ammonia, in which he described some of the pioneer experimental work on the process of manufacturing nitric oxide and nitric acid from ammonia, derived from waste gas liquor, by catalytic oxidation with very fine platinum gauze. The conditions of temperature, the preparation and construction of the catalyst, concentration and purity of the gases, and other factors which govern the capacity and efficiency of the oxidising unit were discussed. It was shown that the mixture of air and ammonia which is sufficiently rich in ammonia to maintain the catalyst temperature at its optimum value, does not yield the highest efficiency. The best result, *i.e.*, an efficiency up to 94 per cent., is obtained by using a mixture containing less than 10 per cent. by volume of ammonia and maintaining the catalyst at about 850° C. Catalyst poisons, especially hydrogen sulphide, phosphine and pyridine, were also dealt with. In the discussion it was pointed out that no unchanged ammonia passes the catalyst, so that the product contains no ammonium nitrate; ammonia not oxidised to nitric oxide appears as nitrogen.

MONTREAL

At the meeting held on November 20, the chairman, Dr. A. R. M. MacLean, presiding, Prof. Ruttan read a message of greeting from the President, Dr. Armstrong, to the Dominion Sections, which was greatly appreciated. There were present about 40 senior students from McGill University and the Université de Montreal, and the spirit of good-fellowship displayed between the two nationalities was a happy augury for still closer co-operation in the future.

"The Manufacture of Calcium Carbide" was the subject of the evening's lecture, by Mr. Witherspoon, General Manager of the Canada Carbide Co., who described the development of the electric furnace from the small experimental Moissan furnace to the present-day furnaces producing a ton an hour by a continuous process. He emphasised the fundamental importance of a correct balance between a given weight of material and a given amount of heat. The best method of mixing the lime and coke, and the degree of fineness of the two substances have been the subject of much experimentation, and the conclusion reached is that rough-mixing of coarsely crushed coke of ¼-inch to 1 in. mesh, with lime of 1 in. to 2 in. mesh gives the best yield.

The lecturer then described the developments which led to the adoption of a continuous process of manufacture, the chief of which was the increased supply of current. It was, however, early discovered that a reduction in voltage from the prevailing 75 volts was necessary. Two furnaces were then run in series and an efficiency of 90 per cent. was attained with 1000 kw., but developments rapidly followed, and to-day each furnace is rated at charges, based upon the total amount of salaries

15,000 kw. It is not correct to describe the modern furnace as an arc furnace, as the charge itself is a conductor, and the current passes quietly and steadily through the pasty mass. The arc exists only during the warming-up period, and a true balance in one of these large furnaces is not reached for several days. The different forms of electrodes were described.

The numerous derivatives of acetylene were referred to and a new, entirely Canadian product, Acetylene Black, was introduced to the audience. This substance has a very low specific gravity; it can be easily compressed, and even when compressed is 50 per cent. more bulky than carbon black. Rubber manufacturers have found it satisfactory, and when used in paints it yields a clear neutral grey. As a decolorising black in sugar-refining, and for filtering water, it has proved very efficient.

LIVERPOOL

At a meeting held on December 8, in the University, Dr. J. T. Conroy presiding, a paper was read by Mr. H. M. Langton on "Some Problems connected with the Saponification of Fatty Oils."

After a brief reference to the importance of industrial saponification, the author discussed the theory of hydrolysis of oils and fats, and pointed out that, as a result of the work of Lewkowitsch, Marcusson and others, we must conclude that the saponification of the triglycerides takes place in stages, passing from the triglyceride through the diglyceride to the monoglyceride, and ultimately to the products of complete saponification, fatty acids and glycerol, the complete reaction consisting of three consecutive bi-molecular reactions which are interdependent, though not necessarily taking place at the same rate. The author emphasised the fact that as industrial saponification involves a heterogeneous system, it might well be that physical considerations outweigh purely chemical ones, and experimental facts were quoted in support of this view. It is important to realise that as saponification resolves itself ultimately into a reaction between molecules of a triglyceride and of water, three possibilities are open, viz., (a) reaction in the oil phase, (b) reaction in the aqueous phase, (c) reaction in the surface of contact between the two phases; and Treub has shown that it is the third possibility which supplies the clue to the operation. The importance of emulsification in saponification is made apparent from the circumstance that in an emulsion, the velocity of the reaction which takes place at the surface of contact of the two phases, depends on the magnitude of this surface; anything which increases this surface, *i.e.*, diminishes the surface tension between the fatty matter and the aqueous solution, accelerates the reaction. From this aspect, the function of the particular reagents used technically in the acid, autoclave, Twitchell and fermentation methods of saponification, respectively, becomes apparent.

The importance of the time factor in saponification was then dwelt upon, reference being made to the conflicting views of different investigators, some of whom concluded that all oils and fats are saponified at the same rate, and others that the glycerides of the fatty acids are more easily hydrolysed the higher the molecular weight of the fatty acids. The author pointed out, however, that as most of the experiments were carried out in homogeneous solution, they may have little bearing on industrial saponification. A summary was given of previous industrial investigations on the rate and extent of the hydrolysis of different oils and fats, but as the conditions differed considerably no definite conclusions could be drawn. The author then described his own large-scale experiments on the rate and extent of saponification, by the autoclave process, of tallow, palm oil, linseed oil, palm-kernel acid oil, Nos. 1, 2, and 3 whale oils, lime and magnesia being used as the splitting bases. In all cases a constant steam pressure of 8 atm., a charge of 3 tons of oil or fat, an amount of base equal to 2½ per cent. of the weight of oil, and a period of treatment of 10 hours, were employed, the course of the reaction being followed by the withdrawal and testing of samples hourly. The results obtained were shown in a series of curves, which are of the exponential type, being characterised by a slow initial stage followed by a rapid second stage, when about 90 per cent. of the oil is split in the first 4 hours, after which the rate of reduction is much retarded. Magnesia was the most effective base for tallows, palm-kernel acid oil and the whale oils, lime being superior for palm oil, but with linseed oil the rate and extent of hydrolysis were identical for each base. Using magnesia as the base, tallows were hydrolysed most quickly, and in decreasing order come whale oils, linseed oil, palm oil and palmkernel oil. Beef tallow hydrolyses much more quickly with magnesia than mutton tallow. In the case of the whale oils, whichever base is used, the rate of hydrolysis is in the order No. 1, No. 2 and No. 3, No. 1 giving the highest value. Lastly, the author submitted in tabular form numerical details of the average extent of hydrolysis of various oils and fats after treatment with lime and magnesia, respectively, for 8 hours under the conditions outlined above. These averages are compiled from the working of 625 3-ton charges. It appears that a split of upwards of 98 per cent. was obtained with tallow and 92 per cent. with linseed oil.

NOTTINGHAM

On December 13, Mr. S. F. Burford presiding, Prof. H. E. Armstrong gave an address on "Legislative and Departmental Interference with Industry and the Common Weal."

The future of chemistry in England, and the welfare of an industrial population greater than the country can carry depend upon the extent to which chemists are mastered by the idea of their solidarity, and insist on being represented on all bodies dealing with questions in which chemistry is involved. By an abuse of the Food Acts, the lowering of the quality of milk has been allowed to continue unchecked for fifty years. The Act providing for the sterilisation of milk by heating was passed with insufficient knowledge, but evidence is accumulating that the new dangers so introduced are greater than those which were to be removed in this manner. The bureaucrat and the sentimentalist are trying to deprive us of our most effective paint. This is clearly shown by the inner history of the Home Office inquiries and of the proceedings of the International Labour Conference last year.

The inquiries into the smoke nuisance were entrusted to technically unqualified persons, who concentrated on a totally unnecessary proof of the nuisance and almost neglected the question of low-temperature carbonisation. Private persons of vision and imagination have investigated this problem with a success that will never be attained by H.M. Fuel Research Board. The Safeguarding of Industries Act is a most unhappy example of lack of clear thinking. The chief, if not the only, gainers are the members of the legal fraternity. Chemists should protest against the shameful way in which the traditions of their craft have been treated. The whole lists should now be put in order by competent advisers. In the dyestuffs industry the first condition of success is direction by persons who understand. No general in the army, however distinguished, can lead the attack on dyestuffs.

In the matter of research freedom of action, which is as much the right of scientific investigators as of artists and poets, is being threatened by a bureaucratic body, largely in the hands of literary men. This has displaced the Royal Society, which has made no attempt to influence the public, as it did in the days of Faraday.

COMMITTEES OF COUNCIL

PUBLICATIONS COMMITTEE

The President and Hon. Treasurer (*ex-officio*), J. Allan, J. L. Baker (chairman), F. H. Carr, W. H. Coleman, J. W. Hinchley, H. Levinstein, G. T. Morgan, J. A. Reavell.

Co-opted Members: E. R. Bolton, C. F. Cross, W. R. Hodgkinson, E. Grant Hooper, J. R. Partington, W. F. Reid, W. G. Wagner.

Nominated by Local Sections, etc.: J. T. Dunn, C. J. Goodwin, W. J. Jones, E. Lewis, L. L. Lloyd, B. D. W. Luff, F. M. Potter, and H. D. Richmond.

WEEKLY JOURNAL EXECUTIVE COMMITTEE

The President and Hon. Treasurer (*ex-officio*), Sir W. J. Pope, W. J. U. Woolcock, F. H. Carr, C. S. Garland.

GENERAL PURPOSES COMMITTEE

The President and Hon. Treasurer (*ex-officio*), J. L. Baker, F. H. Carr, C. S. Garland, J. M. Wilkie, W. J. U. Woolcock (chairman).

REPRESENTATIVES ON OUTSIDE BODIES, 1922–23

Federal Council for Pure and Applied Chemistry: F. H. Carr, Dr. S. Miall, and W. J. U. Woolcock.

National Physical Laboratory (General Board): Sir W. J. Pope and Prof. F. G. Donnan.

Institute of Chemistry Standards Committee: Dr. A. Holt, Prof. A. R. Ling, and Mr. W. G. Wagner.

British Engineering Standards Association: Aircraft Sub-Committee on Chemicals: Prof. W. A. Bone. Sub-Committee on Textiles: Mr. C. F. Cross. Sub-Committee on Dopes: Dr. J. N. Goldsmith.

Imperial Mineral Resources Bureau: Lead, Silver, Zinc, and Cadmium Sub-Committee: Mr. H. M. Ridge. Aluminium, Magnesium, Potassium and Sodium Sub-Committee: Dr. R. Seligman. Minor Metals Sub-Committee: Mr. W. G. Wagner. Publications and Libraries Sub-Committee: Mr. W. J. A. Butterfield. Abstracts Sub-Committee: Prof. H. Louis and Mr. T. F. Burton. Chemical Industries Sub-Committee: Mr. C. S. Garland.

British Empire Sugar Research Association: Prof. A. R. Ling and J. W. Macdonald.

Committee on "Tests of Graduated Glassware": J. L. Baker, F. H. Carr and Dr. B. Dyer.

Governing Board of Imperial College of Science and Technology: Sir W. Pearce.

Sectional Committee of Chemical Engineering of the British Engineering Standards Association: C. J. Goodwin, J. A. Reavell, C. S. Garland and Dr. W. R. Ormandy.

MEETINGS OF OTHER SOCIETIES

SOCIETY OF PUBLIC ANALYSTS

Mr. P. A. Ellis Richards presided at the meeting held in the Chemical Society's Rooms on December 6, when the following papers were presented.

A note on the estimation of formaldehyde and acetaldehyde, by Messrs. E. W. Blair and T. S. Wheeler, stated that in investigating the action of oxygen and ozone on various hydrocarbons, the authors had had to devise accurate methods of analysing solutions containing mixtures of (a) formaldehyde and acetaldehyde, and (b) formaldehyde, hydrogen peroxide, formic acid, with a trace of ozone. For (a), satisfactory results were obtained by estimating the total aldehydes by Ripper's bisulphite method (Monat. für Chem., **21**, 1079) and the formaldehyde by the cyanide method. For (b), the components were estimated *seriatim*, the formic acid with $N/100$ alkali, ozone with neutral potassium iodide, hydrogen peroxide by Kingzett's method (Analyst, **9**, 6), and formaldehyde by Romijn's method.

Mr. H. A. Peacock has found that sulphur dioxide may be absorbed by cattle cakes and meals during fumigation, but that it disappears after about a week. Therefore any harmful effect ascribed to the consumption by stock of such cakes is not due to sulphur dioxide. The amount absorbed was found to depend on the variety of cake, the harder cakes absorbing less than the softer, and on its physical condition, *i.e.*, whether in block or powder form.

Mr. C. H. D. Clark described a sliding scale designed to assist in titrating strong solutions against weaker standards by dilution and measurement of a known volume. The scale, which is easily made and set in positions depending on the dilution, indicates what alternative dilutions are available in any particular case, in order that a convenient burette-reading may be obtained at the end of the process.

Some notes on the unsaponifiable matter of fats were presented by Mr. D. W. Steuart, who dealt with the difficulty of deciding whether a margarine containing no coconut, palm kernel or butter fat is made of true animal fat, or whether it contains palm oil or hardened vegetable oil. The amount of sterol in the unsaponifiable matter and the melting-point of the sterol acetate do not give the information desired. The proportion of sterol in the unsaponifiable matter varies from 48 per cent. in maize oil to 7 per cent. in palm oil, and from 38 per cent. in lard to 9 per cent. in hardened whale oil. Highly hardened fats still contain sterol. The cholesterol acetate of animal fats melts at 114°—114·5° C., and the phytosterol acetate of vegetable fats is a mixture, of which a fraction melts at 125° C. or higher, but some pure vegetable oils yield a fraction melting about 114° C.

In a note on the sulphuric-acid test for fish-liver oils, Messrs. N. Evers and H. J. Foster show that the sensitiveness of this test is greatly increased by adding natural oils (*e.g.*, olive, arachis, lard oils, tallow) which do not give a colour reaction. Oxidation of the oils destroys this power, but it is unaffected by hydrogenation. The active substance is not cholesterol or phytosterol, and it is not present in commercial oleic or stearic acids, mono- or di-glycerides. The brown coloration produced by sulphuric acid with liver oils, after oxidation, is also intensified by the addition of natural oils.

BRITISH LEATHER MANUFACTURERS' RESEARCH ASSOCIATION

Following the third annual general meeting of the Association, held on December 7, Dr. R. H. Pickard, director of research, gave a lecture on the work of the Association in the large hall of the Leathersellers' Company. The lecture was open to all members of the trade and was attended by members of the Association and a large number of others. Mr. J. H. Williams, Worshipful Master of the Leathersellers' Company, presided, and in opening the proceedings emphasised the importance of research to the industry. Col. W. E. Walker, chairman of the Association, explained that the results of research were, of course, the property of the members, but that this meeting had been arranged to increase the interest of the trade in the Association.

Dr. Pickard commenced by paying a tribute to the work of Prof. H. R. Procter, to whom was practically due the creation of the science of leather manufacture. Some tanners were at present wondering whether they could afford to join the Association; it would soon become apparent that they could not afford to remain outside. The policy of the Association had been to study fundamental principles, and he believed that they had now reached the point at which the laboratory results were capable of being translated into works practice. As an example, they had started to investigate the composition of the actual chrome-tanning agent. Initally, he had been told that this was not likely to interest the tanners and, moreover, was already being done in America. They were still trying to do it in America. He and his staff were now hot upon the trail of the actual chrome-tanning agent, and incidentally believed that they had discovered one of the main causes of, and probably the means of preventing, the occurrence of a very important trouble in chrome-tanning, namely "spue." After referring to some common misconceptions in the trade, Dr. Pickard exhibited a remarkable series of lantern slides, showing the effects on the arrangement and structure of the fibres in goat, ox, and sheeps skins of various swelling, plumping, and depilatory agents; and by means of a projection microscope he demonstrated the swelling of single fibres in acid and other liquors.

Mr. J. Turney Wood said that the lecture had been a revelation to most of them. If there was any part of the work of the Association which tanners could not understand they should employ a chemist who could. Dr. Gordon Parker congratulated Dr. Pickard on the work generally and on the magnificent lantern slides. Mr. Seymour Jones proposed a vote of thanks to Dr. Pickard and his staff for their valuable work, and this was seconded by Mr. E. D. Evans, president of the United Tanners' Federation.

THE BIOCHEMICAL SOCIETY

A meeting was held in the Biochemical Department, Institute of Physiology, University College, London, on December 11. Prof. J. C. Drummond occupied the chair and the following papers were communicated.

"Cod-liver Oil in the Winter Feeding of Milch Cows," by J. C. Drummond, J. Golding, J. Mackintosh, S. S. Zilva and K. H. Coward.

Further confirmation was brought forward of the fact that the amount of vitamin A in cow's milk is largely determined by the diet of the animal. In an experimental group of cows brought in to stall under winter conditions and fed on a typical winter ration of roots, hay and concentrates deficient in vitamin A, the milk secreted soon showed a marked falling off in vitamin content. It was found possible to raise the amount of vitamin A in the milk very considerably by giving the animals a small supplement of cod-liver oil of high potency daily. As little as 2 oz. per day was highly effective. Amounts up to 4 oz. per day were given without any evidence being obtained that the taste or flavour of the milk or butter were affected, but it is advisable to employ only oils of high grade. Cows permitted to have limited access to pasture during the winter show a gradual improvement in the vitamin-A value of their milk as the spring advances and the pasturage freshens.

"The Chemistry of the Vitamin-A Fraction of Cod-Liver Oil," by J. C. Drummond and K. H. Coward.

The vitamin A can be almost quantitatively transferred to the unsaponifiable fraction of highly potent fish-liver oils if precautions are taken to prevent oxidative changes. The only crystalline substance which has been isolated from this fraction with certainty is cholesterol, which constituted about 35 per cent. of the fraction in the case of the sample of oil examined. The whole of the cholesterol may be removed by crystallisation from methyl alcohol and precipitation with digitonin, leaving the physiological activity wholly in the filtrate. Small traces of another crystalline material have been obtained from the cholesterol-free residue but in an amount too small for identification or growth tests. Benzoylation, acetylation and bromination of the unsaponifiable fraction yielded only the derivatives of cholesterol. From the filtrates, which retained the activity, no further crystalline substances could be obtained. There was no evidence of the presence of hydrocarbons of the spinacene type nor or ketonic or aldehydic substances. Incomplete removal of the lipochrome pigment did not appear to lessen the activity of the fraction, so that it is improbable that the active substance is of this class. No confirmation of Iscovesco's work on the association of the active substance with a substance of the lecithin type could be obtained. Many highly active oils gave no precipitate by following his technique. The active fraction, if prepared from a high grade oil, is free from nitrogen, iodine, sulphur and phosphorus. Attempts to separate the potent substance by steam distillation, super-heated steam or high vacuum distillations of the unsaponifiable matter demonstrated that this substance is volatile under these conditions but no sharp separation was obtained. In most cases there was a considerable loss in spite of all operations being carried out in a vacuum or an inert atmosphere. Fractional crystallisation from numerous solvents only yielded cholesterol with concentration of the vitamin in the mother liquors.

THE PHYSICAL SOCIETY

At the meeting held on December 8, a paper on "The Relation between Molecular and Crystal Symmetry as shown by X-ray Crystal Analysis" was read by Mr. G. Shearer. After a discussion of the nature of the elementary crystal lattice, a table was given showing the number of asymmetric molecules per unit lattice necessary to produce the symmetry of the various crystal classes, thirty-two in number. These range from 1 in the case of the triclinic asymmetric class to 48 in the case of crystals of the hexakisoctahedral class. The existence of fewer molecules than the "symmetry number" in the unit cell implies the existence of symmetry in the molecule itself. Only certain positions of the variously oriented molecules in the crystal lattice are possible. Supposing that the minimum material necessary to satisfy the symmetry conditions is employed in building crystals, it follows that each unit cell contains one and one only of each differently oriented molecule. There is considerable evidence to show that certain molecules possess symmetry which, in crystal building, is shared with the crystal. Thus the fact that naphthalene and anthracene form monoclinic crystals with two instead of four molecules in the unit cell implies that each of these molecules possesses a two-fold symmetry. Such symmetry is destroyed by the addition of an OH-group to one side of the naphthalene molecule. Similarly, the addition of COOH and other groups to the benzene molecule, as in benzoic, salicylic and phthalic acids, which form monoclinic prismatic crystals having four molecules to the cell, destroys the symmetry of the benzene molecule. The symmetry of the benzene molecule is found to be fourfold, consisting possibly of a plane of symmetry and a diagonal axis perpendicular to the plane. Neither the Kekulé nor the Claus structural formula for benzene satisfies this condition. The formulæ of Ladenburg and Dewar, respectively, conform with the condition.

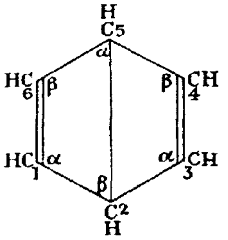

FIG. 1

Dewar's formula is shown in Fig. 1, and much chemical evidence in support of its validity has recently been advanced by Ingold. If the structure is a puckered hexagon, as suggested by Bragg, the points α lying above, and those marked β lying below the mean plane of the ring, it is found that the molecule has the required symmetry. X-ray analysis shows that the naphthalene molecule has a two-fold symmetry—probably a centre of symmetry. All formulæ hitherto proposed for naphthalene appear to possess too great symmetry. Structural formulæ 2a and 2b satisfy the symmetry requirements of the naphthalene molecule.

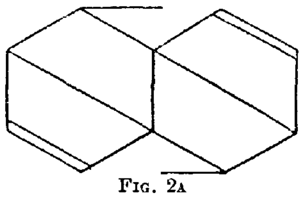

FIG. 2A

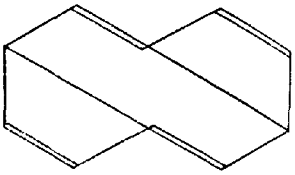

FIG. 2B

The structure of anthracene is shown in Fig 3. Among inorganic compounds, the results of X-ray analysis and the theory developed in the present paper were applied to determining the molecular structure of ruby, silica, ice, sodium and potassium chlorides, calcium carbonate, sodium nitrate and sodium chlorate. It was shown that if the molecule of sodium chloride actually exists, the sodium atom to which any particular chlorine atom belongs is not one of the six surrounding it at equal distances, but one of the sodium atoms disposed diagonally relative to the chlorine. In any case, molecular models having the requisite symmetry can be constructed by consideration of the distribution of electrons round the atomic nuclei. Finally, the factors underlying the selection by a molecule of some particular crystal class were briefly discussed.

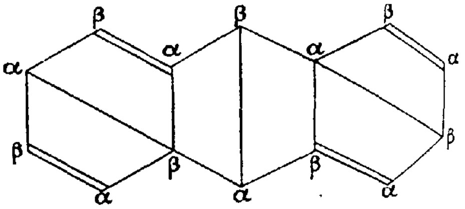

FIG. 3

A paper on "A Modification of the Powde Method of Determining the Structure of Met Crystals" was submitted by Dr. E. A. Owen an Mr. G. D. Preston. Instead of being reduced to powder, the metal to be investigated is subjected t heat treatment necessary to produce throughout i volume a mass of crystals about 1 mm. or less i size; the plate is etched to remove the deforme surface layer of crystals or oxide, and is smeare with vaseline to prevent further oxidation. Th plate of metal is then mounted on the X-ray spectr meter and its structure investigated by the ionisation method devised by Bragg. Crystal structures of aluminium, copper and lead are derived from the face-centred cube, iron from the centred cube. The values of the length of the side of the elementary cube were found to be respectively 4·041, 3·628, 4·983 and 2·869 Ångstrom units. Magnesium possesses a hexagonal lattice of the close-packed type. The length of the side of the hexagon is 3·17, and the axial ratio 1·631 Ångstrom units.

Dr. A. B. Wood submitted a paper on "The Cathode-ray Oscillograph." The instrument is a robust form of oscillograph of the type used by Sir J. J. Thomson and D. A. Keys in the application of piezo-electricity to the measurement of high pressures and is adapted for commercial production. Photographic records are best obtained by action of the cathode rays upon Schumann plates containing a proportion of calcium tungstate, a type of plate previously employed for X-ray purposes by Levy, West and Baker. A visible photographic impression is obtained on Schumann plates when the velocity of the beam across the plate is as great as 1000 metres per second. A further increase in sensitivity of the plates is desirable.

A low-voltage form of cathode-ray oscillograph was exhibited by the Western Electrical Company.

THE CHEMICAL SOCIETY

The ordinary meeting, held on December 7, was presided over by Prof. S. Smiles. Prof A. Smits, of Amsterdam, attended the proceedings.

The papers read were as follows:—(1) "The Iso-Electric Condition of Gelatin": S. O. Rawling and W. Clark. (2) "Studies on Metal Hydrides: the electrolytic formation of stibine in sulphuric acid and caustic soda solutions": H. J. S. Sand, E. J. Weeks and S. W. Morrell. (3) "Three-carbon Tautomerism in the Cyclopropane Series": F. Goss, C. K. Ingold and J. F. Thorpe.

(1) According to the latest theory, gelatin possesses the formula HX.OH, where X is a large complex which may undergo ionisation in the following two ways:—$HX^{\cdot}+OH' \leftarrow HX.OH \rightarrow H^{\cdot}+XOH'$. In the case of gelatin the left hand and right hand reactions become equal at the iso-electric point. The P_H value of gelatin at the iso-electric point was found to be 4·7, and at this point certain physical properties have a maximum and others a minimum value. The authors have studied the relationship between minimum viscosity and the presence, in increasing quantities, of sulphuric and acetic acids.

(2) Dr. Sand dealt with the relationships between the yield of stibine in caustic soda and sulphuric acid solutions, and overvoltage and current density, the yield being measured by passing through silver nitrate solution.

(3) Dr. Ingold, in an interesting paper, adduced evidence which pointed to a possible new form of isomerism.

The three papers, concerned respectively with the debatable subjects of the constitution of gelatin, overvoltage, and isomerism, gave rise to good discussions.

On December 14, in the Institution of Mechanical Engineers, Prof. C. H. Desch lectured on "The Metallurgical Applications of Physical Chemistry."

Corrigendum.—In the issue for December 15, page 519 R, line 2, delete "Louis."

PERSONALIA

Prof. A. Mailhe, of Toulouse, has been appointed to the Chair of Liquid Fuels in the University of Paris.

Mr. T. Edward Lescher has been appointed managing director of Evans Sons, Lescher and Webb, Ltd., drug manufacturers, of Liverpool and London.

Dr. H. Plauson, the inventor of the Plauson mill, etc., has been appointed professor by the Government of Esthonia for his researches in colloid chemistry, and in particular for his work on the utilisation of oil-shales.

Dr. Anthony McGill, Chief Analyst and Head of the laboratories of the Department of Health of the Dominion Government, Ottawa, has retired, upon superannuation. He has been chief analyst for 17 years and in the Government service for 35 years.

The following have been nominated executive members of the Italian Government Commission on Chemical Industry:—Prince Ginori Conti, president; Prof. Nasini, vice-president; Prof. Serono, treasurer; and Professors Paternò and Villavecchia.

Other official appointments announced from Italy are:—Prof. D. Girasoli to be professor of chemistry in the Royal Industrial Institute of Reggio Calabria; Prof. A. de Dominicis to the chair of agricultural chemistry in the Royal Agricultural High School at Portici; and Professors M. Betti, G. Daccomo, and P. Spica have been appointed directors of the schools of pharmacy in the Universities of Genoa, Modena, and Padua, respectively.

Dr. E. H. Tripp, who has edited the "Review" section of this *Journal* since its inception 5½ years ago, is retiring from the Society's service at the end of the year, when that section will be replaced by the new weekly periodical "Chemistry and Industry." Dr. Stephen Miall, who will edit the new venture, assisted by Mr. G. H. Ford, was formerly a practising solicitor and is now chairman of the Brimsdown Lead Co., Ltd., a position which he will retain.

The following appointments are announced from Germany and Austria:—Prof. E. Müller, director of the electrochemical laboratory in the Technical *Hochschule*, Aachen; Dr. F. Straus, professor of chemistry in the Technical *Hochschule*, Breslau; Professor Börnstein, to the chair of fuel chemistry in the Technical *Hochschule*, Charlottenburg; Dr. J. Eggert, to the chair of physical chemistry in the University of Griefswald. Dr. H. Suida has been appointed professor of organic chemical technology in the Technical *Hochschule* of Vienna, and Prof. Dr. Fuhrmann to the chair of technical mycology and food chemistry in the corresponding institute at Graz.

* * *

Among the deaths recently announced on the Continent are those of Prof. F. P. A. Barbier, a pupil of Berthelot, at the age of 75 years; of Prof. August Horstmann, one of the earliest workers in the field of thermochemistry, aged 80 years; and of Dr. C. von Martius, formerly chemist to the Osmose Gesellschaft and managing director of the A.-G. für Anilin-Fabrikation, Berlin.

CORRESPONDENCE

THE "REVIEW"

The subjoined correspondence has been received by the Editor for publication in the last issue of the "Review." In one or two cases, the letters and messages have had to be condensed slightly, owing to pressure on our space. The Review Editor wishes to take this opportunity to thank not only those who have communicated with him on this occasion, but also the many friends and contributors at home, in the Overseas Dominions, and in foreign countries who have helped to make the "Review" the success which our correspondents claim it to be. He would like especially to thank Dr. Charles A. Keane, for several years chairman of the Review Committee, Mr. W. J. A. Butterfield, Dr. Charles Carpenter, and other members of that Committee for much helpful advice and criticism received, particularly in the early days of the "Review."

From Dr. R. F. Ruttan, Professor of Chemistry, McGill University, Montreal, and President of the Society in 1921–22:—

I saw, with great regret, in the minutes of the Council of the Society of November 13, which only reached me on December 1, that you were severing your connexion with the Editorial Staff of the *Journal*.

The "Review," which you have developed to such a high degree of interest and importance during the past five years, has always been the attractive portion of the *Journal* to the Canadian members of the Society. It must be a satisfaction to you to have the Council recognise your efforts by converting it into a weekly publication. Wishing the new venture of the Society every success . . . .

From Prof. E. C. C. Baly, F.R.S., Professor of Chemistry in the University of Liverpool:—

I most cordially wish success to the new venture of the Society of Chemical Industry in issuing the "Review" as a weekly publication. There is no question but that the "Review" has fully justified its existence since its inception a few years ago. As time progressed it was felt by many of us that the old *Journal* did not entirely meet the needs of the day, and that the aims and objects of the Society were not fully served. The decision of the Council to issue the "Review" was a wise one, and the new *Journal* was most enthusiastically welcomed on all sides. Under the direction of its editor, Dr. Tripp, it has steadily consolidated its position, and it now occupies a very high position among the chemical industrial journals of to-day. The weekly publication of the "Review" under its present standard of excellence will certainly be a landmark in the Society of Chemical Industry, and its success cannot but enhance the reputation of the Society.

From Prof. A. R. Ling, Professor of Biochemistry, University of Birmingham:—

I consider that during the past five years the "Review" has been a most valuable supplement to the *Journal* of the Society of Chemical Industry. The promises that were made in the leading article printed on page 1 of the first number of the "Review" in 1918 have been fulfilled in every way, and I learn of the "Review" Editor's retirement with great regret.

From Dr. H. E. Howe, Editor of the *Journal of Industrial and Engineering Chemistry*:—

Believing as I do in the importance of publishing scientific information of all kinds, and holding that one of our most important functions is quickly to advise research men of the accomplishments of their fellows, I cannot do otherwise than applaud the Society of Chemical Industry upon its decision to issue a weekly under the title of "Chemistry and Industry."

At the same time it will be something of a loss no longer to find the "Review" in the *Journal* of the Society. We have come to look upon this section as one of much value to us, particularly as regards many fields of work in Great Britain and other parts of the world. The "Abstracts" have been most helpful, the "Transactions" are always read with interest, and the reports of foreign meetings are particularly helpful. The place which the "Review" section has won sets something of a high mark which, to be surpassed by the weekly, will require an unusual amount of hard work and persistent effort.

From W. J. A. Butterfield, Esq., M.A., Gas Referee, London:—

I desire to put on record my appreciation of the signal service which the "Review" section of the Society's *Journal* has rendered to chemists and chemical industry during the five years of its existence, and at the same time to express my deep regret that it is no longer to be issued as such. In its early years I think no member of the Publication Committee devoted more time to the "Review" than I did, and I much regretted that my association with it was severed through my resignation of membership of the Council and Publication Committee on account of my disapproval of the policy of the Council. I believe that the "Review" will stand as a model of a succinct record of current affairs in chemical industry, and will be more valued for reference in the future than the more cumbersome reports of the weekly technical press. You, Sir, are to be warmly congratulated on your five years' work, much of it done in times of great difficulty, as Editor of the "Review."

From Mr. E. Grant Hooper, late Deputy Government Chemist:—

I was originally opposed to the establishment of the "Review," as I thought that everything necessary and desirable by way of addition could have been inserted in the "Transactions" and "Abstracts" at a minimum cost to the members of the Society. I feel bound to say, however, that the "Review" has most successfully and most usefully cultivated a field previously somewhat neglected and occasionally contemned. The subjects treated have covered a wide range; the matter has appeared timely; the presentation has been generally attractive; and attention has been promptly called to all new work. I have myself found the "Review" most interesting, though as a busy man I had previously demanded useful, rather than merely attractive matter. I am sure that a great many members of the Society feel as I do, and I offer you both thanks for what we have received and congratulations on the success of your work.

From **Mr. W. T. Burgess**, F.I.C., Water Analyst and Consulting Chemist, London:—

It is with much regret that I learn from the last number of the *Journal* that the present arrangement of publishing the "Review" fortnightly is to be discontinued. I do not subscribe to any of the trade journals, and the information under the various headings in the "Review" kept me in touch with the state of chemical affairs, both at home and abroad, at sufficiently frequent intervals.

From **Sir Edward Thorpe**, C.B., F.R.S., President of the Society in 1894–95:—

It is news to me that the "Review" is to cease publication at the end of this year, and that your editorship terminates with it. I am very sorry to gather that your connexion with the Society's publication comes to an end. I know nothing of the inner working of the *Journal*, but my general impression, as derived from a constant perusal of the *Journal* itself, was that it was eminently satisfactory. The *Journal* appeared with unfailing regularity and the editorial business, as it was conducted, left nothing to be desired. The issue of the *Journal* weekly is an experiment which I shall watch with interest.

From **Prof. Arthur Smithells**, C.M.G., F.R.S., retiring Professor of Chemistry in the University, Leeds:—

The addition of the "Review" section to the *Journal* seems to me to have achieved something like the transformation of an automaton into a living being. I say this with all respect to old friends, who brought the *Journal* into being and showed so much solicitude and discretion in establishing its impartiality and its security from caprice. I do not think that these essential elements have been impaired in the slightest degree by the change which has taken place, whilst the interest of the *Journal* has been increased beyond measure. I should like to join in what I am sure will be a chorus of congratulation to the "Review" Editor on the great skill and judgment with which he has carried out a most valuable reform.

From **Prof. A. G. Perkin**, F.R.S., Professor of Colour Chemistry and Dyeing in the University of Leeds:—

I was originally an opponent of the addition to the *Journal* of a "Review" section. I feared that the extra expense incurred by such an extension, and which appeared to be hardly necessary, would injure the circulation of the *Journal*, and also that the additional work in conjunction therewith might detract from the attention given to its other very important sections. I am happy, however, to own that my apprehensions have proved to be groundless, and as a constant reader of the "Review" I now consider this to be a valuable addition to the *Journal*, and of service to myself.

From **Principal J. C. Irvine**, F.R.S., Principal of the University, St. Andrews:—

With many others, I regret the passing of the "Review." This section of the Society's activities served a useful purpose and added to the value of the *Journal* by the inclusion of subjects possessing a real human interest. Our President, who yields to no one in his appreciation of what a chemist ought to be, sounded a true note when he reminded us recently that we must not content ourselves by being merely chemists, and I believe the "Review" has been a factor in securing this end. At least it has prevented some of us from remaining merely academic chemists, and the "Review" Editor has earned the gratitude of those who have to look out on the busy world of chemical industry from the seclusion of the Professor's Chair.

From **Colonel Sir Edward Brotherton**, Leeds:—

I have always looked to the "Review" section of the *Journal* to give me some general acquaintance with movements in the chemical trade in various parts of the world, as well as to present me with valuable information respecting the latest publications in chemical literature. I am, therefore, sorry that this section of the *Journal* is not to appear after the end of the present year in its present form.

From **Prof. T. Phillips Bedson**, late Professor of Chemistry in the Armstrong College, Newcastle-on-Tyne:—

So we are to have a change in the *Journal*. Changes come, but improvement lingers. It is much to be regretted that this change is coincident with the loss of the services of the "Review" Editor, in whose skilful hands it has been created, and has grown from month to month to be *the* feature which, by the interest of its articles and the information supplied, has procured a circle of constant readers of the *Journal*—the great asset of the Society. To the "Review" Editor are the members greatly indebted, and all will join in expressing their regrets at the severance about to take place, and all are grateful to him for the able manner in which he has contributed to the success of the venture.

From **Dr. W. R. Ormandy**, London:—

In the last issue of the *Journal*, I noted with great regret that Dr. Tripp would shortly be ceasing to work as "Review" Editor; I am one of the many who appreciate very highly the wonderful improvement in the *Journal* that has taken place since his connexion therewith. To those of us who are interested in the world-wide ramifications of the chemical industry, but have not time to read up the subject, the "Review" has proved of the greatest value and interest. I should not like Dr. Tripp's connexion with the *Journal* to cease without taking an opportunity of expressing appreciation of his past services, and regret that he has found it necessary to sever that connexion.

From **Dr. Thomas R. Duggan**, of New York:—

It is with regret I notice that the "Review" Section of the *Journal* is to be discontinued, and think I am voicing the view of my American friends in this statement, that ever since its commencement it has been one of the great features of the *Journal*. Most of us are busy people and can usually turn to the "Review" to find matters of interest without wading through some dozen or so of other journals, knowing that the matter is sound, otherwise the Editor would not have passed it. I sincerely hope that with the new form of *Journal*, the "Review" will not be entirely overlooked.

SAFEGUARDING OF INDUSTRIES ACT

SIR,—Now that the opposition to the Safeguarding of Industries Act is dying down somewhat, one may perhaps be allowed to inquire where things went wrong from the chemical standpoint, for there is no doubt that chemists as a body have not covered themselves with glory in their appearances before the Referee. Much has been learned from these hearings, but much remains to be learned, not only by the individuals concerned, but by the profession as a whole.

Some are beginning to appreciate the difficulties in combating nonsense (especially scientific nonsense) before a lay tribunal, especially when it has to be done through the medium of words, often of uncertain meaning. Some are beginning to realise after all that chemical merchanting is apparently the important thing in chemical industry; so very useful when the enemy was at the gate, and our men dying by thousands for want of proper support in the factory line! Some have not yet recovered from the shock of realising that what "So-and-so" wrote in '92 is necessarily of far greater moment than the dictates of common sense to-day. And some have realised that chemists have failed in their public duty, and are not a little worried as to what is to be done about it. Reference is particularly made to those chemists who are in contact with the industrial world (though who amongst us is without blame?), for upon them rests the honour of upholding the profession of chemistry in the public mind. When they fail we all suffer, and it is difficult to see how the position can be improved until all chemists indulge in some good plain thinking. At Leeds, on November 22 last, Mr. F. W. Richardson spoke very plainly to the Institute of Chemistry on the subject of unprofessional conduct and the ethics of expert evidence. He said that they needed some special permanent committee to deal with unprofessional conduct. He reminded his hearers of the low estimate in which expert evidence was held—particularly in the legal profession—and he pleaded for the oath, "The truth, the whole truth, and nothing but the truth," in giving expert evidence. Mr. Richardson is right, and I trust that a leader will arise to see the matter through.

It is granted that many chemists have been drawn into these disputes under conditions wholly alien to the spirit of their science. It is appreciated that they have been misunderstood, but it is their duty to make themselves understood. Technical things can be explained, and non-technical people can be made to understand them, but not when the superior "take it or leave it" attitude is adopted. So long as the legislature must deal in technical matters, and must appoint non-technical lawyers to deliver technical judgments, then it is the duty of the professional societies, as well as the individual chemists concerned, to appoint themselves advisers to the lay mind without fear or favour except for the truth. Too often the appearance of expert chemists for opposite sides in a dispute has been as unseemly and just about as useful as would be the spectacle of the Archbishops of Canterbury and York discussing the doctrine of transubstantiation at a meeting of the L.C.C. Is it surprising that the lay mind cancels them out? When chemists appear in public, above all things let them appear for chemistry.

To chemists it is obvious that there is much less between the views expressed by different chemists than is appreciated by the non-technical person who neither knows nor understands the subtlety of chemistry. But we ought not to air our petty differences except in debate in the privacy of our own societies. If there is uncertainty as to the meaning to be given to the terms which form the basis of the chemist's work, then surely the appropriate societies can do good work by initiating thought and discussions on the subject, if they do not go further and stabilise the views to be put forward for consumption by the public. Surely if quasi-scientific definitions of technical terms can evolve from a squabble between conflicting trade interests (and where interests clash opinions are bound to differ) before a non-technical lawyer, there is surely hope that chemistry may show a sufficiently united front to do a little better.

No one apparently can influence the present Act or its administration, but we ought at least to be prepared for the future. Why should not the Society of Chemical Industry, as being the appropriate Society to connect chemistry with the world of industry, develop functions akin to those of the British Engineering Standards Association, and have its precepts embodied as a glossary in the preamble to any future Acts of Parliament affecting chemistry. We should all, chemists and lawyers alike, know then that we were at least talking about the same thing.

Surely the Geneva Conference on Nomenclature did good work for academic chemistry and provided something of a parallel to the present need for precision in industrial chemistry.

However, such a suggestion may be too venturesome, but I do fervently hope that the societies may do something so that in the near future when British chemists have dealings with the outside world, whether it be the law or public generally, they may be helped to place their professional appearances on a higher plane than obtains to-day. The profession of chemistry is worthy of being respected and feared; its members should not be merely figures who have their say and cancel out.—
I am, Sir, etc., L. A. JORDAN.

Manningtree, Essex.
December 14, 1922.

LEGAL INTELLIGENCE

ARSENIC IN COCOA

On December 18, in the Richmond Police Court, the Home and Colonial Stores, Ltd., and Messrs. Rowntree and Co., York, were summoned by the Surrey County Council under the Sale of Foods and Drugs Act, 1875, for selling, and aiding and abetting the sale, respectively, of cocoa containing white arsenic to the extent of one-fortieth of a grain per pound. Both defendants pleaded guilty, and Messrs. Rowntree took absolute responsibility for the position in which the Home and Colonial Stores had been placed.

For Messrs. Rowntree it was stated that the most competent scientific opinion held that the cocoa in question would not endanger the health of those who drank it; and that the contamination was an accident which might have happened to any manufacturer of a foodstuff. Last July it was discovered that some of the cocoa the firm had been making contained faint traces of arsenic, which, after immediate and intensive search, was found to be present in the potassium carbonate used in the manufacture. Immediately the whole of the cocoa left in stock—some 300 tons, valued at £100—£250 a ton—was sacrificed, but it was held to be useless to attempt to get back what had already been sold to the trade. The Home and Colonial Stores had destroyed 85 tons of the material, worth about £1200. Sir William Willcox, medical adviser to the Home Office, stated that this was the first instance he had heard of in which arsenic had got into a food through potassium carbonate.

The Home and Colonial Stores, Ltd., was fined 40s. and Messrs. Rowntree £20, with 50 guineas costs.

NEWS AND NOTES

FRANCE

Industrial Notes

Chemical Industry.—The plant erected at Bully by the Compagnie des Mines de Béthune to produce synthetic ammonia by the Claude process is now working successfully. By this process 45 to 50 per cent. of the hydrogen in coke-oven gas is separated by liquefaction at the very low cost of 0·50 francs per cb. m. The synthetic ammonia produced is converted into ammonium sulphate and the coke-oven gas from which the hydrogen has been extracted is used as a source of heat and power. So good have been the results obtained that the Societés des Mines de Lens et d'Aniche have also decided to erect a plant. If the process comes into extended use, the increased output of ammonium sulphate will affect the fertiliser market, especially if the State powder factory at Toulouse is transformed into a large synthetic-ammonia plant, as is contemplated. Experiments are being conducted with the new fertiliser, "phosphazote" (*cf.* J., 1922, 390 R), which is expected to cost less to manufacture than superphosphate.

The paper industry is greatly concerned about the enormous increase of imports of paper and paper pulp from Canada, Scandinavia, Finland, Germany, Belgium and Switzerland. Imports of mechanical and chemical pulp during the first nine months of 1922 amounted to 1,680,459 metric tons, compared with 154,069 t. for the whole of 1921. The reason for this large increase lies in the shortage of timber in France, due to the destruction of forests during the war and the great consumption of timber for reconstruction in the devastated areas. Before long the Government will have to consider the question of re-afforestation, and there appears to be no reason why France should not become an important producer of paper, especially as she is as well supplied with water power as is Sweden.

The question of substituting alcohol for petrol as motor fuel still absorbs much attention. Recent work has shown that mixtures of alcohol and petrol are much more stable if the alcohol is practically anhydrous. Such a mixture has been used successfully as a motor fuel in the munition works at Sevran-Livry. But even such a mixture would not solve the problem; the question of quantity is equally important. At least 220 mill. galls. of alcohol would be required to replace the 132 million galls. of petrol consumed yearly in France; the annual output is only 22 mill. galls. Production from wood-cellulose, *e.g.*, by the Prodor process (*cf.* J., 1922, 435 R) appears to be the most promising.

Prices in the chemical market are firm, owing to the appreciation of the pound sterling and the dollar. Following a rise in the prices of Italian and Spanish pyrites, and also in freights, there has been a marked increase in the cost of sulphuric acid.

"Synthetic" Mother-of-Pearl

In the October issue of *Chimie et Industrie*, MM. L. Clément and C. Rivière describe their researches into the formation of "synthetic" mother-of-pearl. Natural mother-of-pearl consists of a cellular skeleton of "conchyoline," an albuminoid material secreted by the oyster containing grains of calcium carbonate, and water. When calcium carbonate is precipitated in a colloidal medium, under certain conditions, it forms a network of particles which displays the optical phenomena of a grating. Similar but less pleasing effects can be obtained with salts of barium, lead, silver and copper, the superiority of calcium carbonate being apparently due to its fine grain. To reproduce this effect a solution is made of a calcium salt (preferably the lactate, glycocollate or other salt of an organic acid) 15 parts, gelatin (to replace the conchyoline) 5 parts, and water 80 parts. This solution is heated, filtered, spread over the object to be treated, and allowed to set. A solution containing sodium carbonate 10 parts, trisodium phosphate 2 parts, gelatin, albumin, or casein 8 parts and water 80 parts, is then poured over the object to precipitate the calcium as carbonate. The characteristic iridescence appears after 30—60 minutes, and the object is then carefully washed, hardened with formaldehyde, and dried. The character of the nacreous appearance depends on the closeness with which the lines of cells containing calcium carbonate are packed, the most intense effects being obtained with 1000 to 1400 lines per mm. By varying the composition and rate of application of the precipitating solution, effects are obtained which vary from the weak lustre of oystershell to the iridescence of true mother-of-pearl. If a celluloid cast is taken of the surface of an object thus treated, the resulting film is also iridescent, thus showing that the effect is due to refraction from the fine reliefs reproducing the contours of the original. Films produced in this way may find application in decorative work. The mechanism of the precipitation of calcium carbonate in a colloidal medium is described as periodic or rhythmic precipitation (Liesegang, Leduc) and is of interest in the investigation of biological phenomena.

UNITED STATES

A News Edition of "Industrial and Engineering Chemistry"

Industrial and Engineering Chemistry, the technical journal of the American Chemical Society, announces an extension of its service in 1923. Besides the present journal, which will not be changed in form, there will be issued twice a month, on the tenth and twentieth, a chemical newspaper to be known as the "News Edition of Industrial and Engineering Chemistry."

The News Edition is designed to provide current information, much of it non-technical in character, supplied to a large extent by staff correspondents. There will be a leading short article written in non-technical language on some phase of chemistry. Industrial developments, items on foreign and domestic commerce, digests of both Federal and State legislative action, tariff decisions, personal items, happenings in various local sections, announcements and preliminary programmes of the semi-annual meetings of the Society, and of local sections, will constitute the bulk of the material. A maximum of four pages will be devoted to employment service information under regulations soon to be announced.

With this publication available, the "Clip Sheet" of the News Service will be discontinued, and newspapers will be invited to use as much material as they please from the News Edition.

The News Edition will be issued under the joint auspices of *Industrial and Engineering Chemistry* and the A.C.S. News Service, in co-operation with corresponding editors in the various chemical centres and representatives of other chemical societies. The first issue will appear on January 10, 1923.

Production of Acids in 1921

Preliminary statistics issued by the U.S. Department of Commerce show that the output of factories manufacturing chiefly sulphuric, nitric, and mixed acids in the United States declined considerably in 1921. Of the 35 factories that reported, 5 were located in New Jersey, 5 in Pennsylvania, 4 in Ohio, 3 each in California and New York, 2 each in Maryland and Virginia, and 1 each in 11 other States. New Jersey was the leading producer, its output representing 27 per cent. by value of the total production. The statistics for 1921 and 1919 are summarised in the following table:—

		1921	1919	Decrease %
o. of factories		35	39	—
rsons employed		3,139	5,860	46·4
Salaried employees		450	899	49·9
Wage earners (average)		2,684	4,961	45·9
Salaries and wages	$	5,243,000	10,096,000	48·1
Salaries	$	1,317,000	2,179,500	39·6
Wages	$	3,926,000	7,916,500	50·4
Cost of materials	$	9,714,000	15,857,000	38·7
Value of products	$	20,529,000	31,470,000	34·8
Sulphuric acid (50° Bé.)	Short tons	1,457,500	1,685,300	13·5
"	$	15,332,700	18,113,000	15·3
Nitric acid	Short tons	2,110	3,150	33·0
"	$	363,700	536,700	32·2
Mixed acid	Short tons	16,400	28,200	41·8
"	$	1,316,000	2,671,500	50·7
Other products	$	3,516,500	10,149,300	65·4

—(*Oil, Paint and Drug Rep.*, *Nov.* 13, 1922.)

An Indicator of Static Electricity

The accumulation of static electricity where inflammable dust or vapours are handled is a great but often unsuspected fire hazard, and the Westinghouse Lamp Co. has recently converted a laboratory curiosity into a very practical test for this hidden danger. The discharge of electricity through the gas in a Geissler tube is used to show the presence of high voltage near by; the gas used is neon, which readily conducts the discharge and causes the lamp to emit a bright reddish glow as a danger signal. The tube, mounted in an insulating case, has a metallic contact-tip at one end and a small condenser-plate at the other, and the whole apparatus is small enough to be carried about by an inspector; but it may be mounted where electricity accumulates and the charge run off to earth. The indicator is sensitive enough to glow when the person holding it walks across a rug and connects its metallic tip to a radiator or other grounding device. A small neon-tube has also been marketed for use in testing sparking plugs on automobiles which may be running badly.

Fatigue of Metals

An investigation on the fatigue or progressive failure of metals has been carried out at the University of Illinois Experiment Station under the auspices of the Engineering Foundation and the National Research Council, with Prof. H. F. Moore in charge. The most probable explanation of such failure was found to lie in a progressive spread of microscopic fractures. A nucleus for damage may be a very small area of high localised stress, due to a groove, a scratch, or a crack. In other cases, failure may arise from internal inclusions or irregularities of structures, from internal stress remaining after heat treatment, or from a grain or group of grains being placed unfavourably to resist stress. Definite indications were found that tough steel possesses a specific endurance limit.

Cheap Furfural, a Substitute for Formaldehyde

As a result of more than six years' research work, the U.S. Bureau of Chemistry has devised a cheap method of producing furfural from corn (maize) cobs and farm waste. This method, it is expected, will eventually make possible the production of low-priced substitutes for a wide variety of hard rubber and synthetic-resin products, provide a good market for farm by-products now wasted, conserve the native supply of methanol and of forest products, particularly hardwoods, used in making methanol, and possibly provide a supply of motor fuel. When heated together furfural and phenol condense to form a solid resin, which is dissolved only with great difficulty; "tetralin" is said to be the only substance that will dissolve furfural resins. Three firms are now producing synthetic-resin products, using furfural instead of formaldehyde, and are obtaining satisfactory results. The furfural resins have a harder surface, and are naturally black or dark, rich brown in colour. They are somewhat flexible, and are better electrical insulators than hard rubber or other synthetic resin products. It has also been found that furfural is an excellent paint and varnish remover, and that it can be used in making fine dark varnishes. It is hoped, eventually, to obtain furfural from corn stalks, bagasse and rich hulls, as well as from corn cobs and oat hulls.

The process of manufacturing furfural, from corn cobs, etc., which was discovered by Dr. F. B. LaForge, of the Bureau of Chemistry, is rapidly being developed commercially. The present demand for furfural in the United States is said to be small. Two years ago it cost $30 per lb., but now the one company producing furfural on a commercial scale is selling it at 25 cts. per lb. Dr. LaForge says that eventually, with production on a large scale, the price should be as low as 6 cts. More than twenty other firms are considering the building of furfural plants.

Furfural can also be used as a motor fuel, with a specially designed carburetter, and if greater yields were obtainable from farm waste, a subject now being investigated, its use as a fuel would be practicable.

BRITISH INDIA

Nux-Vomica Industry in Madras

Although *Strychnos nux-vomica*, the tree from which commercial nux vomica is obtained, is widely distributed throughout the tropics, the world's supply of the drug is almost entirely derived from India; and two-thirds of the Indian supply is furnished by the Madras Presidency. Despite the value of nux vomica as the source of strychnine and brucine, the tree is not cultivated, and in certain areas has almost disappeared owing to careless exploitation. The fruits are gathered by forest tribes, the pulp is washed away, and the seeds, after drying in the sun, pass through various hands until they reach the exporters, usually in December. For export the seeds are washed, sorted, and sold in bags of 164 lb. or 182 lb. each; they will keep for long periods, but storage is not usual. In 1920-21 exports amounted to 2268 long tons, distributed as follows: United Kingdom 1820·4 t.; Ceylon 13·2 t.; rest of British Empire 0·05 t.; Belgium 190 t.; France 0·6 t.; Italy 5 t.; United States 737·2 t. It is stated that the export in 1921–22 declined to 2010 t., but lately prices and shipments have increased. This year's crop on the west coast promises to be poor, but that on the east coast is above the average.—(*U.S. Com. Rep., Nov.* 6, 1922.)

AUSTRALIA

Bounty on Shale-Oil Production

In 1917 the Federal Parliament passed an Act providing for the payment of a bounty on shale-oil produced in Australia. As this Act has expired, the House of Representatives has revived it for another year and increased the bounty from 2½d. to 3½d. per gallon, because the shale-oil company in New South Wales has been working at a loss. The increase in the bounty will involve an additional expenditure of £7000, the total cost for the year being about £74,000.—(*Ind. Austr., Oct.* 19, 1922.)

GERMANY

Chemically-resistant Iron

Articles made of a 15 per cent. aluminium-iron alloy develop, on being heated to redness, a thin but highly resistant surface layer of aluminium oxide which does not scale and prevents further oxidation of the metal, so that no appreciable alteration of the surface is noticeable after heating at a high temperature for one hour in a strongly oxidising atmosphere. The alloy gives good castings and may, with care, be forged. Similar results are obtained by treating soft-iron articles by the Alitier process, which consists in heating the metal for some time surrounded by a powder containing aluminium, whereby the latter penetrates the surface of the iron for a certain distance and forms a surface layer of iron-aluminium alloy that behaves in a similar manner to the 15 per cent. alloy described above. An iron crucible treated by this method was practically unattacked after heating to 1000° C. for 60 hours, whereas a similar untreated crucible was destroyed in 24 hours.

Filter for Industrial Dust

The Cottrell dust-precipitator has the disadvantage that the finest dust tends to form hard crusts on the precipitating walls, and in the case of metallic fumes, the crust has to be chiselled away owing to the metal in the fume welding itself to the walls. Cloth filters are rapidly clogged by the dust and cannot be used with hot gases. On the other hand filters consisting of metal vessels packed with small ring-shaped pieces of metal or wire nets of fine mesh have none of these drawbacks and work very efficiently. For temperatures below 80° C. the filters are treated with a special oil, having a viscosity of 3·8 at 50° C., a solidifying point of −20° C., a flash-point of 155° C., and an evaporation loss of 0·02 per cent. in 5 hours, in such a manner that the surface of each wire is coated with a thin layer of oil. For higher temperatures oil is not used. In the collecting chamber for coarse dust, which is provided in front of the filter, 60 per cent. of the total dust is precipitated, and another 35 per cent. is collected on the filter. In each case the dust is readily removed either by mechanical shaking or by pneumatic means.

The Potash Industry, Jan.–June, 1922

According to official statistics the German output of potash during the first half of 1922 was 5,893,711 metric tons of potash salts, equivalent to 682,787 t. of pure potash (K_2O). Details of the production and inland sales of potash salts (calculated as K_2O) are given as follows:—

	Production Jan.—June, 1922 1000 t. K_2O	Inland sales
Carnallite	22,739	1·34
Crude salts	139,710	137·92
Manure salts (18-22%)	39·20	18·61
,, ,, (28-32%)	19·35	16·02
,, ,, (38-42%)	241·34	245·47
Potassium chloride (50-60%)	90·78	102·91
,, ,, (over 60%)	37·80	
Potassium sulphate (over 42%)	17·11	3·98
Potassium-magnesium sulphate, calcined	6·25	0·46

Inland sales during the first six months of 1922 increased by 58 per cent. compared with the same period of 1921, largely owing to improved transport facilities and rebates granted on orders. Roughly 490,000 t. of potash, equivalent to 93 per cent. of the total inland sales, was consumed by agriculture, and 7 per cent. was sold for industrial purposes Sales on foreign account were below expectation.

Following the increased consumption inland, the potash works have been fully occupied. From January to June, 1922, the number of workers rose from 39,594 to 42,139, or inclusive of subsidiary workers, from 44,244 to 47,577. However, pre-war conditions have by no means been re-established. Of the 206 works which were authorised to make deliveries, 76 were idle at the end of June.

The Welfare of Chemical Workers

The following observations on the influences affecting the health of workers in chemical factories were made in 1921, and have been published recently.

The advisability of having long pauses for meals and rest has been established; when these are cut down to a minimum, production by manual workers falls off, and brain-workers suffer from nervous exhaustion, sleeplessness, and gastric complaints. Among industrial poisons, lead still takes first place, although this danger has been much exaggerated, lead-poisoning being frequently suspected where the symptoms really arise from other causes; it now appears, too, that the only really reliable indication of lead poisoning is obtained from the blood-test. In many places changes in the methods of winning and working the metal have reduced the danger. Chromium also acts prejudicially to health. Other causes of poisoning have been phosphine (from moist ferro-silicon), sulphur dioxide, hydrogen sulphide, cyanogen, chlorine, nitrous gases, blast-furnace gases, illuminating gas, nitro- and amido-compounds, picric acid, trichloro-ethylene, and tetrahydronaphthalene. Numerous cases of poisoning by dinitrobenzene were observed in the breaking up of ammunition. Various skin diseases were caused by chemicals and impure oils.

Hygienic conditions in the factories have generally improved, especially in the large works. The installation of improved ventilating and dust-removing apparatus has been very difficult owing to the exceptionally high cost; and the provision of cloak-rooms and rooms for rest and refreshments still leaves much to be desired. Washing conveniences, especially bathrooms, are often badly treated by the workers, and in many cases not used at all. Among special installations for the benefit of workers may be mentioned a mechanical remover of ashes and slack from boilers. The neglect and ill-treatment by workers of protective devices introduced for their benefit was regrettable. Members of industrial councils and foremen seem to have a far greater appreciation of measures developed to protect health than measures to prevent accidents, and in respect of the former, there is frequently successful co-operation with the workers; in many districts lectures and special courses are held for their instruction.

GENERAL

Pasteur Celebrations

Prior to the celebration of Pasteur's centenary in May, 1923 (*cf.* J., 1922, 111 R), meetings in his honour will be held in this country from February 2 to 19, 1923, under the auspices of the Federated Committees of the Alliance Française in the United Kingdom. The hon. secretary of the Federated Committees, Mlle. Yvonne Salmo, of 14, Morgan Road, Reading, informs us that Dr. Pasteur Vallery-Radot, the grandson of Pasteur, will deliver a lecture on his grandfather's life and work in the rooms of the Royal Society of Medicine, London, and this will be followed by a banquet which will be attended by members of that Society and of the Institute of Brewing, and to which it is proposed to invite members of the various chemical societies. M. René Vallery-Radot will come to London, but his health will not permit him to go to the provinces, where Dr. P. Vallery-Radot will visit Manchester, Newcastle, Bradford, Liverpool, Cardiff, Reading, Leicester, Wolverhampton, Southampton, and Portsmouth (Feb. 19). In each of these towns the local branch of the Alliance Française is inviting the medical and chemical societies to take part in the proceedings. The Lord Mayor of Cardiff will extend a civic welcome to the visitors, and at Newcastle-on-Tyne Sir Theodore Morison will offer the hospitality of Armstrong College.

Glasses for Flame Safety-Lamps

The report of the sub-committee appointed to compare flame safety-lamp outer glasses made in Great Britain, Germany, Austria, and Czechoslovakia from the standpoints of safety, transparency, and price has recently been issued by the Mines Department (H.M. Stationery Office. 2d.). Tests carried out at the Mines Department Experimental Station have shown that there is no difference in quality between British- and foreign-made glasses; the former are more transparent, free from flaws, and uniform in surface, but the latter are usually more uniform in dimensions. All the British glasses and most of the foreign glasses passed the heating and mechanical tests satisfactorily. In the absence of reliable data, no conclusion was reached concerning the price of foreign glasses, but information was received that, apart from import duty levied in this country, Czech glassware is now more expensive than British glassware, and that the cost of production in Germany and Austria is less than in this country. It is recommended that the difference between the prices of British glasses to lamp makers and to colliery companies, viz., 8s. 6d. and 10s. 9d. per dozen, respectively, be investigated. No approved glasses have been imported from the United States for some time and no glasses of French or Belgian manufacture have been submitted for approval for use in this country.

New Oil-nuts from South America

Nuts from a palm growing abundantly in the Magdalena Valley, Colombia, and known locally as "Mamarrón," have been examined at the Imperial Institute, and found to belong to a species of *Attalea*, allied to the corozo and cohune nuts. Analysis showed the kernels to contain 3·8 per cent. of moisture, and 69·9 per cent. of fat, or 72·7 per cent. calculated on dry material. The percentage of shell (79·3 per cent.) is too high to allow the export of whole nuts, but commercial quantities of the kernels should realise about the same price as palm kernels (£17 10s. per ton in June, 1922). The kernel oil, which is cream-coloured, hard, and has an odour like that of coconut oil, should be suitable for use in manufacturing edible fats, and as the residual meal is free from alkaloids or cyanogenetic glucosides, it might be used as a cattle-food.

"Fruta de conejo" (rabbits' fruit) nuts belonging to a species of *Heisteria*, were also sent from the same district for examination. The kernels, which constitute 66 per cent. of the nut, contained 5·4 per cent. of moisture and 61·2 per cent. of a clear, golden-brown viscous oil, equal to a yield of 64·7 per cent., from the dry material. Although the oil has a high iodine value (140 per cent.), it does not possess good drying properties, and is unsuitable for paint manufacture. On heating it polymerises, yielding a product like polymerised tung oil, and therefore might be used in making rubber substitutes, etc. The residual meal is of high nutritive value, but as a trace of alkaloid is present, feeding trials would be necessary before using the meal for feeding cattle.—(*Bull. Imp. Inst., XX, No.* 2, 1922.)

Power Alcohol in Cuba

H.M. *Chargé d'Affaires* at Havana reports that increasing attention is being paid to the production of fuel alcohol in Cuba. As the alcohol distillery can easily be made part of the sugar factory, a great part of the lower grade material may in future be converted into alcohol instead of sugar. At present only two mills distil alcohol from the final molasses or waste material. Under proper conditions a gallon of alcohol can be produced from 2 galls. of molasses containing 56 per cent. of fermentable sugars, but with the inefficient methods generally used 3 galls. of molasses yield only 1 gall. of 95 per cent. alcohol. In 1919–20, when the sugar crop reached 3·75 milion t., the output of molasses was over 185 mill. galls., an amount which could yield from 60 to 90 mill. galls. of alcohol. It is estimated that, with a plant capable of producing 7200 galls. of fuel alcohol per 24 hrs., *i.e.*, able to utilise the daily output of molasses from a 3000-ton raw sugar plant, the alcohol could be produced at 12·55 cents and sold at 20 cents per gall. Production of alcohol is most important in the province of Matanzas, where there are 3 distilleries with storage capacities for 2,880,000, 2,660,000 and 1,200,000 galls., respectively, and two distilleries each capable of storing 175,000 galls. Local consumption, formerly less than the production, has now risen owing to the increasing use of fuel alcohol for automobiles, and there is a large export trade, chiefly with the United Kingdom, South America, Morocco and, latterly, Germany. Efforts are being made to increase the consumption of power alcohol.—(*Bd. of Trade J., Nov.* 16, 1922.)

Artificial Silk in Italy

The Italian artificial-silk industry, founded about 15 years ago, has an invested capital of 420 million lire, and comprises five large factories at Pavia, Padua, Venaria Reale, and Cesano Maderno, which produce nearly 11 metric tons of silk per day; it employs 12,000 workers now, and will probably employ 20,000 a year hence. Some of the necessary raw materials, *i.e.*, soda, carbon bisulphide, and sulphuric acid, are produced locally and it is hoped that in time wood pulp will be obtainable in the country. At present, the production is below the home demand, and there is both an import and export trade.

	Imports		Exports
		Metric tons	
1919	78·6	..	230·4
1920	374·1	..	396·4
1921	254·9	..	906·1

Belgium, Switzerland, and the United States are the chief sources of the imported artificial silk, and the United States, France, and Switzerland the destinations of the exports. Exportation has naturally been directed to countries possessing a relatively high rate of monetary exchange (*cf.* J., 1922, 314 **R**).—(*U.S. Com. Rep., Sept.* 25, 1922.)

Kaolin Deposits in Dobruja, Rumania

Kaolin was known to occur in the hill-country between Balcic and Cavarna prior to the war, but recently large deposits of this mineral have been discovered. The Rumanian Government has decided to erect a large porcelain factory at Balcic, and to use skilled labour, mainly from Czechoslovakia and Austria.

Method of Renovating Old Corks

Old cork stoppers can be cleaned and softened by boiling them, suitably weighted, in a 5 per cent. solution of sulphuric acid for 15 minutes. After rinsing several times in water, the corks are boiled in clean water for 15 minutes, and when cold they are placed in a 5 per cent. solution of alum for 6 hours, and then dried in the sun for 2 or 3 days. —(*Chem.-Z., Sept.* 28, 1922.)

PARLIAMENTARY NEWS

HOUSE OF COMMONS

Imports and Output of Beet Sugar

Answering Major T. Hay, Sir P. Lloyd-Greame said that importations of unrefined beet sugar into the United Kingdom in 1921 amounted to 13,685 tons, compared with a home production of 6363 t. The trade returns did not distinguish between refined sugar manufactured from beet or from cane.—(Dec. 11.)

British Dyestuffs Corporation

Sir P. Lloyd-Greame, in reply to Major M. Wood, stated that during the three months ended November 30, commission paid to the Corporation amounted to £4600, and the proceeds of sales of "reparation" dyestuffs was approximately £66,000. The sterling value of the dyestuffs received during that period was, according to the Reparation Commission, about £107,000.—(Dec. 11.)

Trade Information Register

In answer to Sir H. Brittain, Sir W. Joynson-Hicks said that 2766 firms were enrolled on the special register of the Department of Overseas Trade for the purpose of receiving information from abroad. The Department was in touch with many more firms, but prompt distribution of commercial information would be facilitated if firms desiring such information would enrol on the special register. —(Dec. 11.)

Scotch Shale-Oil Industry

Replying to Mr. Shinwell, Mr. Baldwin stated that sale of the Government holding in the Anglo-Persian Oil Co. was not contemplated, but if it ever were, the Scotch shale-oil industry and other relevant considerations would be taken into account.—(Dec. 11.)

Australian Zinc Concentrates

Viscount Wolmer informed Mr. Collison that, owing to the improvement in the market price of spelter, probably no loss would result from the operation of the contract for the supply of Australian zinc concentrates.—(Dec. 12.)

Imports of Petroleum

In a written answer to Lieut.-Col. James, Mr. Ormsby-Gore gave the following statistics of the imports of petroleum from Empire territories enjoying Imperial Preference and of the output of those countries:—

	Output 1921	Imports into U.K. 1921	Output Jan.–June 1922	Imports into U.K. Jan.-June, 1922
		Tons.		
Canada	25,000	nil	12,000	nil
Australia	8,000	nil	4,000	nil
Trinidad	334,000	108,205	161,000	60,076
British India ..	1,285,000	11,170	575,000	7,318
Sarawak	199,000	13,955	178,000	nil

—(Dec. 13.)

Insulin Treatment for Diabetes

Answering Sir W. Bull, Sir W. Barlow said that the Medical Research Council was doing all it could to accelerate the production and use of insulin for treating diabetes. It was not true that the remedy had passed the experimental stage, there was no question of any Government monopoly, and the suggestion that the Medical Research Council should grant licences for manufacture was on the lines of the practice actually followed.—(Dec. 13.)

Safeguarding of Industries Act

The following are summaries of answers given by the President of the Board of Trade to questions relating to the operation of the Act:—

Duties.—Up to and including December 8 the duties collected in Great Britain and Ireland under Parts I and II amount to £445,324. Since the Act was passed the expenditure of the Customs has decreased.—(Dec. 11.)

Domestic Glassware.—Imports of domestic and fancy glassware during the first half of 1922 included 2052 tons from Germany and 4334 t. from Belgium.—(Dec. 11.)

COMPANY NEWS

MAGADI SODA CO., LTD.

Addressing the eleventh ordinary general meeting of this company on December 11, in London, Mr. S. Samuel, the chairman, said that the very unsatisfactory position of the company had been brought about by causes beyond the control of the directors. Production had been hindered throughout by the failing of machinery, and the fixing of the rate of exchange at 2s. to the rupee had seriously interfered with all industries in East Africa. The directors were still confident of ultimate success, and he personally had guaranteed the advances made by the bank to the company; in 1921 no less than £72,500 was advanced. The defects in the new bucket-dredger which had been sent to Magadi had now been made good, and the dredger had been restarted; in a few weeks there would be a minimum production of soda at the rate of 100,000 tons a year. It would be necessary to write down drastically the existing capital and to raise further capital; if the shareholders would find a further £500,000, he would contribute £50,000; if a million of new money were found, he would put up £100,000.

MAYPOLE DAIRY CO., LTD.

Sir W. G. Watson, presiding at the annual general meeting in London on December 15, discussed the difficulties confronting the company owing to the fiscal policy of foreign countries. During 1921, over 1000 tons of margarine had been imported each week, the result being unemployment and unprofitable prices in this country. Abroad, imports of oil and margarine were dutiable, but the raw materials used in manufacturing edible fats were duty-free; in consequence the factories could work at full capacity, thereby reducing working costs. This state of affairs gave an advantage of at least 1s. per cwt. to the foreign manufacturer competing in the free British market. The large Continental companies controlling both Continental and British factories had already adopted the policy of transfering manufacturing operations from England to the Continent, but the Maypole Company would do this only under pressure of necessity, as it would lead to increased unemployment, reduce supplies of British-made cattle cakes, and render the country dependent in war-time on foreign supplies of essential food. The amounts paid in dividends were not quite covered by the year's profits, as it was expected that the Company's claims against the Government would have been settled before the accounts were presented.

THE PEACHEY PROCESS CO., LTD.

At the second annual meeting held recently in London, Sir J. P. Hewett, chairman of the company, said that the expectation of improved industrial conditions during the past year had not been realised, and the uncertain political and economic situation both at home and abroad had delayed the manufacture of a number of raw products by the Peachey process. Licences had been issued in this country for the vulcanisation of crude rubber articles, such as boot soles and mats, and for surfacing leather with rubber. The production of moulded goods by the two-solution method had been perfected, and manufacture should begin in the spring. Licences had also been granted for manufacture in Belgium, Ceylon and Malaya, and as soon as the appeal against the decision of the United States Patent Office in favour of the company's application had been heard, manufacture would begin in the United States. The prime aim of the company was to secure the manufacture of its products on a commercial scale in the United Kingdom, and success in this direction would materially assist negotiations abroad. There was reason to be confident that in the coming year Peachey products would be manufactured on a large scale by substantial undertakings in this country. The sum paid up for preference and ordinary shares amounted to £79,006.

REPORTS

Report on the Economic Conditions in South Africa, Dated July, 1922. *By* W. G. Wickham, *H.M. Senior Trade Commissioner in South Africa. Department of Overseas Trade. Pp.* 49. *H.M. Stationery Office*, 1922. *Price* 1s. 6d.

Several new industrial enterprises have been initiated during the past two years, among which may be mentioned a rubber factory at Howick Falls (Natal), a blast furnace at Newcastle, the manufacture of sheep-dips and fertilisers in the explosives factory at Somerset West, a paper factory, and an additional cement works. Experiments on the distillation of coal have been continued, and the production of power alcohol is being investigated. Difficulties still confront the winning of natural soda, and a steady output has not yet been attained. The mining industry has suffered from high costs of production and the low prices of metals, the diamond and gold mines being particularly affected. There was a short boom in the coal-mining industry, due to the coal stoppage in the United Kingdom; and it is hoped that with the provision of improved facilities for handling coal at the ports and on rail, the output will steadily increase. The Government has decided to encourage the production of iron and steel and copper by paying bounties on production. (For the mineral production of 1921, *cf.* J., 1922, 199 R). The Government is assisting agriculture with legislation designed to ensure that only produce of uniform grade and best quality shall be exported; and methods of preventing drought are being investigated by a commission.

Excluding imports for the Government valued at £7,922,024, the value of the imports in 1921 was £49,878,292 (£93,404,962 in 1920); among the chief items were: Iron and steel £1,266,384; leather, unmanufactured, £115,561; wax, paraffin, stearin, £249,931; glass, glassware £428,667; oils £2,777,465; paints, etc., £333,384; drugs, chemicals, medicines, £1,063,648; rubber goods £338,605; paper, all kinds, £1,119,318. The imports originated as follows, per cent.: United Kingdom 54·8; rest of British Empire 11·4; United States 16; Germany 2·3; Sweden 2; Japan 1·4. Competition from Japan and the United States has decreased, but German competition was severe in aluminium ware, enamelware, glassware, earthenware, china, and cement. The United Kingdom gained a larger proportion of the trade in glass and glassware, but lost ground as a source of fertilisers, basic slag being supplied by Holland and Belgium and superhosphate by Holland. Exports were valued at 57,960,154 (£77,799,172 in 1920), and included: ark, wattle and extract, £570,127; hides and kins £1,226,876; sugar £2,065,359; coal (except unker coal) £1,949,014; diamonds £1,355,487; old, crude, £34,453,586; oil, whale, £25,191; soap 19,957; fertilisers £31,317. Of the total exports he United Kingdom took 79·8, Germany 4·1, and he United States 2·6 per cent.

RAPPORT SUR LE COMMERCE ET L'INDUSTRIE DE LA SUISSE EN 1921. *Pp.* 438. *Zürich: Union Suisse du Commerce et de l'Industrie*, 1922. *Price* 9 *francs* (*Swiss*).

In the section of this report that is devoted to chemical industry it is stated that during 1921 there was little demand for hydrochloric and nitric acids, and that after a long stoppage the soda factory at Zurzach was sold to the Solvay company. Sales of nitric acid made by the arc process were also limited, but improved towards winter, when the demand for sulphuric acid also improved. The new sulphuric-acid factory at Martigny began to produce in the autumn, but that at Schweizerhall has not yet made any sales. Heavy losses were made by the fertiliser industry, owing to the small demand and foreign, especially Belgian, competition. At the close of the year prospects for the Swiss heavy-chemical industry were unfavourable, and it was felt that relief could only come when home prices approximated to foreign prices.

The electrochemical and electrometallurgical industries depreciated further during the year and several factories began to utilise their power for other purposes. Most of the carbide factories remained closed, and though the export was the same as in 1920, viz., 9890 metric tons, the average value fell from 44·9 fr. to 35·93 fr. per quintal. About 2000 t. of acetaldehyde, metaldehyde, acetic acid, etc. was prepared from carbide, and cyanamide was made only in one factory, that of the Société des Produits Azotés at Martigny, which also manufactures sulphuric acid for use in making ammonium sulphate and a new fertiliser, "phosphazote" (*cf.* J., 1922, 390 R). The output of ferrosilicon was at most 3000 t., and that of ferro-alloys fell to 200 t., exports of abrasives practically ceasing. Manufacture of "synthetic" iron was continued with difficulty, owing to German competition, and the factory at Bex is now making cement as well as electric iron; many factories, however, consume their own production of electric iron. No progress was made by the aluminium industry and supplies of raw materials did not permit production at full capacity, but exports increased by 2490 t. to 8610 t. Nitrate of lime had difficulty in meeting competition from Chilean nitrate.

Electrolytic products suffered from the small demand and low prices, but there was a steady sale of electrolytic soda lye; the demand for potassium chlorate improved towards the close of the year; the consumption of bleaching powder decreased by one-half. Production of hydrogen peroxide increased slightly, but high prices limited the demand for percarbonates, perborates, and persulphates. Production of copper sulphate and salts of various metals proceeded normally at Bex throughout the year.

Unfavourable conditions prevailed in the manufacture of dyestuffs, photographic chemicals and synthetic perfumes, the colour, lake and varnish industry being severely affected by the economic crisis. The explosives industry, already suffering, was still further depressed by the abolition of import prohibitions on explosives; no advances were made by the industry and the trials of liquid air as an explosive gave unsatisfactory results. The position of the manufacturers of pharmaceutical products would have been most serious had not the Germans begun to quote prices in foreign currency in October, and had not the quality of their products been unsatisfactory. Slightly better conditions prevailed in the soap industry, although soap for industrial purposes was in small demand. Many of the match factories reduced their output until relief was obtained by restrictions on the heavy imports from Czechoslovakia in December. Stagnation prevailed in the ceramic and glass industries generally and despite reductions in the cost of fuel, prices were still above the foreign level.

THE BACTERIOLOGY OF CANNED MEAT AND FISH. *By* W. G. SAVAGE, R. F. HANWICKE *and* R. B. CALDER. *Food Investigation Board, Special Report No.* 11. *Pp.* 72. *Department of Scientific and Industrial Research. H.M. Stationery Office*, 1922. *Price* 2*s.* 6*d.*

The objects of the investigations, described in the report, were as follows:—(*a*) To study how far canned foods contain living bacteria or poisonous products thereof. (*b*) To ascertain to what extent canned foods passed for consumption are sterile and if not sterile, the significance of the organisms found in them. (*c*) To study the bacteria associated with the spoilage of canned foods with a view to diminishing waste from such causes. The report deals only with canned meat and fish.

Methods of Examination.—Every precaution was taken to avoid outside contamination, and in doubtful cases the organism isolated was rejected. Reliance was mainly placed on liquid media. Egg-meat-broth, nutrient broth, and nutrient Agar were the primary media most employed, and a general reaction of $p_H = 7{\cdot}2$ was found suitable.

For anærobic cultivations palladium-hydrogen jars[*] were used, but as the complete removal of oxygen by this method is doubtful, or uncertain, additional precautions were taken in certain cases. The incubation period sometimes extended to three or four months, and the temperatures adopted were 21°, 37°, and 55° C.

---

[*] Med. Research Committee, Special Report, No. 12

The characters of the organisms isolated were all studied in pure cultures, and special stress was laid on the following:—

(1) Spore formation; (2) oxygen requirements; (3) optimum temperature for growth; (4) ability to decompose proteins, as indicated by liquefaction of blood serum; and (5) ability to decompose carbohydrates with gas production. In all, 116 tins of meat and 207 of marine products were fully examined, the larger number being tins which had been rejected at the port of entry and the remainder sound tins purchased from shops. A few other tins were used for inoculation experiments and in other ways. The organisms isolated come under the following groups:—

(1) *Moulds.* These were only found in 8 samples, and there was no evidence that they could cause either "blowing" or extensive decomposition, though their presence rendered the meat unsaleable. Their presence indicates access of air.

(2) *Obligate anærobes.* Found in 27 tins. Most of the strains isolated were proved to be capable of producing "blowing" as well as extensive putrefaction.

(3) *Sporting anærobes.* Owing to their wide prevalence in both sound and unsound samples, to their power of resisting heat and to their proteolytic activity, this group is of great importance.

Of the five sub-groups of organisms isolated the majority liquefied blood serum, and were therefore potential causes of decomposition. Absence of sufficient air would prevent their growth in sound tins. Long incubation of tins inoculated with the non-proteolytic strains left the contents quite unaltered. Some strains were found to grow well under the severest anærobic conditions which could be obtained, without, however, any decomposition being observed, possibly because the proteolytic enzymes are produced under strict anærobic conditions.

No strains of pathogenic type were found.

(4) *Thermophylic Bacteria.* These were widely distributed in both sound and unsound tins. Some could only grow above 37° C. Few of them liquefied blood serum, and none produced gas from carbohydrates. They were non-pathogenic, and their presence has little significance.

(5) *Non-sporing ærobes.* Of these 78 varieties were isolated. Some of the proteolytic strains could also produce gas from carbohydrates. Some of *B. Proteus type* were markedly pathogenic.

(6) *Micrococci.* These occurred in 23 per cent. of the tins of which the majority were sound. None was gas-producing, and only three were proteolytic. They are not a cause of spoilage, and were not found to be pathogenic.

The results as a whole inculcate that the aim of manufacturers should be to obtain their raw material as fresh as possible, can it as quickly as possible at the right temperature and under the cleanest conditions, and by the use of good quality tinplate and efficient closing methods, to ensure the presence and the *maintenance* of a vacuum in the tins.

The report closes with a review of previous work on the subject and an excellent bibliography.

OFFICIAL TRADE INTELLIGENCE

(From the Board of Trade Journal for December 7 and 14)

OPENINGS FOR BRITISH TRADE

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence, 35, Old Queen Street, London, S.W.1), from firms, agents or individuals who desire to represent U.K. Manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number.

Locality of firm or agent	Materials	Reference number
Austria	Manganese ore with 70-92 per cent. manganese and little iron	628
Canada	Metals	625
,,	Celluloid articles	645
,,	Rubber manufactures	646
Cuba	Leather	6131 F.L./M.C.
Egypt	Soap (tender for)	9482 F.E./T.C.
,,	Soap, perfumery	638
Norway	Pig iron, galvanised iron, tinplate	632
Portugal	Lard, margarine	654
Switzerland	Iron and steel	637
Trinidad	Tinplate, solder	627
United States	Oils, pigments for making artists' colours	639
,,	"Stainless" steel and iron	658
Uruguay, Argentina	Glassware	661

TARIFF CUSTOMS EXCISE

Australia.—Definitions have been issued in connexion with the application of "dumping" duties. A special anti-dumping" duty has been applied to gold paint from Germany. The method of assessing *ad valorem* duties has been revised.

Costa Rica.—An additional tax of 0·25 centimo (gold) per kg. is leviable on all imported goods that are dutiable.

China.—The revised schedule of duties leviable under the revised import tariff is set out in the issue for December 14. Many chemicals, dyes, pigments, fats, waxes, oils, etc. are affected.

Egypt.—A list of revised tariff valuations for non-ferrous metals is given in the issue for December 7.

France and Algeria.—Recent modifications of the customs tariff affect animal wax, olive oil, vaseline, aluminium, copper and bronze foil, ammonium compounds, iodine and its compounds, tanning extracts, chloral hydrate, monochloroacetic acid, glycerin, tartaric acid, colours, soap.

France and Italy.—A complete translation of the commercial arrangement between France and Italy is published in the issue for December 7.

Grenada.—Rules have been issued controlling the importation of matches.

Mozambique.—The export duties on oilseeds have been modified. Building materials and material for sugar factories may be imported duty-free.

Poland.—The export duty on crude petroleum has been raised from 15 to 50 Polish marks per kg.

San Salvador.—Insecticides may now be imported free of duty.

Sudan.—The importation of alcoholic liquors is prohibited, save under licence.

United States.—All imported goods must be marked with English words indicating the country of origin. Certain goods not so marked may be marked after arrival under customs supervision and delivered after payment of an additional duty of 10 per cent. *ad valorem.*

TRADE NOTES

BRITISH

New Zealand in 1921

According to the report issued by the Department of Overseas Trade on commercial conditions in New Zealand (H.M. Stationery Office. Price 1s. 9d.), imports were valued at £42,942,443 and exports at £44,828,827 during 1921, compared with £61,595,828 and £46,441,946 in the previous year. The apparently favourable balance of trade in 1921 is misleading, as the customs valuations of imports are below the trade value and the amount of interest payable on foreign loans is not included. During the early part of the year, deliveries under old orders were heavy, but very few new orders were placed, and not till later in the year did buying improve. Some of the chief imports and countries of origin are given below:—

	£		Origin, per cent
Oils, fats, waxes ..	2,948,636	..	U.S. 81, U.K. 5·5
Paint, varnish ..	393,648	..	U.K. 60, Australia 24, U.S. 12
Metals, crude or partly manufactured, and ores..	538,288	..	U.K. 52, Austr. 37
Rubber and manufactures of (excluding tyres)	87,807	..	Austr. 64, U.K. 24, U.S. 9
Leather and manufactures of	440,168	..	U.K. 52, Austr. 31, U.S. 14
Ceramic wares, cement	1,113,719	..	U.K. 56, Austr. 13, U.S. 10
Paper	1,286,932	..	Canada 42, U.K. 36, U.S. 9
Drugs, chemicals, etc..	1,082,436	..	U.K. 47, U.S. 22, Austr. 20
Fertilisers	367,074	..	Austr. 24, U.S. 8, Japan 6, U.K.2

Per head of population, New Zealand is now the largest importing country in the world, and also the largest importer of British goods. Imports of dyes in 1921 were valued at £98,257, of which the United Kingdom supplied £47,835 and the United States £17,690; imports of German dyes rose from £28 to £14,820, but these were largely "reparation" dyes sent from Great Britain. The United Kingdom maintained its position as the chief source of medicinal preparations, drugs, perfumery, etc., but lost ground in the trade in basic slag and superphosphates, which were derived mainly from Belgium. The exports included 452,231 bales of wool, large quantities of dairy produce and meat, 329,113 hides and 8,336,702 sheep skins.

Kenya in 1920–21

The official report on the Colony and Protectorate of Kenya during 1920–21 states that although agricultural development proceeded actively during the early part of the year, the subsequent fall in prices caused a decline in production. The fertility, favourable climate, and cheap labour supply of the Colony suggest that it will eventually become an exporter of coffee, maize, sisal, flax, and certain oilseeds. The natives cultivate 24,280,000 acres of very fertile soil, whereas the Europeans cultivate only 3,157,000 acres; in addition there is 9 million acres under pasture. Sisal was grown on 30,698 acres in June, 1920; there were 21 sisal factories, with a daily capacity of 52·5 tons of fibre, and the industry seems fairly profitable. Native coconut plantations cover a large area, and the output of copra should increase considerably when the plantations on European estates come into bearing. An area of 6000 acres near Kibos has been alienated for the cultivation of sugar-cane, and a factory is to be erected to supply the requirements of the Colony and adjacent territories in sugar. An attempt to prepare limejuice has failed, but efforts are now being made to manufacture concentrated citric acid for export. Apart from a small quantity of graphite no minerals have been produced except for assay, but 974 prospecting licences were issued and 322 claims were registered, of which 166 were for gold and 93 for precious stones.

Imports increased in value by 48 per cent. to the record figure of £6,911,858, of which £3,516,075 represented goods from the United Kingdom. The value of the combined exports from Kenya and Uganda rose by 4 per cent. to £4,699,498; they included: cotton 1926 tons (Kenya 81 t.); coffee 7913 t.; grain and oilseeds 22,446 t.; fibre 5702 t.; carbonate of soda 12,829 t.; copra 468 t. The percentage distribution of the sodium carbonate was as follows: United Kingdom 7, India 26, Norway and Sweden 37, and Japan 19.—(*Col. Rep.—Ann., No.* 1122, 1922.)

Zanzibar in 1921

Although no cloves have been planted in Zanzibar for 20 years and many trees have died, the production has not diminished, and in 1920-21 the crop increased to 8555 tons. Government nurseries of clove trees and coconut palms have been established to assist planters. Exports of copra amounted to 6942 t., but the quality will not improve until drying-plant can be obtained. The export of chillies was 48,432 lb. The total imports increased by 21·5 per cent. to 72,611 t., valued at Rs. 3,22,32,946, gains being shown by cotton textiles, motor-spirit, petroleum, etc. Exports amounted to 45,036 t. (Rs. 3,24,64,049), the increase of 15·9 per cent. compared with 1920 being due to the heavy clove crop and to re-exports of motor-spirit and petroleum. The foreign trade of the Colony was distributed as follows (per cent.):—India and Burma 26, Tanganyika Territory 19, United Kingdom 16, Kenya 8, France 6, the order of importance being the same as in 1920.—(*Col. Rep.-Ann., No.* 1125, 1922.)

FOREIGN

Fertiliser Prices in Germany in October, 1922.

During the period July to September, prices of fertilisers in Germany increased by 210 per cent. Figures showing the prices at the works in marks per 100 kg. in 1913 and in July and October, 1922, are given below:—

Average prices of fertilisers in Germany

	1913		July, 1922		Oct. 11, 1922		Inc. over price in 1913
							Per cent
Carnallite	0·765	..	32	..	114	..	148·8
Kainite	1·20	..	51	..	182	..	151·9
Manure salts (20%) ..	2·80	..	110	..	412	..	147·1
" " (30%) ..	4·35	..	120	..	767	..	176·2
" " (40%) ..	6·20	..	317	..	1,310	..	210·2
Potassium chloride (50%)	13·50	..	442	..	1,787	..	132·4
Potassium sulphate ..	16·80	..	573	..	2,855	..	169·9
Potassium magnesium sulphate	8·06	..	341	..	1,699	..	210·8
Basic slag	3·75	..	278	..	1,200	..	320
Superphosphate ..	5·95	..	572	..	2,295	..	385·7
Cyanamide	21·28	..	1,135	..	4,904	..	230·5
Ammonium sulphate—							
Ord..	27·78	..	1,415	..	6,131	..	220·7
Dry	28·08	..	1,464		6,344	..	225·9
Sodium nitrate ..	22·40	..	1,324	..	5,749	..	256·6.

Italian Trade in Sulphur

Exports of sulphur from Italy are now confined almost entirely to Europe and countries on the eastern Mediterranean, as many markets have been lost entirely or in part to American producers owing to the high cost of production in Sicily, which is due to antiquated methods of extraction and the high cost of labour. The export of sulphur during the nine months ended March, 1922, was 54,402 metric tons, valued at 44,666,740 lire, and during the first quarter of 1922, 36,434 t., worth 29,493,350 lire, of which 16,280 t. was taken by Greece, 4344 t. by France, and 2860 t. by Germany.—(*U.S. Com. Rep., Nov.* 27, 1922.)

REVIEWS

THE CHEMISTRY AND TECHNOLOGY OF GELATIN AND GLUE. *By* DR. R. H. BOGUE. *Mellon Institute Technical Series. Pp. xi.*+644. *London: McGraw-Hill Book Co., Ltd.*, 1922. *Price* 30*s. net.*

The aim of the author has been to supply a want, long felt by students and investigators, of an up-to-date account of the principles of the manufacture, testing and general applications of gelatin and glue. No book has appeared before which has treated these matters purely from a scientific point of view. The subject is a very complex one, like all others depending upon colloidal chemistry, and the fact that the method of treatment is new increases the difficulty of producing a standard work. Nevertheless, in spite of these difficulties, the author has produced an excellent book which will be of value to both the chemist and manufacturer. It should be stated that the latter is only catered for indirectly, and that the details of practical manufacture are too scanty to be of much use to him. What he can learn is the scientific principles underlying the various operations.

The book is divided into two parts, viz. (1) Theoretical Aspects, and (2) Technological Aspects. An appendix contains details of the measurement and expression of hydrogen-ion concentration, p_H values and various tables. In the first part, the chemistry of gelatin is dealt with fully, the work of all recent investigations of its colloidal properties being clearly described under the following heads:—(1) The constitution of the proteins; (2) the chemistry of gelatin and its congeners; (3) the physicochemical properties and structure of gelatin; (4) gelatin as a lyophilic colloid; (5) gelatin as an amphoteric colloid. Chemical equations and mathematical expressions are used freely. Good descriptions are given of the cleavage products of proteins and of the determination of amino-acids and the Hausmann numbers.

Among the details of manufacturing processes is a suggestive description of the application of the determination of the specific conductivity of a glue liquor as a means of controlling its clarification. But the author appears to have limited his experiments to determining the point at which the soluble salts are at a minimum. He states, quite rightly, that indicator colour changes are of little use in controlling glue liquors. Seventy-five pages are devoted to the testing of glue and gelatin. A large number of physical and chemical methods is described and a useful attempt is made to divide the tests into "fundamental" and "secondary." As the result of work previously published by himself, the author concludes that the jelly strength of a glue depends upon the percentage of the total nitrogen present as unhydrolysed protein and that "amino" nitrogen is of little value as a factor for analytical purposes. This is in agreement with the conclusions published recently by the Adhesives Research Committee. Stress is laid on the importance of determining the p_H value of a one per cent. solution of the glue, though it is doubtful if the indications given by the test are so clear as the author thinks. The properties of a glue or gelatin are largely determined by the washing and boiling processes, and no subsequent adjustment of its p_H value could make good mistakes made in these operations.

The book concludes with a description of some of the uses and application of glue and, in dealing with glue as an adhesive, the factors affecting the strength of a glued joint are fully dealt with. The book is excellently printed and the bibliography full and generous.

S. R. TROTMAN.

(1) THE GENERAL PRINCIPLES OF CHEMICAL ENGINEERING DESIGN, *by* H. GRIFFITHS. *Pp.* 63.
(2) THE WEIGHING AND MEASURING OF CHEMICAL SUBSTANCES, *by* H. L. MALAN *and* A. T. ROBINSON. *Pp.* 63.
(3) MATERIALS OF CHEMICAL PLANT CONSTRUCTION: NON-METALS, *by* H. GRIFFITHS. *Pp.* 64.

(5) PUMPING IN THE CHEMICAL WORKS, *by* N. SWINDIN. *Pp.* 80.
Chemical Engineering Library. London: Benn Brothers, Ltd. 1922. *Price per volume* 3*s. net.*

Messrs. Benn Bros. have published a set of five booklets on various sections of chemical engineering, which, although quite useful compilations, hardly justify the claim made on the printed wrapper that they will form a complete and authoritative reference library.

(1) In this volume the need is pointed out of breeding chemical engineers, of whom so few yet exist. Much has been written on the subject, but events are now moving and the position of the chemical engineer at the moment is somewhat similar to that of the electrical engineer in the 'eighties. The monograph gives a brief but good outline of the subject indicated by its title, showing the necessity for the pure chemist to be well up in *all* branches of science as well as his own, and to have a good knowledge of physics. The writer urges the necessity for an intelligent use of formulæ, many of which are necessarily empirical, and regards too much "common sense" as a sign of ignorance and rule-of-thumb. He emphasises the need for research in chemical engineering and the preliminary study of the ground before any plant is designed. A chapter is devoted to many details, small and large, which go to make up a plant, and the whole monograph is one that will be read with pleasure by any practical chemical engineer.

(2) The writer gives a general survey of the methods of intermittent measurements of liquids by filling tanks or eggs, with a polar diagram for the calibration of large cylindrical tanks, but entirely

omits the gauged-flow method for this operation, which is by far the quickest and most accurate. He describes the various types of water-meters in use, viz., reciprocating and turbine meters, and gives a good description of the Venturi-meter and weir-recorder. A short chapter is devoted to the outlines of automatic weighing machines and continuous volume-measurement of granular substances. The limits of space, no doubt, preclude the mention of many designs of apparatus of equal interest to that mentioned.

(3) This booklet devotes its first chapters to all general building materials and especially to their acid-resisting properties. There are some noticeable divergencies in the figures given for fire-bricks. On page 16 the writer states the porosity to be 7 per cent., and on page 19 gives a figure of 10—15 per cent. The crushing strength per square foot is given as 250 tons on page 16, and on page 19 as 110—128 tons. Specific gravity he quotes as 1·8 on page 25 and on page 16 as 2·16. Also, surely Volvic stone comes from the centre not the south of France? Stoneware and glass, artificial stones and "vitreosil" are mentioned with their good and bad points. The use and abuse of wood are discussed in very useful detail, and paints, cements and jointing materials described, but the acid-workers' old friend, "blackman," is not mentioned. This brochure is a useful one, and the few errors mentioned will, no doubt, be corrected in a subsequent edition.

(4) The author reviews the work of Reynolds, Poiseuille, D'Arcy, Stanton and Parry, gives a clear exposition of each, and makes a plea for a general standard of units in place of c. g. s; ft.-pd.-second; metre-kg.-second. He gives an account of the conditions governing the flow of liquids in pipes and channels with a wealth of diagrams and tables, including those for losses due to bends and cocks in pipes. He demonstrates the saving in power by the use of large pipes, which allow the rate of flow to be slow enough to keep within the stream-line limits; also the fact that the mean velocity is a definite function of the velocity at the centre of the pipe, so that only one reading with the pitou-tube is necessary. There are some gaps in the tables given yet to be filled up. He omits any use of the calculus and so provides a handbook that is quite suitable for popular consumption.

(5) In this volume are described most of the types of pumps and methods of pumping met with in chemical manufacture, special regard being had to the movement of corrosive liquids. The writer deals fairly with the different types, but the details are necessarily meagre owing to the small size of the book. His statements will not perhaps meet with universal agreement; for instance, he alleges that a theoretically-minded man would prefer mechanical pumps. This is quite contrary to the experience of the reviewer, who has frequently had to apply the brake to the ultra-theoretical man. In the section devoted to centrifugal pumps, the writer gives a list of makers' names with a digest of their statements, but it is rather noticeable that he omits the firm which has been longest in this field and whose experience must be as great as that of all the others put together. He mentions the difficulties in the making of pumps from iron alloys, due to the brittleness of this material, but omits the troubles due to variations in composition which have caused chemists much tribulation in the past. Rotary pumps are described shortly and receive all the attention they deserve, but no mention is made of wear, which in most cases is a serious item. Pumping by means of air pressure and eggs is very fully gone into, and the use of steam- and air-ejectors explained. The author reserves his approval for the air-lift, pure and simple, which he describes, and of which he explains the theory in detail, although it may perhaps be permitted to doubt the efficiencies he mentions. This small book is a good one, and within its limitations covers the ground in excellent fashion.

F. A. Greene.

Physical and Chemical Examination of Paints, Varnishes and Colours. *By* Henry A. Gardner, *Director, Scientific Section, Education Bureau of the Paint Manufacturers' Association of the United States, and the National Varnish Manufacturers' Association Incorporation. Pp.* 218, *and supplement of about* 150 *pages consisting of Circulars issued by the Interdepartmental Committee, Standard Specifications Board, U.S. Government. Washington: P. H. Butler,* 1845, *B Street, N.W.,* 1922. *Price* $9.

The name of the author of this volume is familiar to everyone acquainted with the scientific and technical literature of the Paint and Varnish Industry, for as Director of the Scientific Section of the Educational Bureau above named, Mr. Gardner is probably the most prolific contributor to the literature of the industry. The present work consists of a collection of methods for the physical and chemical examination of paints, varnishes and colours, together with copies of a number of Standard Specifications issued by the United States Government. In these days, when the mass of technical literature is so great, it is often difficult for those engaged in industry to read, let alone thoroughly digest, all the new work dealing with their own industry, and, viewed from this standpoint, the volume under review has a certain value; subsequent editions can, however, be considerably improved by careful revision.

Chapters I to XIV show clearly the rapid development which is taking place in the application of physical methods of investigation in the paint and varnish industry, and these chapters prove the most attractive, for therein the author deals with the most up-to-date work on such problems as oil absorption, viscosity, surface tension and interfacial tension of varnishes and paint liquids, and colour standards.

The chapter dealing with the testing of paint films, the Pfund Cryptometer, the colorimeter, and paint film gauge, is of particular interest, the construction and use of the instruments being carefully described. No attention is given to the microscopic examination and measurement of pigment particles, and this is a serious omission, because it is generally agreed that by no other means can the fineness of a pigment be determined. The chapter on the texture of pigments is an interesting but too discursive treatment of a difficult subject, and its value is not sensibly increased by the photomicrographs reproduced. The treatment of a most important subject, viz., exposure tests, is meagre and by no means sufficient for a work of this type, and in a new edition page 77 might be recast with advantage so as to secure uniformity of method of expression.

A number of chapters deal with the analysis of mixed driers, shellac, resins, bituminous paints, white paints, lead oxides, vermilions and other pigments, and it is only possible in a review of this description to draw attention to a few features which might with advantage be altered in a new edition. It is important to note that the composition of English basic sulphate of lead is not similar to that quoted by the author for the American product. In English brands, the zinc-oxide content is usually less than the 5·5 per cent. stated to be American standard.

Methods for the analysis of the new titanium pigments are given, but whilst mention is made of the use of antimony oxide as a pigment, the reader is referred to another publication for details of methods of analysis—an inconvenient feature in a work of this type.

Exception must be taken to the statement on page 183 that whilst the lead oxide pigments in the pure form are of the generally accepted formula Pb_3O_4, they are "probably mixtures of lead monoxide and lead dioxide" and further, that "in chemical composition they are the same, the proportions of lead monoxide and dioxide varying, however, but by their physical structure and colour they can be readily differentiated." The first statement is incorrect and the second is so involved that its meaning is not clear.

The remaining pages of the book consists of actual copies of 18 Circulars issued by the United States Government. These are excellent productions, each being a complete work in itself. This feature, however, involves much repetition, particularly of methods of testing and preparation of reagents. Thus, the same methods for the preparation of standard solutions of sodium thiosulphate, starch solution, standard iodine solution, alcoholic sodium hydroxide, etc. are described at least a dozen times, and similarly, the same laboratory methods for the examination of dry pigments are described time over again. Such repetition is unavoidable when the circulars are printed for sale as separate complete works, but it makes tedious reading in a work such as that under review. Further, each specification can be purchased at 5 cents per copy, so that 150 out of the 380 pages contained in the volume are purchasable for 90 cents, leaving less than 250 actually written by the author. In view of this, the price of 9 dollars for the work is excessive and will certainly militate against the free sale of the book, even though, as is always the case with the author's productions, the volume is well bound, clearly printed and free of printer's errors.

C. A. Klein.

With reference to the review of Die Lösungsmittel der Fette, Oele, Wachse und Harze, by Dr. H. Wolff, which appeared in our issue for October 16, the publishers, Die Wissenschaftliche Verlagsgesellschaft m.b.H., Stuttgart, write to say that the book is to be had bound as well as in brochure form; for reasons of economy the latter form is sent out for review. The price to purchasers in England has now been reduced to 5s., bound, whilst the price in Germany has been raised to 1600 marks.

PROCEEDINGS OF THE

FORTY-FIRST ANNUAL GENERAL MEETING

Glasgow, July 4th to 11th, 1922.

The forty-first annual general meeting was held at the Institute of Engineers and Shipbuilders, Glasgow, on July 4, under the Presidency of Prof. R. F. Ruttan.

The Lord Provost of Glasgow (Mr. Thomas Paxton), in extending to the Society a very cordial welcome to Glasgow, congratulated the Society on the great progress it had made since it had last met in Glasgow in 1910, both in the increase in its membership and in the contributions it had made to our knowledge of the scientific and practical applications of chemistry. It was recognised that the Glasgow district owed much to its chemical industries, and in the interval that had elapsed since the Society had last come to Glasgow the City had not stood still in its efforts to show its appreciation of the furtherance of science in all its aspects. The Corporation of Glasgow was largely interested, in a corporate capacity, in chemical industry. They had established highly specialised chemical sections in connexion with the health, the gas, and the sewage departments; he believed Glasgow had some of the best organised gas works in the country. Alluding to the manner in which the University of Glasgow appreciated the place of chemical science in its organisation, he referred to the fact that during the past few months the chemistry department had been very considerably strengthened by the addition of new chairs. As showing the interest the University took in the work of the Society, he referred to the presence of Sir Donald Macalister, the Principal of Glasgow University, at that meeting. He expressed the hope that the result of the meeting in Glasgow would be to increase interest in the objects of the Society. He concluded by again extending a hearty welcome to the Society on behalf of all the citizens of Glasgow.

The President expressed the sincere thanks of the Society for the welcome to Glasgow that had been so courteously and heartily offered. He considered it his good fortune that during his term of office the meeting should have been held in Glasgow, for he knew of no other city in Great Britain better fitted for a meeting of the Society of Chemical Industry than Glasgow. Not only had it a most interesting and historical environment, but it was a city known throughout the Empire as a great seat of chemical industry, one of the great centres at any rate of the coal and the iron and steel industries. It had been a pioneer in the establishment of the bichromate industry, sugar refining, and the distillation of shale, and, above all, in the manufacture of chemical plant. It was of interest to note that the first great plant for the distillation of wood which had been sent to America had come from Glasgow. The process was known as the Scotch process, and it had only been slightly modified since that time except in the direction of making the plant very much larger and of greater capacity. The Empire associated the City of Glasgow with the great pioneers of chemistry and the industry of chemistry; the names of Joseph Black, and Tennant, and later on of Kelvin and Ramsay, were indissolubly connected with the City of Glasgow. The influence of Kelvin and Ramsay had extended to the outermost quarters of the British Empire and beyond that, throughout the whole realm of civilisation and had advanced the development of science. Therefore, the citizens of Glasgow might well be proud of their city, which had taken such a very prominent part in the past in chemistry, and to-day was playing such a very important part in chemical industry. He again thanked the Lord Provost for his very cordial welcome.

The **Lord Provost** having briefly expressed his thanks, the President took the chair.

Messrs. D. A. McCallum and J. McGregor were appointed scrutineers for the ballot, which was declared closed.

The minutes of the fortieth Annual General Meeting, held in Montreal, were taken as read.

Report of Council.

During the past year the Council has held 12 Ordinary Meetings, and the following Committee Meetings have been held:—Finance 4; Publications 25; and General Purposes 8.

The number of members on the Register at July 4, 1922, was 5270, as compared with 5654 last year.

Since the last Annual Meeting 260 members have been elected, 22 former members have been restored to membership, and the losses have been 665.

The Council regrets to record the deaths of 37 members (of whom 10 were original members).—J. R. Appleyard, H. J. Barnes, Dr. Chas. Baskerville, E. J. Bevan, Dr. J. F. Bottomley, T. Lynton Briggs, Wm. C. Carnell, John V. Casey, W. B. Cogswell, George H. Coy, W. S. Curphey, Fred P. Dewey, T. W. Dukes, Charles Estcourt, F. L. Gallup, W. B. Giles, Gustave Gillman, George Golding, W. Gowland, E. W. T. Jones, W. Arthur Kershaw, Dr. E. J. Lederle, James Lyle, John S. Macarthur, Dr. Andrew McWilliam, E. Kennard Mitting, Dr. F. W. Passmore, Arthur F. Price, A. E. Sadler, Irwin J. Smith, John W. Smith, J. Spiller, Frederick C. Weld, R. Lloyd Whiteley, Frank Wilson, Louis S. Winsloe, John W. R. Youll.

Mr. John Spiller was an Honorary Life Member of the Society.

Sir William J. Pope, F.R.S., was appointed Chairman of the Council during Prof. Ruttan's year of office as President.

Professor R. F. Ruttan retires from the office of President of the Society at the close of the Annual General Meeting, and the Council has nominated Dr. E. Frankland Armstrong, F.R.S., of Warrington, as his successor in office.

Mr. E. V. Evans and Prof. Henry Louis have been re-elected Hon. Treasurer and Hon. Foreign Secretary respectively.

Professor Ruttan has been nominated a Vice-President and to the other vacancies caused by the retirement of four Vice-Presidents Dr. H. Levinstein, Prof. G. T. Morgan, F.R.S., and Mr. S. J. Pentecost have been nominated.

The Council accepted with deep regret the resignation, owing to illness, of Dr. C. A. Keane as an Ordinary Member of Council, and chairman of the Publications Committee.

Three ordinary members retire from the Council, and to fill the vacancies thus created, and that caused by the resignation of Dr. Keane, six nominations have been received. A ballot will therefore be taken.

Mr. W. T. H. Williamson has been appointed Hon. Secretary and Treasurer of the Edinburgh Section in place of Dr. Lauder resigned.

The following Chairmen of Local Sections retire: Mr. S. R. Church (American), Dr. H. W. Brownsdon (Birmingham), Mr. Noble W. Pirrie (Canadian Pacific), Mr. J. H. Young (Glasgow), Mr. H. W. Matheson (Montreal), Dr. J. H. Paterson (Newcastle), Mr. J. H. Dunford (Nottingham), and Mr. S. H. Davies (Yorkshire). The following have been elected to succeed them respectively:—Professor R. H. McKee, Dr. E. B. Maxted, Professor E. H. Archibald, Mr. W. E. Moodie, Dr. A. R. M. MacLean, Mr. A. Trobridge, Mr. S. H. Burford, and Dr. L. L. Lloyd.

The following Honorary Secretaries of Local Sections retire:—Mr. F. R. O'Shaughnessy (Birmingham), and Mr. W. P. Dickson (Montreal). The following have been elected to succeed them respectively:—Mr. George King and Mr. W. B. Woodland.

The Council desires to express its cordial thanks to the retiring officers for their services to the Society.

The Council has approved proposals from the Edinburgh and Nottingham Sections to admit "Associates" to meetings of the Sections at a nominal annual subscription, on the same conditions as were laid down in the case of the Glasgow Section (see Report of Council 1921).

A new Section of the Society has been formed for South Wales with headquarters at Cardiff. Meetings will be held alternately at Swansea and Cardiff and it is hoped that a considerable accession of new members to the Society will result. The area covered by the new Section has hitherto formed part of the Bristol and South Wales Section, which in future will be known as the Bristol Section.

Reference was made in the last Report of Council to a tentative proposal which had been submitted to the Council for the formation of another Subject Group. This matter is still under discussion.

The Annual Meeting of the Society for 1921, which was held in Montreal, was followed by visits to the Sections at Shawinigan Falls, Ottawa, Toronto and New York, as well as to other places of interest in Canada and the State of New York. A full account of the trip and the various functions will be found in the Journal.

The experiment which was made in October of holding a Dinner of the Society in London was most successful, and it is proposed to hold a similar function in London each year that the Annual Meeting takes place in the Provinces or in one of the Overseas Sections.

With regard to the proposal of the Chemical Society that papers intended for its Transactions might be read at provincial Sections of the Society of Chemical Industry, and that Fellows of the Chemical Society resident in the locality be invited to such meetings, the Committees of the Sections have now expressed their cordial approval of the scheme, and a working arrangement has been entered into between the two Societies for the purpose of giving effect to it.

The audited Balance Sheet and Statement of Income and Expenditure for the year ending December 31, 1921, which have already appeared in the Journal for June 30, will be laid before the Annual General Meeting.

The audited accounts of the Messel Fund have also appeared in the Journal for June 30 and will be laid before the Annual General Meeting.

The whole of the income from this Fund has been invested—partly in 5% War Loan and partly in 3½% Conversion Loan, and there is a small balance on deposit account with the Society's Bankers.

Dr. H. E. Armstrong, F.R.S., is to deliver the first Messel Memorial Lecture in Glasgow on July 4 on the occasion of the Annual Meeting of the Society, and the first award of the Messel Medal will be made to him on that occasion.

The Council decided not to re-elect the large number of Committees which have been in existence for the past three years, but has continued the Publications Committee and the General Purposes Committee. The membership of these Committees is given in the Journal, 1922, page 5 R.

Mr. E. V. Evans has been elected chairman of the Publications Committee, until the end of the Annual Meeting, 1922, in succession to Dr. C. A. Keane resigned. Dr. W. R. Ormandy resigned his membership of the Committee.

The Journal for 1921 contained 1698 pages of text (Review 480, Transactions 310, Abstracts 908) compared with 1636 pages in 1920. Advertisements:—1160 pages in 1921, 1246 in 1920.

Volume VI. of the Society's Annual Reports of the Progress of Applied Chemistry has been published this year.

The Council approved the establishment of a General Council to look after the interests of the Society as a whole in Canada and to deal with questions which may arise with regard to Federal and Provincial Legislation. The names of the members of this Committee are given in the Journal, 1922, page 94 R.

A second joint meeting of the Society and of the Institution of Mechanical Engineers was held on January 6, 1922, when a paper was read by Mr. G. M. Gill, Chief Engineer of the South Metropolitan Gas Co. (see Journal, 1922, p. 5 R).

The new scheme for the Latham Research Fellowship, proposed by Mr. C. F. Cross, F.R.S., and approved by the Council, is now in operation. Full particulars will be found in the Journal, 1921, page 384 R.

The Council has renewed for 1922 its donation towards the expenses incurred in connexion with the extension scheme of the Chemical Society's Library.

In response to the application which the Council made to the Government through the Conjoint Board of Scientific Societies for financial assistance in defraying the cost of a Collective Index to the Journal for the years 1906 to 1920 the Chancellor of the Exchequer regretted that in view of the paramount importance of reducing public expenditure he is unable to contemplate any increase of existing grants. The Committee of the Conjoint Board considered that in the circumstances it would be useless to press the matter further, and the Council concurred in this view.

A list of the Society's representatives on outside bodies is given in the Journal, 1922, page 5 R. Owing to the resignation of Dr. C. A. Keane, Mr. W. J. U. Woolcock, M.P., has been elected to the Federal Council for Pure and Applied Chemistry and Mr. Julian L. Baker to the Conjoint Board of Scientific Societies.

Mr. Julian L. Baker and Mr. F. H. Carr were appointed representatives upon a Standing Committee to be set up by the National Physical Laboratory to deal with the standardisation of scientific glassware and kindred problems.

The President of the Society was invited to join the General Committee of the British Empire Exhibition, 1924.

Mr. E. V. Evans and Mr. R. H. Clayton represented the Society on a deputation which was received by Sir Alfred Mond, Bart., Minister of Health, on March 20, to urge the Government to take immediate steps to deal with the subject of Smoke Abatement.

The Council of the Association of British Chemical Manufacturers has expressed its willingness to co-operate with the Council of the Society in a scheme of chemical propaganda in connexion with the British Empire Exhibition, 1924.

Mr. J. H. Young moved the adoption of the report.

Mr. E. Grant Hooper, in seconding, said that he was sure they would all wish to welcome their President from Canada. They might congratulate themselves that the report of the Council represented, on the whole, distinct progress—not, he was sorry to say, in the matter of members, because they had to lament a slight diminution in the number; but there had been an increase in the number of Sections, and he thought they might reasonably look forward to an increase in the membership as a result. The members owed a great debt of gratitude to the Council for the work it had done during the past year, and of which the report so eloquently spoke.

The report was unanimously adopted.

Hon. Treasurer's Report.

The Hon. Treasurer, Mr. E. V. Evans, said that he was pleased to be able to report that the balance-sheet for 1921 showed that the Society's financial position had continued to improve, and it might be truly claimed that there was an excess of income over expenditure of £3747 11s. In addition to that the Society's stocks had appreciated in value; whereas the depreciation from cost price reported last year had been 36·5%, this had been reduced to 29·8% in December last; this difference represented an increase in the valuation of the stocks to the extent of £1214 18s. That was a very satisfactory state of affairs, but he asked the members not to become too optimistic from this general survey. The income of the Society was not a stabilised one, and examination of the balance sheet would show the important contribution made last year by the Advertising Department to the revenue of the Society. In fact, whereas the expenses of the Society (which related mainly to the costs of producing the Journal and to Sectional expenses) amounted to approximately £5 7s. per member, this figure was reduced to £2 16s. as the result of the revenue received from Advertisements. These figures illustrated the important part played by the Advertising Department, and he was sorry to have to report that owing to the slump in trade, which appeared to have been accentuated in the case of the chemical trade, it was not now so easy to secure advertisements as had been the case last year. This would without doubt affect adversely the finances of the current year, and it was for that reason that it was necessary to curb undue optimism.

Since the last Annual Meeting the Council had given considerable attention to certain ideas and schemes which had been formulated with a view of extending the activities of the Society and of increasing its usefulness to members. Although expenditure had been increased in certain directions, none of these schemes had yet been put into operation owing to the fact that the Council had strictly adhered to its decision to re-establish the financial position of the Society before incurring further responsibilities. It was owing to the continuance of the trade slump that the Council had to continue in a state of strict economy, its main object being to strive to attain a sound financial backing in order that the activities of the Society might be extended beyond those of to-day.

In regard to the Messel Fund, it would be seen that not only had this been kept intact during the first year, but all dividends had been re-invested. The initial expenditure involved in the creation of the Messel Medal represented the first outlay under this Fund, and he felt confident that the members of the Society would be in full accord with the steps taken by the Council to perpetuate the memory of Dr. Messel.

In conclusion he expressed his indebtedness to the Council for the detailed consideration and advice that they had given in matters relating to the finance of the Society.

Dr. Stephen Miall, moving the adoption of the accounts, said the satisfactory position that had been reported was in no small measure due to the great care and trouble and immense amount of time which the Hon. Treasurer had devoted to the well-being of the Society. He had watched over the expenditure in a most exemplary manner.

Mr. F. H. Carr seconded the motion and supported all that Dr. Miall had said with regard to the work of the Hon. Treasurer. Two years ago, the duty of taking on the treasurership of the Society had been by no means an easy task. Mr. Evans, however, had accepted that task and had carried it out in a remarkably successful manner, and his work had been a really great achievement during two such troublous years as those which had just passed.

The financial statement was then adopted.

President's Address.

The President then delivered his address, as follows:—

By selecting a Canadian chemist as your President for this year, you have conferred upon Canada the highest honour in your gift. On behalf, then, of the Canadian Sections of the Society and myself, I wish to express my deep appreciation of this recognition.

The year 1921 was recognised in Canada as a most inconvenient one for the British chemists to hold an annual meeting across the Atlantic, as it was a period of great anxiety to all interested in chemical industry. Difficulties in connexion with conditions of foreign trade, labour and transportation were calling for the closest attention, and new legislation of vital interest to the chemical industries was pending or being applied. We appreciated, therefore, all the more the sacrifices made in the interests of chemistry by those who did us the honour of accepting our invitation to hold the Annual Meeting of the Society in Canada in that year.

Members of the Society in the British Isles, not in intimate touch with conditions in America, can scarcely understand how far-reaching was the influence of that meeting in Montreal and the congress of chemists in New York to which it gave rise. It has not only greatly strengthened the Society itself, but it has done a greater service by stimulating public interest in the science of chemistry and its applications throughout Canada and the United States. The Society fully realised its objective by bringing into closer relations with one another the far-flung Sections of the North American continent. At this meeting was organised the Canadian Executive Committee, composed of the Chairman of the various Canadian Sections, which will act as a medium of communication with the parent Society and organise annual meetings of all the Sections in the Dominion. The first of these "all-Canada" meetings was held recently in Ottawa, and was attended by more than one hundred chemists. It was felt that some such nucleus, around which to crystallise and develop, was necessary for Sections extending over a distance of more than three thousand miles.

The Annual Meeting of the Society in Montreal also served as a means of recognising and promoting the interest shown by the Canadian Sections in the parent Society, and, by bringing the officers and members of the Canadian Sections into personal relations with the executive of the Society, went far towards harmonising and unifying the aims and ideals of the new and scattered Canadian Sections with those of the older ones in England and Scotland. This meeting further served to accentuate the imperial character of the Society: to bring home to chemists both in England and Canada the fact that this great Society has for its object the advancement of chemistry and its application to industries beyond the confines of the British Isles.

It is to be hoped that as a result of this overseas meeting not only, with the revival of industry, will the number of Sections in Canada be increased and each Section strengthened, but that in the near future Sections will be established wherever centres of industry exist throughout the whole Empire.

Incidentally, the voyage to Canada of the representatives of the Society played an important part in the great movement in progress last year for consolidating and strengthening the various interests of the British Commonwealth. During the year a congress of Premiers and other representatives of the Dominion was held in London; university and public school teachers from almost every part of the Empire met in Canada during July; and at the same time a congress of the Universities of the Empire was held in the several great universities of England and Scotland. This desire for unity and co-operation among the countries in the British Empire is that which makes it a real and substantial League of Nations.

The large and representative Congress of Chemists held in New York was the direct outcome of the visit of the Society to Canada. British and Canadian members of the Society were the guests of our American Section, who arranged for a meeting of the American Chemical Society during the same week. This Congress, following the Canadian meeting, directed public attention to the international character of the Society. No scientific meeting in America has received wider publicity or created greater interest among the chemists, in the industries, and among the people at large. Our common interest in chemical science and the opportunities of informal meetings between ourselves and the chemists of the United States undoubtedly served to add another bond to those of a common national origin and a common language to link England more closely with the Anglo-Saxons of the American continent.

It will then be seen that, although you accepted our invitation to cross the Atlantic for your Annual Meeting last year at considerable inconvenience to yourselves, the Council was fully justified in the course it took. The results, in enhancing the prestige of the Society, in consolidating its membership, and in creating a new interest in chemistry among those in America who should make use of its applications, will prove no small satisfaction to the executive of our Society.

I have ventured to select as the chief topic of my address some aspects of the war-worn subject of scientific and industrial research. It must not be forgotten that the most obvious of truths are those which require the most frequently to be recalled. They are so obvious that they cease to attract attention. It is to be hoped, therefore, that the active propaganda carried on some years ago to arouse the general public to a realisation of the national importance of science and scientific education will not be allowed to fade into a painless death.

I propose to discuss the present general trend of the development of scientific and industrial research, to refer to international organisation of science, to trace in outline the post-war efforts of the overseas Dominions to apply scientific methods to their industrial and economic problems, and, based upon our experiences of the last five years, to draw some tentative conclusions regarding the relation of the State to this vital problem.

We are living in the age of a second renaissance, one which will leave an impression on the civilised world as indelible as that left by the great revival of literature and art in the fifteenth and sixteenth centuries. It is a renaissance in which the attention of the civilised world is concentrated upon science, its outstanding achievements and its power to enhance our intellectual pleasure and our material welfare.

At the close of the war the world was ringing with appreciation of what science had achieved in the great struggle. How best to develop this great power and use its forces in times of peace became an international, as well as a national, problem of the first magnitude. So profoundly was the world impressed by the efficiency of co-operation and organisation in the conduct of the war, that extraordinary emphasis was laid on these as guiding principles in all activities of national life.

The general recognition of the value of co-operation may be truthfully described as the best positive product of the great war. Its impression on the organisation of science has been a permanent one. It has also penetrated and influenced the political, industrial, and scientific activities of all the allied nations. It has given birth to what has been called "Internationalism," the moving spring of which is the idea of a world-wide community of the human race and a desire for its realisation. This has taken definite form in the League of Nations—an effort at world-wide political and national co-operation—a unification of the whole human race into a single organised group or community. This high ideal of the internationalist may be difficult of realisation, as it comes into almost fatal collision with the principle of nationality, of patriotism, everywhere active and powerful.

Among the international movements resulting from this appreciation, the beginning of an attempt to organise the world of science is of conspicuous interest. This has taken the form of an International Research Council established in 1919 at Brussels. The second meeting of this organisation, which embodies the concept of international co-operation in science, has been called for the end of this month in Brussels.

This International Research Council is composed of delegates nominated by the representative councils and scientific national academies of the Allies and of the neutral nations. It has definitely refused to admit the nationalities which formed the central Powers during the war. Affiliated with this Council are a number of unions representing all branches of science, among which the International Union of Pure and Applied Chemistry is one of the most active, influential, and thoroughly organised. The constitution of the Council is drafted so carefully that there is no clashing of interests or infringements on the rights of the older international societies existing before the war. The Council, with Dr. Schuster of London as its Honorary Secretary, has been launched with the active sympathy and loyalty of nearly all the national scientific associations among the allies and neutral nations. It is obviously the beginning of a human enterprise much vaster than is indicated by its present form. It has been carried to its present stage of development by the momentum imparted to scientific investigation by the activities of the war, but it is as yet little more than a nucleus around which may gather the scientific organisations of the neutral and allied countries with their various unions. It has great possibilities in future years.

The ultimate goal at which the Council seems to aim would make it a veritable parliament of science composed of delegates from all countries and of affiliated unions. It would become the express image of the science of the world. At its triennial sessions would be enacted legislation governing the formation of new unions of scientists, as well as plans for the inter-relation and development of international unions already in existence. The unions in turn, meeting at more frequent intervals, would be made up of representatives of organisations of special sciences from every country of the civilised world. They would thus serve to develop and integrate for international purposes investigations carried out in different parts of the world, as well as to stimulate research and provide for scientific discussion and publication. Behind these International Unions stand, in every nation, the National Research Councils, National Departments or Advisory Councils of Research, whose activities are devoted to the national development of science and its applications. These National Councils in turn have as subsidiary organisations the various scientific societies, such as physical, astronomical, and chemical societies, the scientific departments of the universities, of the government and research institutes. A world-wide scientific effort would become organised, of which co-operation would be the nervous system carrying afferent and efferent impulses in all directions from the centre to the periphery.

Such a world-wide organisation of pure science is a type of internationalism strictly democratic and free from the semblance of super-national authority, which is one of the sources of danger in the League of Nations. It is a type of community interest which seems especially adapted to world-wide development, and if so developed should bring us nearer to the unification of mankind than any form of internationalism hitherto suggested. In pure science, communism is a natural law; race, religion, nationality should count for nothing. The underlying principle here is the universalism of science and the catholicity of truth. The plan merits hearty recognition among the nations, it is full of possibilities.

The successful development of science in each ation taking part in this international movement es at the very foundation of the edifice designed y the International Research Council. As obrved by Sir Ronald Ross, it should be regarded as duty by every country to participate in the disoveries of the laws of nature, and thus to enhance e powers of man and widen the range of his vision. his is a national duty to humanity and should be dequately supported by national endowment. The cultivation of pure science yields results which re more lasting than the Pyramids, of world-wide ecessity and which increase in value with every eneration of workers."

While we should regard the support and development of fundamental science as a national obligaion to the civilised world, it is also of supreme nportance to the individual nation, in order that s findings may be utilised to create national ealth through the development of its natural esources and increasing the efficiency of its ndustries.

When the war was giving us such a convincing emonstration of the dependence of modern nations pon scientific achievement, the nations of the mpire were looking forward to post-war reorganiation through the scientific method of scientific rganisation.

The prompt establishment by Great Britain of an dvisory Council for industrial and scientific reearch under a committee of the Privy Council in 915, and its subsequent organisation as a separate tate Department of Scientific and Industrial Reearch, furnished a model of organisation which the ther portions of the Empire quickly utilised. It was not only an early recognition of the fact that he development of national resources in time of var is dependent upon scientific methods and reearch, but it also indicated the path to be followed n organising the industries of the nation to meet the post-war conditions.

Of the many useful activities of this Department, the most outstanding is its co-operation with the industries of the country in the foundation and maintenance of approved associations for research, for which the Government placed one million pounds at its disposal. These associations, now twenty-nine in number, have encountered criticism and possibly are not perfect in detail, but their influence has been felt throughout the English-speaking world. The general acceptance by manufacturers of this principle of industrial unions indicates that the policy of industrial secrecy, which has so greatly hampered the application of science to industry, is now almost obsolete. Manufacturers of Great Britain by their action demonstrated their belief in the statement that for most industries "the closed door shuts out more than it shuts in."

This pooling of the expenses and proceeds of scientific research may to some have an objectionable Teutonic flavour, but its effect is to transform isolated crafts into highly developed industries, eliminate needless duplication of effort, and, what is of the highest importance, it has prevented at the present critical period incalculable loss through arrested development. This courageous and original method of organising and developing research has spread to Canada and the United States and has there helped to eliminate unnecessary trade secrecy and promote co-operation in technical and scientific investigation.

The plan in its present form is not easily adapted to conditions in the overseas Dominions, where it will take time and a great controlling motive to bring into effective co-operation the large number of scattered, isolated, and sometimes conflicting industries. The absence of available laboratories and the consequent necessity of constructing laboratory buildings for each association have also had a strong deterring influence. It is, however, as generally recognised overseas as it is here, that co-operation and organisation are the most efficient means of capitalising science—of making it commercially useful.

This general conclusion was reached as each of the large units of the Empire recognised that the creation of new industries and increased production were required to restore material prosperity and to meet its enormous national debt. It is interesting to note, however, the lines along which the overseas Dominions have been working to develop scientific method and research. All followed the lead of England in 1916 by establishing something analogous to a scientific advisory body for the Government.

In Australia an Advisory Council of Science and Industry was called into existence by the Prime Minister, the Right Honourable W. H. Hughes. This was considered to be a preliminary step towards the centralisation of scientific work in that country. The work of the Advisory Council covers similar ground to that investigated by the Advisory Councils of the other Dominions. The same order of procedure is to be found in each of the Dominions; first, a census was made of the problems of special importance to the Dominion; then a census of the industrial activities of all the laboratories for scientific research, their personnel and the character of the work in progress. The result of this preliminary work was to disclose a great shortage everywhere in the supply of trained investigators necessary to carry on the researches.

To remedy this an investigation was made of the training afforded by the universities and technical institutes, with a view to increasing the future supply of scientific investigators. Students were encouraged to enter a course of research by the establishment of Fellowships. Those who had demonstrated capacity for investigation were granted assistance for researches in contemplation or partially completed. Not only were these researches encouraged in this way, but the attempt was almost invariably to bring about co-ordination of researches already in progress, as well as stimulate the initiation of new ones. This stage in the development of research work in Australia was completed by the end of 1918, and we find India, New Zealand, South Africa, and Canada had developed efficient schemes for Fellowship and assisted researches by the end of 1918.

Australia met with the same experience as did the other Dominions when attempting to utilise existing laboratories, scattered in the universities and Government departments, for the purpose of carrying out the work of the Institute. The experience of a year or two convinced the Council that it was impracticable for its research work to be carried out efficiently and economically solely in existing laboratories. They found that Government laboratories were manned and equipped for work of a routine nature, laboratories in works were small and inefficiently equipped both as to men and facilities, while the staffs in university laboratories were too fully occupied with instructional and executive duties to give the prolonged attention necessary for the successful and speedy solution of industrial and scientific problems. None of these classes of laboratories were equipped for conducting large-scale experiments of semi-commercial magnitude, hence, in Australia, the Council submitted resolutions to the effect that the immediate establishment of a permanent research institute was a matter of urgency, as the financial and executive powers of the temporary organisation were wholly inadequate for the purposes in view. This Institute was planned to work in co-operation between the Commonwealth and the six State Governments. Steps have also been taken with a view to evolve a suitable scheme for the establishment of industrial research associations among the industries themselves, similar to those in existence in the United Kingdom.

The establishment of a Bureau of Information and a technical and scientific library in connexion with the Institute is also decided upon. This met with the general approval of the Government.

The hopes of bringing about efficient organisation and co-operation of scientific work in Australia are centred around a National Institute of Science and Industry.

Scientific development in the Union of South Africa took its origin in a Board called the Industries Advisory Board, established by Act of Parliament also in the year 1916. This Board, consisting of eleven representatives chiefly of commerce and industry, had to deal with statistics of production and make recommendations regarding scientific and industrial research, factory legislation, encouragement of industries, development and utilisation of natural resources. At about the same time the various scientific societies in the Union formed a committee for industrial research with an executive head, and a committee, styled the Scientific and Technical Committee of the Board, was then appointed by the Government. This committee had to deal with all scientific or technical questions and with research work referred to it by the Government or the Industries Advisory Board. The original Board and the scientific and technical committee were later amalgamated under the title of "The Advisory Board of Industry and Science," which has strongly recommended the establishment of a central Research Institute for the whole Union of South Africa. In the meantime it has established a State Laboratory in connexion with University College, Johannesburg, for the study and development of a ceramic industry in the Transvaal. "In taking this step," its report states, "the Board desires to make it clear that the establishment of the ceramic laboratory or other laboratories of a similar character in connexion with existing scientific institutions, while affording a ready and very economic means of prosecuting industrial research, must not be regarded as in any degree prejudicing the eventual establishment of a central Research Institute."

Unlike the other Dominions, action was taken in New Zealand by the Government through the influence of a learned society, the New Zealand Institute. The Institute, like the British Science Guild in England, has for years pleaded with the New Zealand Government for some definite policy in aid of research.

In June, 1917, the Government endeavoured to find a scheme for providing a proper system of scientific investigation for the Dominion. With the assistance of the New Zealand Institute, a committee, representing the industries and the scientific men of the Government and University, submitted a carefully studied plan of organisation for co-ordinating scientific and industrial research. This scheme, involving a cost of £20,000 per annum for five years, has not yet been submitted to Parliament by the Cabinet, and it seems very unlikely that it will be revived even in a modified form.

New Zealand is essentially an agricultural country, not a wealthy one, and spends half a million pounds annually on national defence, hence the Government naturally felt that the addition of £20,000 to the annual sum required to meet their heavy war debt was not justifiable. It was also found that the University was understaffed and that the graduates were not well trained in science. Men trained for scientific research could not be found in the country. There is, however, a privately endowed institute called "The Cawthron Institute for Scientific Research," which at present practically confines itself to agriculture and fruit growing.

The Indian Industrial Commission, appointed by the Government of India in May, 1916, which sat from 1916 to 1918 under the chairmanship of Sir Thomas Holland, made a most thorough study of the industrial conditions in the whole of the Indian Empire. The results were embodied in an able report issued in 1918. The constructive proposals made by the Commission were (1) that Government must play an active part in the industrial development of the country with the aim of making India more self-contained in respect of men and material, and (2) that it is impossible for Government to undertake that part unless provided with adequate administration equipment and forearmed with reliable scientific and technical advice.

The Government had resigned itself for so many years to the tradition of "laissez faire" in industrial matters, that when in recent years it attempted to play a more active part, its efforts were rendered futile by the absence of scientific and technical advice to assist it in estimating the value of industrial propositions and by the lack of any suitable agency to carry out approved proposals. To remedy the first of these defects a reorganisation of the existing scientific services was advocated.

In February, 1921, an Imperial Department of Industries was constituted on a permanent basis, and again Sir Thomas Holland was placed in charge.

The Imperial Department of Industries has undertaken under its direct control three important projects, viz., an Imperial School of Mining and Geology; a Central Chemical Research Institute; and an Imperial Tanning Institute and Demonstration Leather Factory. Progress in the case of each of these three schemes has been hampered, owing partly to financial stringency and partly to political unrest. The organisation of the All-Indian Industrial and Chemical Services of further complicated by the recent constitutional changes in the Indian Government.

At a conference of the Indian departments held last year much opposition to an All-India

Chemical Service appeared from the local Governments, through distrust of departmentalism and doubt of the necessity of adding another specialised Indian service to the large number now in existence. No decision was reached and the question was postponed for a year, with the prospect of a compromise satisfactory to the provinces and with a certain amount of regard to efficiency of the service in India as a whole.

It is obvious that conditions in India are fundamentally different from those found in the self-governing Dominions, such as Australia and Canada. The development of scientific and industrial research by the State must be linked up with the Indian Civil Service and be largely bureaucratic. Support from the Indian people seems unlikely until the intelligentsia of the native races with their great wealth lose their prejudice against all forms of business.

In Canada our original organisation was modelled more closely on that of Great Britain than perhaps in any of the other dominions. A sub-committee of the Privy Council was constituted in June, 1916, and later an Honorary Advisory Council for Scientific and Industrial Research. This Council was omposed of eleven representatives of the scientific, technical, and industrial interests of Canada. An administrative chairman was selected from mong its members who gave his whole time to he work and received a salary of £2000 per nnum. The work of the other ten members was purely honorary.

It is noteworthy that at this critical period of our history every Government in the Empire had at its command the disinterested and gratuitous services of men whose training and experience qualified them to act as advisors along scientific, echnical and industrial lines.

The Council made a careful survey of the researches carried on in Canada; it successfully directed attention to the value of scientific method and research, obtaining the support of public opinion throughout the whole dominion; by means of a system of fellowships, it encouraged university graduates of special ability to enter the field of research. This year the Council are thus helping over fifty of our most brilliant graduates to obtain training in research methods in the graduate schools of Canadian and English universities. The majority of these graduates are chemists or chemical engineers.

The possibility of utilising existing laboratories in the Government departments and universities received careful consideration, but it was found to be enormously expensive, without the prospect of compensating efficiency, and it was decided to assist the Government departments by advice and by recommendations for special research grants. Substantial financial assistance was given to researches both academic and industrial, on the whole with very satisfactory results.

It was recognised that a permanent and really efficient linking up of science with its application could only be effected by some central organisation which would bring about an intimate co-operation between those who could set the industrial problems and those whose training and knowledge would aid in their solution. A similar conclusion was independently reached by all the self-governing dominions. It was decided in 1917 upon the policy of establishing a Central Research Institute for both scientific and industrial research. As the result of a nation-wide propaganda, the scheme was submitted to the Government, supported by all the Boards of Trade, Canadian Clubs and scientific organisations from the Atlantic to the Pacific. The approval voiced by the Canadian press was equally unanimous. As this plan embodies the experience of many countries and seems to be designed along the lines of the natural evolution of the problem, I shall refer to some details of its organisation and possible advantages.

As finally developed and outlined in a Bill presented before last year's Parliament, a National Canadian Research Institute was practically unanimously approved of by the Cabinet and passed the House of Commons without division, but, owing to an unexpected attack of economy on the part of the Senate, the Bill was not confirmed but was postponed until next session. Notwithstanding the vote of the Senate, the Government gave a special grant of £20,000.

The building which will house the Institute will be erected near Ottawa, the capital city of Canada, on a site large enough to give ample room for expansion, at an estimated cost of over £100,000. This first unit, with a power plant attached, is so designed as to permit of a flexible organisation to enable its activities to be adapted to the varying requirements of a rapidly growing country like Canada. It will be the Bureau of Standards for Canada, and in this respect its work will be similar to that of the Bureau of Standards at Washington or that of the National Physical Laboratory. The unification of standards will be carried on in association with the Canadian branch of the International Committee on Engineering Standards, now doing excellent work in Canada. Closely associated with its function as a Bureau of Standards, it will carry on fundamental research in chemistry, physics, and related fields, investigations in abstract science similar to those carried on in the scientific laboratories of the universities and by the same type of workers.

The activities of the Institute will include investigations in biochemistry and bacteriology, both fundamental and as applied to such industries as the fisheries, the canning, cellulose, and packing industries, as well as investigations undertaken on recommendation of the Research Council from time to time, to promote the utilisation of the natural resources and valuable waste materials of the country.

The permanent staff will consist of a director and eight or ten highly qualified heads of departments, who will carry on independent research and form an advisory body for industrial specialists who may be engaged by the Research Council to promote the utilisation of the natural resources and neglected waste products of the country, or for those who may be employed by industries to improve their technical processes or manufactured products. The heads of departments will be chemists, physicists, engineers, and other scientists who have already shown high capacity for investigation. They will be allowed trained assistants and all facilities and freedom to carry on abstract research, each along his own line. The importance of the individual in research is recognised. The director, in consultation with the Research Council or a committee of the Council, will have the power of deciding on the technical processes and methods which require and would justify investigation, and the conditions under which they should be undertaken.

We are establishing in Canada a number of associations for research in the industries, similar to those in England. These trade guilds for research, as we call them, will pay their own specialists, will be housed in the Institute, which will provide the laboratory accommodation and facilities available in its building without rental, a charge being made only for power and materials at cost price. Several of these guilds for research are now being organised. Under conditions to be determined in each case, laboratories will be placed at the disposal of individual industrial firms for study of improvements in processes and products. Regulations regarding the length of time the laboratories may be occupied, the right to secrecy regarding the work, etc., etc., will be similar to those enforced in the Mellon Institute of Pittsburg, which has so effectively demonstrated to manufacturers in the United States the value of industrial research.

The Canadian Research Institute will parallel the Mellon Institute, but with this difference, that instead of the institute being maintained by private endowment it will be endowed by the Government of the country. It is also a form of State endowment similar to the industrial association for research, but more centralised, permanent, and better adapted to the requirements of the Dominion of Canada.

The Institute will not be under a department of the Government, and will, therefore, be free from political influence and party patronage. The director and the group of scientific and technical officers are appointed by the Research Council, who will prescribe their remuneration and tenure of office, subject to the approval of the Governor in Council. The director will be given a very free hand in organising and directing the Institute, and will receive a salary commensurate with his responsibilities. The responsibility for the success or failure of this whole venture is, therefore, placed upon the shoulders of the Research Council and the director in charge.

The organisation of the institute is based upon the following general principles: First, a recognition of the claims of abstract science for permanent State endowment apart from universities; secondly, the development equally in the institute of fundamental and industrial research, thus bringing into constant and profitable contact men interested and skilled in academic or abstract science with those engaged in its application to industry; thirdly, the encouragement of special workers employed by the industries to solve their specific problems in association with a permanent staff of highly-trained investigators. The last feature involves the endowment by the State of an organisation similar to the Mellon Institute. It is applicable particularly to conditions as they exist in Canada.

What are the advantages of such a plan for developing research? The idea of Government endowment of abstract scientific research is not a new one in England. Sir David Brewster, seventy years ago, in a presidential address to the British Association, advocated the establishment of a State Bureau of Research. The Science Commission of 1870 reported that one of the most efficient methods by which the Government could further research in this country was by the establishment of public laboratories for the pursuit of investigations in connexion with the varying and ever-multiplying departments of physics, chemistry, biology, and other branches of science. The view then taken, and not altogether unknown even at the present time, was that "the more science was left to itself the better for it." Mr. Gladstone, indeed, termed the intervention of the State as "interference" with science, calculated to discourage individual exertion, and so obstruct discovery and progress.

There is now a growing conviction throughout the Empire that the rapid advancement of abstract scientific knowledge, and the efficient applications of science, will not be the outcome of any State policy which leaves industrial research to be developed only in works and fundamental research only in the universities.

The Department of Scientific and Industrial Research has obtained from the State a liberal support of its plan to develop industrial research among the great groups of industries. The value of this experiment in State aid to research has been established, but will this plan provide for the future? Will the associations, after the Government bonuses are withdrawn, continue research on those problems which have no direct and immediate application to the industries but which are of superlative value to the nation?

Let us consider a little more closely the value of research in works and in universities to national progress. Scientific progress in industries is no less an expression of the spirit of research which has permeated the Empire than the scientific activities of the Government and the universities. The advances and improvements made in any commercial organisation add to the volume of knowledge and so, indirectly, to the wealth of the nation. Further, it is generally recognised on both sides of the Atlantic that the permanent success of an industry, especially a chemical industry, depends upon its ability to command a sufficient supply of knowledge especially directed towards the improvement of its methods and products.

Laboratories for routine testing in some form or other are equipped in all industries, exercising analytical control over output and processes, but the class of works research laboratories, which have done so much to introduce scientific methods, are those designed to lessen cost of production by improved processes and products. The success which followed their installation was highly appreciated because of the immediate returns through improved scientific control of operations. They have come to be recognised as permanent departments in the industries but subject to control on purely business lines. A few quotations from a recent article by F. A. Wardenburgh, Assistant Chief Engineer of the Du Pont Company of America, frankly puts research in its place among the activities of an industry. "Industrial research must justify itself in economies." "Research chemists cannot be employed if results do not show a profit." "The prime object of business is the making of money and, if research work is to maintain its proper place in business, it must be conducted so that it will more than pay its way." His plan of directing research lays continual stress on the commercial outcome. At every angle the question is asked: "Is the cost of this particular step justified by the results to be obtained from it?" The author admits there are many problems which should be studied but which are not receiving the attention they deserve because they do not offer sufficient probability of making a satisfactory monetary return to justify the company proceeding with the work. Further, that there is a great deal of research work of high importance to the industry, but it is not done because it is seldom that any one company can justify conducting a scientific research with the hope that the result can be profitably applied in some indefinite way. This is a clear business statement of a firm spending over £40,000 per annum in their various works laboratories. It cannot be expected that any firm will jeopardise its financial standing for the attainment of an academic ideal.

To obtain permanent and outstanding results it is now generally conceded that investigations must be directed chiefly to the theories underlying the operations of the industry; for example, it was the study of chemistry in high vacua which indirectly led to the production of the tungsten nitrogen lamp by the General Electric Company at Schenectady.

As Dr. Mees has pointed out, the value of a research laboratory, working on pure theory and on the fundamental sciences associated with the industry, is esentially cumulative. The results, at first nebulous and suggestive, later became definite and more and more available. The time factor in this type of research is a most serious obstacle in the way of its general introduction by commercial organisations. He states, as the result of his experience in the organisation of industrial research: "Most men acquainted with fundamental industrial research work consider that five years is the earliest date at which any considerable results can be expected from a newly-established research laboratory and that the development of really new material in considerable quantities, so that it will have an effect upon the industry as a whole, cannot be looked for in less than ten years' consecutive work."

This type of industrial research could not be seriously considered by individuals or firms from a business point of view. The industrialist as a rule works for the profits of to-day and not for the preservation of national wealth of the future.

The relation of the scientific departments of the universities to the industries of the country is a very complex and much discussed problem. It is as varied in its aspects as are the types of universities and the varieties of industries.

The value of the association of the university men engaged in abstract science with those interested in its application was so obvious during the war that, to develop and make permanent this relation in times of peace became the first problem before the national scientific organisations of the Empire. The attempts to obtain satisfactory co-operation between industries and universities since the war have proven a very qualified success; many schemes have been suggested and tried on the American continent as well as in the Empire, and, except in isolated cases, the universities have not proven of any great or permanent assistance to the manufacturer. Successful collaboration occurs when the problem is one quickly solved and which can be handed over to the factory in a completed form ready for commercial development. Such conditions are rare. Most industrial problems require continuity of study by the same investigators and along the same line of research extending over a long period. Such conditions in university laboratories are undesirable, rarely possible, and call for special apparatus, often of a kind unsuitable to a university building. It is further recognised in factory practice that the inventor of a process or substance should himself carry it through the semi-commercial stage and be able, by his experience, to meet the new conditions and difficulties of large-scale operations.

The larger new universities and institutes of technology recognise the importance of the technical section in their departments of science to the manufacturer. The staff of the technical colleges are usually men of research ability, who at all times are available in a consulting capacity and are able to attack problems of manufacturers which could with advantage be studied on a laboratory scale, thus keeping in constant and intimate touch with the industrial interests of the country.

Many of the universities of England, Canada, and the United States are situated in industrial centres, in very intimate relations with the industries of the place, and naturally identify themselves with the needs of these industries. They find on the spot the subjects for research and also frequently an opportunity of trying out their ideas in factory practice. Co-operation between the factory and the university in this way is highly desirable and decidedly to the advantage of the university. The universities should feel that, in a sense, they hold their costly laboratories and technical equipment in trust for the community. Every successful research in industrial economic problems is an advance in knowledge and should be regarded as a part of the realisation of the ideals of a university, viz., to add to the sum total of human knowledge. Yet this is not the essential function of the university.

It has been stated that utilitarian motives, arising from war experience and accentuated by the requirements of the present period of reconstruction, largely dominate the scientific life of the world to-day. Investigations along fundamental lines suffered during the war, especially in the universities, from the transference of attention to more urgent needs and the absence of a junior staff with capacity for research. Many university men with high ideals fear what is described as a growing tendency to exaggerate the utilitarian motive in university investigation; as Dr. Schuster expresses it: "Beating the utilitarian drum too loudly."

Research in the abstract sciences and the study of their applications are, however, not incompatible, and they can often be carried out in the same university with advantage to both. There is, however, especially on the American continent, a danger of the essential university function being less developed than the subsidiary function.

The universities should be chiefly the training ground for research men, where those set apart as research instructors should not be overburdened by administrative work, and where ample time, remuneration, facilities, and assistants are available for graduate schools of research and training in the more abstract fields of science.

The undergraduate, let us say in chemistry, is so fully occupied during his regular course in acquiring a knowledge of the essentials of his science that he cannot acquire originality in meeting new conditions or that independence of thought and intellectual dexterity which comes from the experience of being thrown on his own resources. University researches are specially designed for training these advanced students and junior members of the staff in those principles and habits of work which underlie all research, and these are not usually of a type the results of which can be directly carried into the industries.

The high privilege of the universities is the preservation of real knowledge, not only to see that such knowledge, once acquired, should not be lost, but also to extend its boundaries.

Research and the development of initiative in scientific investigation among its graduate students distinguish the university from the mere college. Capacity for research is the valuable product the countries of the Empire expect from the scientific departments of its universities. It is therefore essential that any State system designed to develop the industrial research of the country should especially consider the needs of the universities in order to ensure a supply of men capable of taking positions of higher command in industrial research.

Investigations in the so-called "pure" sciences have hitherto been largely confined to the universities. They claim, however, no proprietary rights to the domain of fundamental research; indeed, they can offer little inducement to a research career.

Scientific work in universities is often hampered by tradition, lack of financial support and proper equipment. A more stimulating and congenial environment for research would be the natural atmosphere of a large State-endowed research institute. The stimulus afforded each other by a group of scientific investigators in daily contact with each other should make for increased efficiency and establish an *esprit de corps* which would be inspiring to themselves and bring about a wholesome rivalry with the laboratories of the universities. The positions of higher command in an institute would be prizes worthy of the best efforts of those with capacity for research. It would thus offer an attractive career for the research worker and be a powerful stimulus to the graduate schools of science throughout the country. It would further aid British science by encouraging research along the border lines between the sciences, where progress in recent years has been so remarkable, and would be particularly well organised to attain the highest results, which come from co-operative work calling for the resources of different sciences to solve some great problem of national importance.

The associated development in the same organisation of abstract and applied science in closest contact with each other is the most recent stage in the evolution of the problem. We find a movement on all sides towards this end. A few of the more advanced type of industrial laboratories in England and America retain men gifted with vision and scientific imagination, who are advancing our knowledge, for instance, of such an academic problem as the ultimate constitution of matter. We find papers on the constitution of the atom and on molecular structure coming from the laboratories of the General Electric Company, and papers on higher mathematics and mathematical physics from the Eastman Kodak Company.

The laboratories of the Bureau of Standards at Washington and the National Physical Laboratory have for many years given numerous contributions to our knowledge of physics and physical chemistry of the highest value.

The Bureau of Standards at Washington is not only conducting, on an increasing scale, fundamental researches in almost every field of physics, engineering physics, and chemistry, but is now carrying on purely industrial research on a very large scale. They have taken over extensive buildings erected during the war and have converted them into industrial laboratories. In these buildings are installed plants and machinery on a commercial or semi-commercial scale to study improvements in methods of production and quality of the output. Only industrial problems of national importance are studied, chiefly to obtain value from waste raw materials and neglected by-products. These are studied in close association with their very exact work on standards of measurement, quality and performance.

The National Physical Laboratory has recently largely extended its field of usefulness to the country. In addition to the accurate maintenance and reproduction of all the primary standards of measurement for the Empire and exact researches in physics, it has now been called upon to enter the field of industrial work. It not only co-operates in researches with many of the industrial research associations, but it is responding to an ever-increasing demand for investigations on the part of manufacturers and private firms, for which the laboratory receives payment of the full cost. An extension of its present activities in the industrial applications of science would in the near future enable it to take over with advantage many of the greater and more basic problems which cannot be completely solved by the research associations during the period of five years allotted to them.

To ensure permanence and inspire confidence among men of science a national Research Institute should be administered by a single responsible body, incorporated if possible so as to encourage private benefaction and with an assured endowment.

The difficulties in equipping and manning any single institute capable of carrying on more than a fraction of the researches required for the manifold industries of such industrial nations as the United States or Great Britain are almost insuperable. These difficulties are largely eliminated if the work of the institute be confined to questions which are of basic importance to the nation, and not directed to problems individual or incidental in their character.

Is it beyond the practical to hope that much of the future scientific and industrial research in Great Britain may be carried out in a State institute where both abstract and fundamental industrial research could be blended?

The industries will conduct research in works because they have found it to be a good business investment, but only along those lines of investigation that obviously and immediately yield a return for their investment. They are not unreasonable in looking to the State to conduct investigations in abstract science and on problems remote from their own particular operations, but basic to the production of national wealth.

A plan of co-operation of the various branches of abstract science with industrial research in a Government Institute and a recognition of the purely commercial side of research may appear to many to be a compromise with scientific ideals. It must be remembered, however, that an institute of a national character, if it is to be permanent, must have popular support, and to obtain and hold such support a certain amount of its work must be understood and appreciated by the majority of the public. Public opinion should be strongly felt by Parliament to ensure favourable legislation and permanent financial support.

The extent and character of the compromise is a difficult question, but with the more general appreciation of science among the unintelligent, as well as the intelligent, public, the development of fundamental and abstract science will in time receive an increased measure of popular support.

"The more enlightened the people, the more general and permanent will be their support of science."

While centres of research in works and in universities must always have a place, and play an important part in fostering scientific advancement and in adding to the wealth of the nation, research in abstract science and its material applications seem now to call for a larger measure of direct State support throughout the Empire.

As scientific research, like education, is subject to social control, it should become one of the accepted responsibilities of the State in a progressive democratic country. The financial support of the abstract sciences as well as of their material application should be as certain, permanent, and free from party politics as is the grant to national education, for, as Sir Ronald Ross expresses it, "Science has become our premier national industry, and governs every other industry, as the work of the architect governs that of the bricklayer."

Dr. E. F. **Armstrong**, President-elect, proposing a vote of thanks to the President for his address, said that Dr. Ruttan had given them much food for serious thought, and he asked him, on behalf of the Society, to allow the address to be printed in the Transactions. They had all often heard of the neglect of science, but this was almost the first time they had heard something about the other side of the picture, of the steps that were being taken throughout the Empire and in the Mother Country to promote science. It would be some years before these steps materialised, but they must be all to the good. Dr. Ruttan had given a picture of what was being done throughout the Empire in this very necessary direction. He could not help feeling that there was going to be a good deal of bureaucratic control about research in the future. If bureaucratic control was the best way to do research all would be well, but he wondered! It was, however, with very great pleasure that he proposed a hearty vote of thanks to Dr. Ruttan for his address.

The vote of thanks was carried with acclamation.

On the motion of Mr. R. H. **Clayton**, seconded by Mr. **McArthur**, Messrs. Price, Waterhouse, and Co. were re-elected auditors.

The **President** expressed the high appreciation and sincere thanks of the Society to the Council of the Institute of Engineers and Shipbuilders for the hospitality afforded in allowing the use of their building in connexion with the meetings. The vote of thanks was carried with acclamation.

Subsequently the **President** announced that as the result of the ballot Prof. W. R. Hodgkinson, Dr. Alfred Holt, Mr. W. A. Williams, and Mr. J. H. Young had been elected Ordinary Members of Council.

Nottingham Section.

Meeting held at University College on May 17, 1922.

MR. J. H. DUNFORD IN THE CHAIR.

THE CHLORINATION OF WOOL.

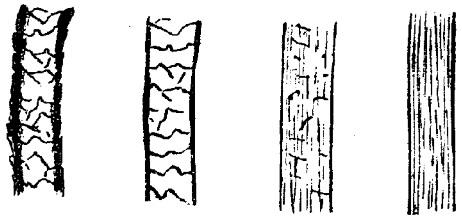
BY S. R. TROTMAN.

The chlorination of wool for the purpose of making it unshrinkable has been carried out entirely as an empirical process, with little attempt at scientific control or critical examination of the product. It is hardly surprising, therefore, that the results are irregular and complaints not infrequent. These complaints are commonly that (1) the material is not unshrinkable, (2) though unshrinkable it wears badly, and (3) much weight is lost during the process. These faults do not as a rule occur together, though (2) and (3) often do. In trying to avoid the first fault the manufacturer often commits the remaining two. He is, in fact, on the horns of a dilemma. If he does not carry the process far enough the goods are not really unshrinkable, while if he does make them unshrinkable they are liable to lose too much weight and wear badly.

The experiments described in this paper were instituted with the view of trying to solve these difficulties. Though not yet complete, sufficient progress has been made to indicate the lines upon which the problem must be solved, and, incidentally, to emphasize the importance of and urgent necessity for carefully planned and patient research. The subject will be dealt with under three heads: (1) The properties of chlorinated wool. (2) Analytical standards for a satisfactory product. (3) The manufacturing process and its control.

The properties of chlorinated wool.

There is a very important difference between the microscopic appearance of ordinary and chlorinated wool. In the former the free edges of the epithelial scales can always be seen distinctly. In chlorinated wool these are no longer visible; the scales appear to adhere to the cortex throughout. This is seen in Figs. 1 and 2. In a well chlorinated sample the outline of the epithelial scales is still perfectly plain. Their surface is smooth and opaque as in natural wool. Incipient damage is indicated by the outline of the scales becoming difficult to observe and their surface rough. Sometimes they become so thin that the underlying cortex can be seen (Fig. 3). Actual damage is denoted by the complete disappearance of the epithelial scales exposing the cortex of the fibre. This gives the fibre a rough surface marked with longitudinal streaks as seen in Fig. 4. This damage may be either local or general. In can be estimated quantitatively by counting the percentage of damaged fibres present. Samples of commercial unshrinkable fabrics contain from 5 to over 50% of damaged fibres. Complaints of bad wearing properties are invariably found to be associated with the presence of large numbers of such fibres.



1. 2. 3. 4.

FIG. 1.—Untreated wool fibre.
FIG. 2.—First stage of chlorination.
FIG. 3.—Second stage showing incipient damage.
FIG. 4.—Third stage showing complete destruction of epithelial scales.

The properties of chlorinated wool are generally stated to be: (1) Decreased tensile strength and elasticity. (2) Increased affinity for dyes. (3) More readily wetted down than ordinary wool. (4) Has a scroop, particularly when wet. (5) Has different electrical properties to ordinary wool. Some of these properties I have proved to be those of over-chlorinated or damaged wool. Other important properties must be added, viz., altered solubility in water, alkalis, acids, etc., and an increased affinity for water.

Tensile strength and elasticity.—I find from many experiments that there is no loss of either tensile strength or elasticity during careful chlorination. Even when a considerable percentage of damaged fibres is present the loss is not immediately apparent, though it may be developed gradually owing to causes to be explained later. It is not until over 50% of the fibres are badly damaged that any marked diminution of either tensile strength or elasticity can be observed. Thus, for example, the breaking strength of an undamaged yarn was 2·6 lb. The same yarn when hardly any epithelial scales were left had a breaking strength of 2·4 lb. Very similar results were obtained in tests for elasticity. In a typical set of experiments the following results were obtained, on six-inch lengths:—

Elasticity of original untreated yarn	1·50
„ „ undamaged chlorinated yarn ..	1·60
„ „ slightly damaged chlorinated yarn ..	1·52
„ „ damaged chlorinated yarn	1·375
„ „ badly damaged chlorinated yarn ..	1·296

Another set of experiments with the same yarn but using a different method of chlorination gave:—

Elasticity of undamaged chlorinated yarn ..	1·620
„ „ damaged „ „ ..	1·475

Apparently, therefore, chlorination, in the absence of damage, actually increases the elasticity slightly, and considerable destruction of the epithelium is required sensibly to reduce it. The results are not surprising. The strength of the wool fibre is a function of the cortex. The epithelial scales have little to do with it. Possibly when large numbers of them are destroyed their cumulative effect becomes apparent, but it is more probable that it is damage to the cortical cells which is being measured. It is obvious that tensile strength cannot be used as a test to check the process, or even as an indication of serious damage. The weakness which is sometimes developed in wear is, in part, due to the gradual wearing away by friction and other causes of the exposed cortex of the damaged fibres.

Increased affinity for dyes.—This is generally described as though it were a valuable property of chlorinated wool. My experiments show that this is quite wrong. If the process of chlorination is carried out properly the increased affinity for dyes is extremely slight, in fact negligible. It only becomes marked as the epithelial scales begin to be attacked and destroyed. In fact, one may say that if an unshrinkable fabric has a marked affinity for dyes it is a bad sign and indicates extensive damage and bad wearing properties. In one experiment four samples of yarn containing 0, 5, 20, and 50% of damaged fibres respectively were dyed in the same bath. It was found that the depth of colour was roughly proportional to the percentage of damage and that the affinity for dyes of the sample free from damaged fibres was but little greater than that of natural wool. In a comparative test on a good commercial fabric containing 4% of damaged fibres and a sample of the same make but containing a much larger percentage, the same difference was again noticeable. Good and bad samples can be sorted by simply dyeing them under exactly the same conditions. Further experiments are in progress upon these points.

Wetting power.—The wetting power of chlorinated wool is actually not much greater than that of ordinary scoured wool. It is, like the increased affinity for dyes, only marked when the fibre is damaged. In fact, the wetting power varies directly with the percentage of damaged fibres. In one experiment, fibres of (*a*) untreated wool, (*b*) undamaged chlorinated wool, (*c*) chlorinated wool containing respectively 5, 20, and 50% of damaged fibres, were suspended with their lower ends dipping in a weak solution of an acid dye. The height to which the solution rose in the fibres was in the order of the percentage of damaged fibres, and there was very little difference between the action of the natural and undamaged chlorinated wool. If a piece of badly damaged fabric is worked in water it wets immediately and becomes soft and almost slimy. This, however, is not noticed in an undamaged sample. This rapid softening doubtless has some bearing upon the breaking down of damaged goods in wearing and washing. When dried again the fibre appears to regain its strength. This peculiarity on wetting is very similar in the case of certain varieties of artificial silk. It is still more noticeable if dilute sodium carbonate or sodium hydroxide is used. Loss of tensile strength is very marked, while with undamaged fibres no such loss is observed. This is illustrated by the following example:—

	Good sample.		Bad sample.
Strength of dry yarn	2·59	..	2·52
Strength after soaking in *N*/10 sodium carbonate	2·58	..	1·80

Closely connected with wetting power is the property of attracting and retaining atmospheric moisture. The standard "regain" depends upon this factor. The regain for wool is 18¼%. For properly chlorinated wool it is the same. For damaged chlorinated wool it is higher and increases with the extent of the damage. A regain of 19% is quite common, and in one case it has reached 21·5%. Untreated wool regained 16·07% under the same conditions. A large number of samples of wool and chlorinated wool have been exposed to the same atmospheric conditions till equilibrium was established and the moisture present then estimated. It was found that in every case (1) the moisture content of untreated and chlorinated wool (when undamaged) was practically the same, and (2) as the fibre became damaged the water content increased gradually.

An interesting experiment was carried out in which a commercial garment—one of the best I have examined, containing only 4% of damaged fibre—was cut in two and one portion treated with chlorine water (3 g. per litre) and washed as usual. The dry weight of each portion was then found in an ordinary conditioning oven. The two dry pieces were exposed, side by side, under exactly similar conditions, to the action of the air and re-weighed at intervals of 24 hours and the regain calculated. The results are given in the following table:—

		Good sample. Regain.		Bad sample. Regain.
After 1 day	.. .. ..	9·76	..	12·40
,, 2 days	.. .. ..	16·84	..	19·59
,, 3 days	.. .. ..	16·16	..	18·04
,, 4 days	.. .. ..	16·49	..	19·07
,, 5 days	.. .. ..	16·49	..	19·07
,, 6 days	.. .. ..	16·80	..	19·07

The atmosphere became dryer on the third day. This is reflected in the regains. Under all conditions the regain of the bad sample is nearly 3% higher than that of the other. This point has, of course, some bearing upon the weight of commercial unshrinkable garments. Another set of experiments was made with commercial garments from different sources. They were again dried and exposed to air, under identical conditions, and weighed every 24 hours. Samples 1 and 4 were badly damaged during chlorination. Nos. 2 and 3 were of fair quality. The results of the tests are given in the following table:—

	No. 1		No. 4		No. 2		No. 3
Regain 1st day	11·11	..	13·04	..	9·54	..	9·00
,, 2nd day	10·92	..	13·52	..	9·81	..	9·89
,, 3rd day	13·81	..	14·10	..	10·88	..	11·01
,, 4th day	13·56	..	14·49	..	11·45	..	11·31
,, 5th day	14·31	..	15·00	..	11·98	..	11·59
,, 6th day	14·88	..	15·46	..	12·26	..	11·98
,, 7th day	15·82	..	15·94	..	12·81	..	13·28

The difference between the good and damaged samples is again very marked. It seems to be quite clear that the capacity for absorbing moisture from the atmosphere is a function of the damage.

These four samples were next wetted out with water, wrung, and hung out to dry in a warm room, the rate of drying being determined by weighing the garments at intervals. The following results were obtained:—

	Percentage of water in sample.						
	1.		2.		3.		4.
After 24 hours	37·14	..	14·44	..	14·10	..	16·91
,, 36 hours	23·27	..	11·72	..	12·08	..	15·07
,, 48 hours	16·90	..	11·72	..	12·08	..	15·07

It will be noted that the bad samples retain more water than the good ones, and that the amount retained is in accordance with the regains in the former experiments.

Solubility of chlorinated wool.—Natural wool and chlorinated wool, both undamaged and damaged, have been treated side by side with (*a*) water, (*b*) *N*/10 sodium hydroxide, (*c*) *N*/10 sodium carbonate, (*d*) dilute acetic acid and salt solution (*i.e.*, artificial perspiration). The dissolved wool substance was estimated colorimetrically by the biuret reaction, and also directly by weighing the sample before and after treatment. The results of these experiments prove that (1) well prepared chlorinated wool, containing no damaged fibres, is not more soluble than ordinary wool; (2) damaged chlorinated wool is, on the other hand, distinctly soluble, and the solubility increases in direct proportion to the percentage of damaged fibres present. This is, no doubt, explained by the fact that the cortical scales are less resistant than the epithelial scales, the latter when present protecting the former from the action of the solvent. The following figures illustrate the percentages soluble in *N*/10 alkali of good and bad commercial samples:—No. 1, 5% damaged, 3·51%; No. 2, 5% damaged, 4·08%; No. 3, 25% damaged, 9·00%; No. 4, 50% damaged, 14·50%. Good and bad samples behave quite differently when placed in *N*/10 alkali. The former tend to swell and the fibre retains its firmness. Damaged samples, on the contrary, wet down almost instantaneously by assuming a "fallen" appearance and aquiring a soft, slimy feel, and breaking unless carefully handled. The colour of both fibre and solution becomes yellowish.

This solubility and "falling" of damaged goods is, in my opinion, one of the chief causes of bad wearing. Every time the goods are washed they are soaked in dilute solutions of alkali. Gradually more and more of the wool substance is dissolved until, ultimately, the fibre breaks down. The solubility in artificial perspiration is of considerable importance as a factor affecting wearing properties. It is much less marked than the solubility in alkaline solutions, but still quite distinct. It is always greater in the case of damaged goods. Untreated and well-treated wool only lose traces of nitrogen even when soaked in dilute acetic acid and salt solution for long periods. Damaged chlorinated wool, on the contrary, gives a biuret reaction in a comparatively short time. This is illustrated by the figures obtained from two garments from yarn from the same source and of the same grade.

	Average sample.		Damaged sample.
Percentage soluble in *N*/10 alkali in 3 hours	6·29	..	16·52
Percentage soluble in dilute acetic acid and salt in 12 hours ..	0·90	..	4·05

The acetic acid extract gave a very strong biuret reaction in the case of the damaged sample, but practically none in the other.

Action of ozonised air on chlorinated wool. It seemed of interest to test the comparative action of ozonised air, under similar conditions, on wool and chlorinated wool. The tensile strength and elasticity of a natural wool and the same wool after different degrees of chlorination were carefully tested. The samples were then exposed to the action of ozonised air for 7 days, after which the elasticity and tensile strength were re-tested. The results of these tests indicate that (1) the elasticity and tensile strength of natural wool are unaffected by exposure to ozonised air; (2) the elasticity of chlorinated wool is also unaffected; (3) the tensile strength of chlorinated wool is distinctly less after exposure to ozonised air. The following table illustrates these points:—

	Tensile strength before exposure.		Tensile strength after exposure.
Natural wool	3·29	..	3·60
" "	3·40	..	3·50
" "	3·45	..	3·42
Chlorinated wool	3·70	..	3·35
" "	3·47	..	3·27
" "	3·93	..	3·50
" "	3·37	..	3·23
" "	3·53	..	3·45

The loss of tensile strength would probably increase with the time of exposure to the ozonised air. Time has not permitted me to complete the tests nor to find out whether the result varies with the degree of chlorination. There appears to be evidence that chlorinated wool does not withstand exposure to air so well as ordinary wool. This fact may have something to do with inferior wearing properties.

I have noticed also that when epithelial scales are damaged during chlorination the damage is increased during the process of boarding. Further experiments are, however, being carried out upon this point.

Treatment with formaldehyde in 2% solution before chlorination causes a considerable decrease in the solubility of even damaged goods, as well as, as will be noted later, a diminution in the loss of weight.

The analysis of chlorinated wool.

Natural, scoured wool contains only traces of chlorine. Chlorinated wool, if properly "dechlorinated" and washed, is also practically free from chlorine. If either of these processes is faulty the quantity of soluble or combined chlorine increases. Soluble chlorine indicates incomplete washing, while combined chlorine denotes over-chlorination or faulty dechlorinating. Soluble chlorine is estimated by a method similar to that used for rag flocks. Combined chlorine is determined in the residue, after removing soluble chlorine, by careful incineration with sodium carbonate and precipitating the chlorides with silver nitrate.

The following are examples of good and bad samples:—

	Good.		Bad.
Soluble chlorine	trace	..	0·033%
Combined chlorine	0·007%	..	0·079%

Solubility in *N*/10 sodium hydroxide, sodium carbonate, etc., artificial perspiration, and water are also tested, the dissolved wool substance being estimated by the biuret reaction.

Chemical analysis should always be accompanied by a careful microscopical examination. I count and examine 100 fibres taken from different portions of the sample. Good samples should fulfil the following conditions:—(1) Only traces of chlorides should be present. (2) Should not contain more than 5% of damaged fibres. (3) Should not have a marked affinity for dyes. (4) After soaking in cold decinormal alkalis the solvent should only give faint reaction for wool substance with the biuret test.

Alternatively, the loss of weight may be determined directly. The following illustrates the method. About 2 g. of the material is dried and weighed in a weighing bottle. It is then soaked for 3 hours in *N*/10 sodium hydroxide solution. At the end of this time it is washed with hot distilled water several times, then with very dilute acetic acid, followed by more water. It is then dried and weighed again in the weighing bottle.

The manufacturing process.

Damage of chlorinated wool may be produced in the following ways:—(1) During chlorination; (2) during finishing; (3) after finishing owing to incomplete removal of chlorine and the breaking down of damaged fibres.

In studying the "unshrinkable" process one is struck, at once, by the incompleteness of published information and often, as will be shown later, by its inaccuracy. The following examples, taken from standard text books, are typical of the unscientific nature of the process itself and of the incompleteness of published information. Yet they are quite typical of the methods of actual manufacture.

(1) "Treat the wool in a bath of 1¼ lb. hydrochloric acid in 10 gallons of water. Squeeze and wash in a bath of bleaching powder, made as follows. For 100 lb. of wool use 15 to 20 lb. of bleaching powder to 330 gallons for hard fibre wool and 20 to 25 lb. to 475 gallons for soft fibre wool. The bleaching powder solution should be 0·6° Tw. to 1° Tw. After half-an-hour add 3 oz. of hydrochloric acid to each 10 gallons and work 10 minutes longer. Wash and treat with bisulphite."

(2) "Prepare a solution of 160 lb. of bleaching powder at 14° Tw. Add 100 lb. of soda ash. Let the precipitate settle and decant. For each pound of fabric use from ¼ to 1 pint of acid."

(3) "Steep for 20 minutes in hydrochloric acid of 1·5° Tw., then for 10 minutes in bleaching powder solution of 3° Tw. Then pass into hydrochloric acid of 1·5° Tw. for 20 minutes."

The most striking point about these published processes, next to their general vagueness, is that in no case is the strength of the bleaching powder solution stated in terms of available chlorine. With regard to this, it should be noted that for such low strengths as 0·5°—1·5° Tw. the error of experiment is greater than the total amount of chlorine present. In process No. 1 the effect of adding hydrochloric acid at the end of half an hour would probably be to cause considerable damage to the goods.

We have but little definite knowledge of the chemistry of the process. Experiments are in progress, the results of which will be published later. When chlorine water acts upon wool the following changes may be observed. (1) Protein nitrogen is gradually dissolved. (2) Sulphur is dissolved as sulphuric acid. (3) The proportions of sulphur and nitrogen in the residual wool are changed. All these changes are directly proportional to the concentration of the chlorine water and the time of action. The dissolved nitrogen gives the biuret reaction. This, together with the fact that sulphuric acid is present, appears to indicate that the keratin molecule is broken down into simpler compounds, probably soluble chloramines, with the liberation of some loosely-combined sulphur atoms. Over-treatment of wool is accompanied by a rapid loss of sulphur. Thus a natural untreated yarn contained 3·74% of sulphur. Treatment with chlorine water (5 g. per litre) reduced this to 3·29%. At the same time the nitrogen content fell from 16·01% to 15·57%. Very similar results were given by fair and damaged commercial garments.

	Fair sample.	Bad sample.
Nitrogen %	15·21	14·90
Sulphur %	2·72	2·51

Bleaching powder solution is a complex mixture containing lime, calcium hypochlorite, calcium chloride, and hypochlorous acid. It owes its action to hypochlorous acid or chlorine separately or conjointly according to the conditions of the reaction. These conditions have been investigated by Taylor, Higgins, and others, and may be usefully recapitulated, as they are of much importance in the treatment of wool.

(1) When bleaching powder is treated with just enough of a strong acid (hydrochloric or sulphuric acid) to neutralise the free lime, hypochlorous acid is liberated by hydrolysis till the accumulation of lime inhibits the action. If more hydrochloric or sulphuric acid is added, the calcium hypochlorite is decomposed with the formation of more hypochlorous acid. This is, in turn, decomposed by the mineral acid giving rise to chlorine. With limited amounts of acid a mixture of hypochlorous acid and free chlorine is produced. If the quantity of acid is increased the proportion of chlorine rises till ultimately only chlorine is produced.

It will be seen that in the commercial processes no account is taken of these facts. It is entirely a matter of chance whether hypochlorous acid or chlorine is used, or both. It depends largely upon the quantity of acid carried into the bleaching powder bath by the soured wool. In any case, it is probable that the first effect is the liberation of chlorine, owing to the excess of acid when the chemick first enters the wool.

(2) Weaker acids, such as acetic and phosphoric acids, act similarly, except that the proportion of hypochlorous acid does not usually fall below 50%.

(3) Boric acid, according to Higgins, even when present in excess, gives only hypochlorous acid and no chlorine. Taylor, it should be noted, does not confirm this statement, though it is agreed that the proportion of hypochlorous acid is high. From experiments made in connexion with this paper, I am of opinion that for weak solutions of bleaching powder, such as would be used in the chlorination of wool, Higgins' view is correct, but that when strong solutions and an excess of boric acid are used free chlorine is also produced. For concentrations up to 3 grams of available chlorine per litre a mixture of bleaching powder and boric acid is practically hypochlorous acid.

(4) Carbonic acid, in the cold, gives a mixture of hypochlorous acid and chlorine, like a mineral acid. As the temperature rises the proportion of hypochlorous acid increases, till at 100° C. only hypochlorous acid is formed.

(5) Chlorine water contains small quantities of hypochlorous acid, but if a little hydrochloric acid is added it may be regarded as containing only chlorine.

By taking advantage of these reactions it is possible to investigate separately the action on wool of chlorine and hypochlorous acid. I may say that, from the study of many samples of damaged goods and of the actual processes used, I had formed the opinion that in all cases the damage was caused by chlorine and not by hypochlorous acid. My experiments were undertaken, in the first instance, to confirm or disprove this view.

In all cases the goods were carefully dechlorinated and washed. After drying, they were examined with the microscope and the percentage of damaged fibres estimated. In most cases the loss in weight was also determined. This is also a measure of the efficiency of the process.

The action of chlorine is shown in the following table:—

Chlorine water.

No. of exp.	Grms. Cl per litre.	% loss in weight.	% of damaged fibres.
1.	0·5	5·2	27
2.	1·0	8·0	46
3.	3·0	15·6	100

It may be mentioned that bleaching powder solution of 1° Tw. contains approximately 2·75 g. of chlorine per litre. The destructive effect of chlorine is very marked. A solution of hypochlorous acid containing excess of hydrochloric acid gave similar results.

The next table shows the effect of bleaching powder solution to which was added the quantity of hydrochloric acid required to liberate all the available chlorine.

Bleaching powder.

No. of exp.	Grms. Cl per litre.	% loss in weight.	% of damaged fibres.
1.	2·0	13·8	Scales nearly all gone.
2.	3·0	20·5	
3.	4·0	23·5	
4.	5·0	25·5	

Exp. 2 was repeated using only one-quarter of the acid, *i.e.*, decreasing the ratio of chlorine to hypochlorous acid. The loss in weight was reduced to 10·6%. A blank experiment with the yarn used, omitting only the chemick, gave 2·2%.

The next series of experiments was designed to test the effect of adding gradually increasing quantities of acid to a definite amount of bleaching powder solution. The latter had a strength of 4 g. per litre. The amount of acid necessary to liberate all its available chlorine was calculated. The same quantities of wool and bleach liquor were taken for each experiment. In the first experiment one-fourth of the total acid was used. In succeeding experiments the quantity was gradually increased till excess was reached. The wool was soured in the measured quantity of acid and the whole of the fraction added to the chemick.

The results are given in the following table:—

No. of exp.	Fraction of acid used.	% loss in weight.	% of damaged fibres.
1.	0·25	8·6	Very little damage.
2.	0·40	15·6	" " "
3.	0·50	13·0	" " "
4.	0·75	13·8	Damaged.
5.	1·00	15·5	Much damaged.
6.	1·20	17·0	" "

Here again the effect of increasing the quantity of chlorine is very marked, as is also the large percentage loss in weight caused by excess. Yet this frequently happens in commercial processes where no control of the acid used is exercised. Commercial liquors nearly always contain free acid after use.

The next series of experiments was carried out by an ordinary commercial process, except that the strength of the bleach liquor was carefully controlled by titration. Varying concentrations in grams per litre of chlorine were used. The process used was:—(1) Steep in hydrochloric acid at 1° Tw. and squeeze. (2) Steep in bleaching powder solution and wash. (3) Steep in bisulphite and wash. (4) Steep in soda ash, wash, and dry.

In every case the amount of acid carried over by the wool was in excess of that required, as it frequently is in practice, thus giving a large proportion of chlorine to hypochlorous acid.

The results of these experiments were:—

No. of exp.		Grms. Cl. per litre.		% loss in weight.		% of damaged fibres.
1.	..	0·3	..	2·26	..	Less than 5
2.	..	0·4	..	2·70	..	,, ,,
3.	..	0·5	..	3·80	..	,, ,,
4.	..	0·6	..	3·85	..	Over 10
5.	..	0·7	..	4·65	..	30
6.	..	1·0	..	6·90	..	Over 30
7.	..	2·0	..	—	..	50—60

These results indicate the danger of using unknown strengths of bleaching powder solution, and that the chlorine content must be estimated carefully and kept below 0·6 g. per litre.

A set of experiments with another make of yarn, on the same lines, gave very similar results, viz.:—

No. of exp.		Grms. Cl per litre.		% loss in weight.		% damaged fibres.
1.	..	0·3	..	1·90	..	Less than 5
2.	..	0·4	..	3·21	..	5
3.	..	0·5	..	3·30	..	5
4.	..	0·6	..	4·00	..	10
5.	..	0·7	..	5·04	..	Over 10

It seemed probable that previous treatment with formaldehyde would cause a decrease in the loss of weight. This proved to be the case, though little difference in the number of damaged fibres was noted. With 0·7 g. of chlorine per litre the loss in weight was reduced from 5·04% to 2·60%. I noticed here a point of some importance, namely, that different types of wool have different powers of resistance to chlorine. Thus in a set of experiments with a fresh variety no damage was observed till 1 g. of chlorine per litre was exceeded. This was particularly noticeable in the case of a coarse, unbleached woollen yarn where no damage was recorded below 3 g. of chlorine per litre. I noted, further, that when a yellow colour appears on the wool, it is indicative of serious damage. I have often been told by manufacturers that the object of the bisulphite or sulphurous acid bath is partly to remove the yellow colour produced by the chlorine. This should be quite unnecessary. The only object of its use should be to remove chlorine left in the wool.

Boarding goods containing traces of unremoved chlorine caused, as would be expected, a great increase in the number of damaged fibres.

Experiments were made next with sodium hypochlorite instead of bleaching powder solution. Rather stronger solutions can be used with safety and the loss in weight appears to be somewhat less.

Sodium hypochlorite.

No. of exp.		Grms. Cl per litre.		% loss in weight.		% of damaged fibres.
1.	..	1	..	6·7	..	10
2.	..	2	..	10·4	..	More than 10
3.	..	3	..	10·5	..	,, ,,

Further experiments are necessary for generalisation.

Hypochlorous acid was prepared by passing chlorine into water containing calcium carbonate in suspension. If, as the foregoing experiments seem to indicate, damage is caused by chlorine, less should be found when hypochlorous acid free from chlorine is used. That this is so is, I think, undoubtedly the case. It is shown in the following tables for some different kinds of yarns.

Hypochlorous acid.

No. of exp.		Grms. Cl per litre.		% of damaged fibres.
1.	..	1·0	..	No damage.
2.	..	3·0	..	Less than 5.
3.	..	5·0	..	30
4.	..	1·0	..	No damage.
5.	..	3·0	..	Scale intact but faint.

As already noted, hypochlorous acid may more readily be obtained by treating bleaching powder solution with boric acid. I give some results together with parallel experiments made simultaneously with other methods.

No. of		Grms Cl per litre.		Acid used.		% of damaged fibres.
1.	..	0·5	..	hydrochloric	..	no damage.
1a.	..	0·5	..	boric	..	no damage.
2.	..	1·0	..	hydrochloric	..	8
2a.	..	1·0	..	boric	..	no damage.
3.	..	3·0	..	hydrochloric	..	80
3a.	..	3·0	..	boric	..	scales intact but faint.
4.	..	5·0	..	hydrochloric	..	no scales left.
4a.	..	5·0	..	boric	..	80
Finer counts.						
1.	..	0·5	..	hydrochloric	..	no damage.
1a.	..	0·5	..	boric	..	no damage.
2.	..	1·0	..	hydrochloric	..	10
2a.	..	1·0	..	boric	..	5
3.	..	3·0	..	hydrochloric	..	20
3a.	..	3·0	..	boric	..	15
4.	..	5·0	..	hydrochloric	..	50
4a.	..	5·0	..	boric	..	40

It is clear that when boric acid is used as the sour a greater concentration of chlorine may be used without causing damage than when hydrochloric acid is employed. *Vice versâ*, less damage is produced at lower concentrations. Not only is the danger of damaging the fibre less, but the loss in weight is also much smaller. This is seen from the following experiments:—

No. of exp.		Grms. Cl per litre.		% loss in weight.
1.	.	2	..	2·6
2.	..	3	..	4·8
3.	..	4	..	5·7
4.	..	5	..	7·5

As before, damage only became visible at a concentration of 3 g. per litre. We may take it as a general rule that hypochlorous acid up to the strength corresponding to 2 g. of chlorine per litre will cause neither damage nor undue loss in weight. The latter is still further decreased by previous treatment of the wool with formaldehyde.

Summary.

(1) Wool is more easily damaged by chlorine than by hypochlorous acid. Hence bleaching powder solution should be used under conditions that minimise the quantity of chlorine present.

(2) Different grades of wool require rather different treatment, some being damaged more easily than others.

(3) For any particular type of wool the maximum strength of bleaching powder solution permissible should be determined by experiments and never exceeded.

(4) For this purpose the Twaddell hydrometer is worse than useless. It should be replaced by a chemical process.

(5) Using bleaching powder solution and a mineral acid, it is rarely safe to exceed a strength of 0·6 g. of available chlorine per litre. The practice of soaking in acid is dangerous, unless the quantity of acid is controlled, since excess of acid carried over into the bleach liquor causes evolution of chlorine.

(6) Excess of either hypochlorous acid or chlorine causes destruction of both epithelial scales and cortical cells, large loss of weight, high solubility, and bad wearing properties.

(7) If boric acid, or other weak acid, is used as the sour, excess is not so dangerous and less damage results since hypochlorous acid is chiefly produced.

(8) Loss in weight and also the solubility of the product can be reduced by means of formaldehyde.

(9) All goods should be required to conform to a standard of "good commercial quality."

(10) Many of the properties usually ascribed to chlorinated wool are those of over-chlorinated wool.

Many of the experiments in connexion with this paper were carried out by my assistant, Mr. H. W. Goodwin, F.I.C.

Communications.

NOTES ON THE COMPOSITION OF THE RESIDUE ON DISTILLATION OF CRUDE GLYCERIN.

BY ARCHIBALD RAYNER, B.SC., F.I.C.

In a paper on the above subject (J., 1922, 97 T) E. Lewis describes an investigation which partly duplicates work carried out by the writer several years ago, with the same objective in view, and although certain conclusions arrived at confirm this earlier work, there are several points raised which seem to need confirmation or amplification.

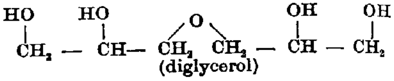
In the first place, it is stated that 25% of the residues consists of glycerol and polyglycerols, and 70% of inorganic matter, from which it follows that the organic soaps etc. can only amount to 5%. This statement seems to need some explanation since, as only negligible quantities of organic impurities pass away with the distillate, it follows that the proportion of inorganic to organic impurities in the residues should be substantially the same as that in the crude glycerin before distillation. It is well known, however, that the organic impurity in soap or saponification crudes is invariably much more than one-fourteenth of the inorganic matter. Examination of the more detailed analyses given later shows similar results which are difficult to reconcile.

In the writer's experience examination of various still residues from soap crudes from various sources has shown that the organic salts usually amount to about 40% of the inorganic salts, which is about what would be expected, since it is about the average proportion in which they occur in soap crude glycerin.

Further, the statement is made that polymerised glycerin is present in commercial crude to the extent of about 2%, and is highest in glycerin produced in autoclaves. Unless it is suggested that polyglycerols exist combined with fatty acids in the original fats, their presence in crude glycerins, and other than such glycerin as has had still residues worked back into it, cannot be explained. Many years' experience of glycerin produced largely by the autoclave process quite fails to support the suggestion that such glycerin contains polyglycerol at all, nor from theoretical considerations, having in view the dilution of the glycerin in the autoclave, can such a production of polyglycerols be considered in the least likely.

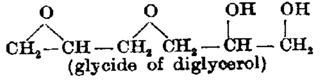
As regards the calculations by which the relative amounts of glycerol and diglycerol in the residues are estimated, as far as the writer is aware, there is no justification for assuming that the acetylisable impurities in the residues are wholly due to polyglycerols, since this would necessitate the assumption that the acetyl value of the residues of crude glycerin is similarly due wholly to polyglycerols in the crude, a suggestion which appears hardly possible of acceptance, since it is well known that various hydroxy-acids etc. are present, which give saponifiable products when boiled with acetic anhydride. Further, the writer has found that the only distillable polymerisation products which are produced from glycerin are also volatile under the conditions of the I.S.M. total residue test if the latter is carried to a correct finish. In any case, however, it does not appear that the chemistry of the polymerisation products of glycerol is so simple as to enable the composition of such products to be estimated in terms of glycerol and diglycerol from their hydroxyl value.

As a result of a long study and examination of these products, the writer was forced to the conclusion that the conversion of glycerol to volatile polymerisation products gives rise to substances of at least two different types, the one class appearing to consist of products obtained by intermolecular condensation of the ordinary diglycerol type, with the molecules linked together thus:—



(diglycerol)

and the other of the glycide type, in which not only is there intermolecular condensation, but also the original glycerol molecule itself has undergone internal condensation giving products of the type:



(glycide of diglycerol)

It is only by assuming the presence of these two types that the discrepant results of different observers of the properties of the volatile polymerisation products can be explained. As a typical instance of these variations in results the following figures may be quoted. In a certain laboratory by heating glycerol for 12 hours at 270°—280° C. and separating that proportion of the distillate boiling at 210°—250° C. at 3 mm., a product was obtained having a hydroxyl value 34·0% and a viscosity 5 times that of glycerol. On the other hand, in this laboratory by boiling glycerin alone for a somewhat longer time and distilling at 10 mm., a large fraction was obtained, boiling at 260°—265° C. at 10 mm., and having a hydroxyl value of 38·0% and a viscosity 13 times that of glycerol. The differences are quite outside any possible analytical errors, and as the product having the higher hydroxyl value has actually a much greater viscosity, it follows that there must be present, particularly in the case of the first distillate, another distinct class of compound, probably of the glycide type, possessing low viscosity and low hydroxyl values. Of this class of compound the glycides of glycerol, diglycerol, and triglycerol are known, the last-named being said to be produced when polyglycerols are distilled.

From their molecular structure it follows that the hydroxyl values are low, whilst they are known to be thin liquids having boiling points considerably lower than the parent glycerols. The presence of such substances in distilled glycerin recovered from residues, on a large scale by a special process worked out by the writer, has been very evident. A sample from a particular batch of distillate was redistilled in the laboratory at 10 mm., and that portion separated which boiled at 174°—176° C. at 10 mm. (b.p. of pure glycerol in same apparatus, 175°—176° C. at 10 mm.). As this distillate appeared to contain traces of bases, it was further purified by treatment with phosphotungstic acid, followed by another redistillation, collecting only the portion boiling within 1°. The resulting product was apparently pure glycerol, containing no moisture, and giving no total residue by the I.S.M. method. Its glycerol value, however, when determined by the I.S.M. method, standardising the solutions used against standard glycerin, gave 96·3% glycerol, and it had sp. gr. 1·2641 at 15·5° C. only, as against pure glycerin 1·26531. If in this case it were assumed that the product was a mixture of glycerol and diglycerol the proportions would be approximately 86% glycerol and 14% diglycerol, a composition which, in view of the boiling point, is impossible, and the low glycerol value can only be explained by the presence of smaller amounts of another compound of similar b.p. to glycerol, but having a much lower hydroxyl value, or possibly no hydroxyl value at all.

Such figures are characteristic of these distillates and other products derived from polyglycerols, and it is on this account that, in the writer's opinion, no information as to the relative amounts of diglycerol and glycerol can be obtained from the hydroxyl value of the mixed products.

If such information is required it is best obtained by submitting the volatile products to fractional distillation, whilst the total amount of volatile products can be estimated by the difference after determining the moisture content and total residue by the I.S.M. methods.

It should be mentioned that attempted polymerisation by 0·05% of iodine, as described, has quite failed to give anything like an 85% yield, very little polymerisation at all being obtained under the conditions described, and this method seems to suffer from the same defects as other methods having as their object the preparation of pure polyglycerols.

I am indebted to Mr. Charles Radburn, Chairman of Price's Patent Candle Co., Ltd., for kind permission to publish these notes.

Belmont Works, Battersea.

THE COEFFICIENT OF VULCANISATION OF RUBBER.

BY G. MARTIN, B.SC., A.I.C., AND F. L. ELLIOTT, A.I.C.

It has been shown by previous investigators that when rubber-sulphur mixings are vulcanised approximately to the same physical properties, there is a small variation in the percentage of sulphur "fixed" by the rubber. This variation does not generally amount to more than 1% of sulphur (Eaton, Agric. Bull. Fed. Malay States No. 27, 1918, p. 134: de Vries, India Rubber J., 1917, 101—103). Except for results showing that "quick-curing" rubbers generally have a high coefficient of vulcanisation at the standard cure, while "slow-curing" rubbers have a low coefficient, no experimental evidence has been published indicating the cause of these differences (Eaton, *loc. cit.*; de Vries, J. Ind. Eng. Chem., 1921, 13, 1133).

De Vries ("Estate Rubber," 1920, p. 489) sums up the position by stating: "Though the coefficient for a fixed cure shows small, though distinct variations, it has not yet been possible to connect these deviations with any property of the rubber in such a manner that, for instance, a coefficient higher than the average would be an indication of certain mechanical properties or of a certain special composition of the rubber."

The object of the present investigations was to determine to what extent, if any, the percentage of sulphur combined with the rubber at the standard cure adopted, is dependent upon the nature and the amount of the usual accessory substances present in raw rubber.

Twenty-four samples of rubber were selected for examination. They consisted of six samples of crêpe rubber and six samples of sheet rubber prepared on an estate in Ceylon from the latex of a group of trees approximately 10 years old, and also of six samples of sheet rubber and six samples of crêpe rubber prepared on the same estate from another group of trees approximately 20 years old. From each lot of latex were prepared one sample of sheet rubber and one sample of crêpe rubber.

Vulcanisation coefficient and resin content of Ceylon Rubbers.

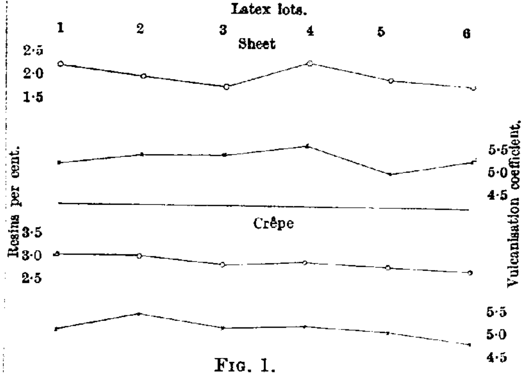

FIG. 1.

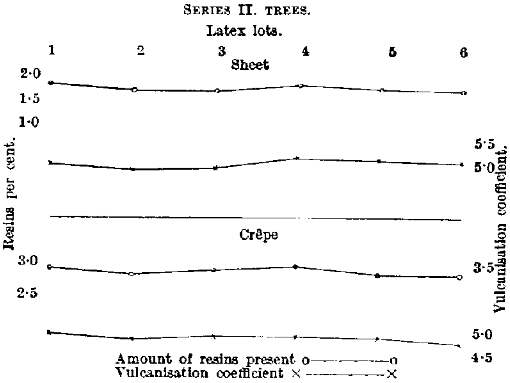

FIG. 2.

An interval of 14 days elapsed between the collection of each lot of latex from each group of trees. It has been found convenient to number the latex lots from each group of trees from 1 to 6, according to their order of collection. The samples were washed, dried, analysed, vulcanised, and tested in the usual way (Bull. Imp. Inst., 1916, 14, 499).

The "free sulphur" was determined by extracting 2 g. of the crumbed sample for 20 hours with acetone and oxidising the dry acetone extract with fuming nitric acid and potassium chlorate. In order to obtain the "combined sulphur," the "free sulphur" was subtracted from 10%, which was the amount of sulphur used in all these mixes. The accuracy of this method was checked by separate determinations of "free" and of "combined" sulphur. The combined sulphur was thus determined for two cures near the standard cure, and the coefficient of vulcanisation at the standard cure calculated from each result. Until nearly the whole of the sulphur has gone into combination with the rubber the rate of combination of rubber with sulphur is constant, so that as long as the two cures are close to the standard cure this calculation can be done with accuracy (De Vries, "Estate Rubber," 1920, p. 487; Eaton, *loc. cit.*; also Delft Comm., 6, 183). It will be seen in the tabulated results that the coefficients of vulcanisation calculated from two separate results are in close agreement. In those cases where only one cure is given the results were checked by repeating the determination.

The standard cure selected was that which gave a stress-strain curve which passed through 830% elongation under a load of 1·36 kg. per sq. mm. In the majority of cases the standard cure was calculated from the position of the stress-strain curve at a cure two to three minutes above or below the standard cure. This could be done with accuracy, since the alteration in the position of the stress-strain curve with time of cure was determined for each sample.

The results obtained in the examination of the rubbers are given in the following tables:—

Series I trees—about 10 *years old.*

Section 1. *Sheet-rubber.*

Sample no.	Latex lot.	Cure. mins.	Combined sulphur found. %	Calculated standard cure. mins.	Calculated vulcanisation coefficient at the standard cure.	Average vulcanisation coefficient at the standard cure.
496	1	60	4·64		5·32	5·28
		70	5·31	62	5·23	
497	2	60	4·62		5·57	5·55
		68	5·20	65	5·52	
498	3	55	4·84		5·66	5·59
		60	5·14	58	5·52	
499	4	48	4·85	52	5·84	5·84
500	5	60	4·43	62	5·09	5·09
501	6	64	4·64	68	5·48	5·48

The average vulcanisation coefficient at the standard cure is 5·47 with an average deviation of ± 0·19.

Section 2. *Crêpe-rubber.*

Sample no.	Latex lot.	Cure. mins.	Combined sulphur found. %	Calculated standard cure. mins.	Calculated vulcanisation coefficient at the standard cure.	Average vulcanisation coefficient at the standard cure.
508	1	95	4·64		5·16	5·13
		100	4·82	95	5·09	
509	2	110	4·98	111	5·58	5 58
510	3	100	4·21		5·16	5·23
		106	4·59	110	5·30	
511	4	110	4·55	115	5·29	5·29
512	5	95	4·44	99	5·14	5·14
513	6	108	4·13	114	4·84	4·84

The average vulcanisation coefficient at the standard cure is 5·20 ± 0·16.

The samples of crêpe rubber in section 2 were prepared from the same latex as corresponding samples of sheet rubber in section 1.

Series II trees—about 20 *years old.*

Section 3. *Sheet-rubber.*

Sample no.	Latex lot.	Cure. mins.	Combined sulphur found. %	Calculated standard cure. mins.	Calculated vulcanisation coefficient at the standard cure.	Average vulcanisation coefficient at the standard cure.
502	1	70	4·41		5·39	5·39
		75	4·71	77	5·38	
503	2	67	4·40		5·18	5·18
		70	4·59	71	5·18	
504	3	64	4·60	66	5·27	5·27
505	4	64	4·83		5·53	5·53
		68	5·13	66	5·53	
506	5	78	4·86	79	5·47	5·47
507	[illegible]	75	4·88	75	5·42	5·42

The average vulcanisation coefficient at the standard cure is 5·38 ± 0·10.

Section 4. *Crêpe-rubber.*

Sample no.	Latex lot.	Cure. mins.	Combined sulphur found. %	Calculated standard cure. mins.	Calculated vulcanisation coefficient at the standard cure.	Average vulcanisation coefficient at the standard cure.
514	1	108	4·49	111	5·13	5·13
515	2	126	4·29	131	4·96	4·96
516	3	125	4·40	129	5·04	5·04
517	4	120	4·31	126	5·03	5·03
518	5	120	4·07	132	4·98	4·98
519	6	125	4·25	128	4·83	4·83

The average vulcanisation coefficient at the standard cure is 5·00 ± 0·07.

The samples of crêpe rubber in section 4 were prepared from the same latex as corresponding samples of sheet rubber in section 3.

The average vulcanisation coefficients are collected below:—

	Series I. trees (about 10 years old).	Series II. trees (about 20 years old).
Sheet	5·47 ± 0·19	5·38 ± 0·10
Crêpe	5·20 ± 0·16	5·00 ± 0·07

The vulcanisation coefficient of crêpe at the standard cure is distinctly less than that of sheet. The vulcanisation coefficient of rubber from the older trees is slightly less than that of rubber from the younger trees and the results are distinctly more uniform.

It is an interesting and possibly significant fact that as the average time of the cure increases, so the average vulcanisation coefficient decreases.

Form.	Series I. trees. Time of cure.	Series I. trees. Vulcanisation coefficient.	Series II. trees. Time of cure.	Series II. trees. Vulcanisation coefficient.
Sheet ..	61	5·47	72	5·38
Crêpe ..	107	5·20	126	5·00

It should be noticed that there is no relation between the time of cure and the vulcanisation coefficient of individual rubbers. The relation is only found to exist when average results of a series of experiments are taken. It is possible therefore that the vulcanisation coefficient at the standard cure is dependent upon some factor indefinitely associated with the accelerator present in the dry rubber.

The average chemical composition of the rubbers is shown herewith:—

	Series I. trees—about 10 years old.				Series II. trees—about 20 years old.			
	Resin.	Protein.	Ash.	Caoutchouc.	Resin.	Protein.	Ash.	Caoutchouc.
Sheet	1·98	2·27	0·28	95·47	1·73	2·09	0·28	95·90
Crêpe	2·86	2·25	0·28	94·61	2·65	2·11	0·25	94·99

The fact that sheet and crêpe rubbers of Series I. trees contain more resin and protein than the sheet and crêpe rubbers of Series II. trees, suggests that possibly the less chemically pure is the rubber, the higher will be the vulcanisation coefficient at the standard cure. Evidence in favour of this can be quoted from the results of other workers. For example, rubber prepared from latex which has been evaporated to dryness and rubber prepared from the first clot in the partial coagulation of latex, both contain more of the accessory substances present in all natural rubbers than does rubber prepared in the usual way, and they both have a high coefficient of vulcanisation at the standard cure (de Vries, J. Ind. Eng. Chem., 1921, 13, 1134). However, the amount of the accessory substances in raw rubber is not the only factor which may affect the vulcanisation coefficient. The nature of these accessory substances, which varies with the form and origin of the rubber, possibly plays an important part.

us sheet rubber contains more caoutchouc than es crêpe rubber, yet it has generally a distinctly gher vulcanisation coefficient at the standard re. It will be shown that some of the accessory bstances in sheet rubber are of a nature fferent from those in crêpe rubber, and have a fferent effect on the vulcanisation coefficient.

Following up the presumption that some of the cessory substances in raw rubber increase the ount of combined sulphur at the standard re, the question arises as to which are sponsible. De Vries (*loc. cit.*) reasoning from e effect of artificial organic accelerators on the lcanisation coefficient, presumes that the natural celerators in raw rubber are chiefly responsible r variations in the vulcanisation coefficient, and es not correlate these variations with any of the her impurities.

With a view to finding which of the accessory bstances are chiefly responsible for variations the vulcanisation coefficient, attempts were made correlate the vulcanisation coefficient of each mple of rubber with the amounts present of ash, resin" (acetone-soluble substances), and protein mpounds, and also with the time of vulcanisation. e latter was taken as a measure of the amount natural vulcanisation accelerators present.

Only in the case of the "resins" could a distinct lation be found between the amount of this esent in each rubber and the corresponding lcanisation coefficient. Attention has already en called in this paper to the relation between e average time of vulcanisation and the average lcanisation coefficient, and it has been pointed t that this relation does not hold for individual bbers. In the case of the resins, however, a ference to the table below and to Figs. 1 and 2 will ow that, with one or two exceptions, there is a lation between the amount of the resin of individual rubbers and the vulcanisation coefficients at e standard cure.

		Latex lots.					
		1	2	3	4	5	6
eries I. trees—							
Sheet	Resin, %	2·21	1·95	1·72	2·33	1·92	1·77
	Vulcanisation coefficient	5·28	5·55	5·59	5·34	5·09	5·48
Crêpe	Resin, %	3·00	3·02	2·77	2·90	2·77	2·69
	Vulcanisation coefficient	5·13	5·58	5·23	5·29	5·14	4·84
eries II. trees—							
Sheet	Resin, %	1·83	1·67	1·66	1·84	1·72	1·67
	Vulcanisation coefficient	5·39	5·18	5·27	5·53	5·47	5·42
Crêpe	Resin, %	2·74	2·56	2·69	2·78	2·59	2·56
	Vulcanisation coefficient	5·13	4·96	5·04	5·03	4·98	4·83

It will be noticed that, with the exception of eet from Series I. trees, which has in previous xperiments displayed more variations than sheet om the older (Series II.) trees, the vulcanisation efficient at the standard cure generally rises and lls as the resin content increases and decreases. he sample which shows the biggest discrepancy eries 1 sheet rubber from Latex lot 3) unfortuately arrived in a wet condition, and had a ashing loss of 1·7%. Previous work has shown at moisture has an influence on the amount of esin present (Bull. Imp. Inst., 1916, 14, 549; 1918, , 435). It is probable that the chemical identity the resin is also affected. This may account for e sample in question being abnormal. There are at the most three other samples which give exceptional results (and this is to be expected in a natural product) so that the evidence in favour of a direct connexion between the acetone-soluble constituents and the variation in the vulcanisation coefficient is very strong.

In order to pursue still further the influence of the resin on the vulcanisation coefficient at the standard cure, samples of crêpe, sheet, and slab were extracted with cold acetone and these extracts each added in turn to the unextracted crêpe rubber in the following mix:—Crêpe rubber, 88; sulphur, 10; acetone extract, 2. The results are shown in the following table:—

Description.	Cure, mins.	Elongation 0·6 kg. sq. mm.	Elongation 1·04 kg. sq. mm.	Tensile strength. lb. per sq. in.	Combined sulphur found. %	Estimated standard cure, mins.	Calculated vulcanisation coefficient at standard cure.
pe	115	785	880	1690	3·24	135	4·2
pe + crêpe resin	115	796	891	1570	3·45	138	4·6
+ sheet resin	115	745	842	1760	4·45	125	5·4
+ slab resin	115	579	—	705	6·20	88	5·3

In columns 3 and 4 are found the elongations under the loads stated, as shown by the stress-strain curve. Taking for these 4 cures an elongation of 800% under a load of 1·04 kg. per sq. mm. as the standard cure, in the 8th column is found the estimated time of cure necessary to give this stretch. The vulcanisation times of the samples of crêpe, crêpe + crêpe resin, and crêpe + sheet resin are so near to each other that the estimated standard cure should be relatively accurate. The sample of crêpe + slab resin cures very much more quickly than the other samples. It is possible that the error in estimating the time of cure in this case may amount to a little more. Even when these errors are allowed for the results in the last column leave no room for doubt that the added crêpe resin increases a little the coefficient of vulcanisation at the standard cure, while the addition of sheet and slab resin has a very marked effect on the vulcanisation coefficient. It is also of interest (column 6) that the addition of crêpe resin increases the rate of combination of rubber with sulphur very slightly —hardly more than lies within the limits of experimental error—while the sheet resin markedly increases and slab resin almost doubles the rate at which rubber and sulphur combine. The sheet rubber resin was obtained from a sample requiring 50 minutes in which to vulcanise. This is much less than is usually required by sheet. The sample of slab took 66 minutes to vulcanise. This is longer than slab usually requires.

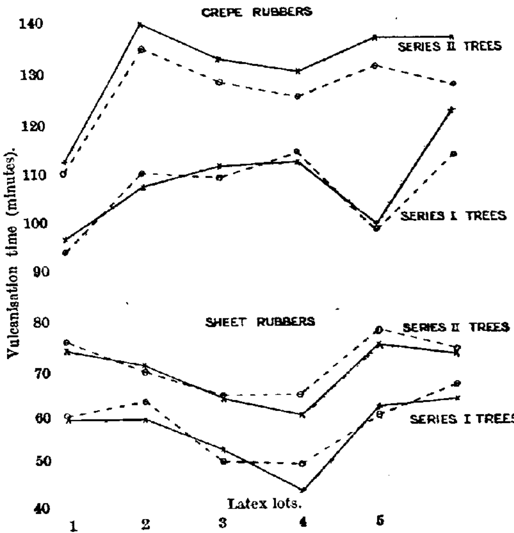
Numerous investigations at the Imperial Institute have shown that slab rubber and also rubbers which have been machined, and then kept in a wet state, usually have a higher amount of resin and a lower amount of protein than has sheet or crêpe; moreover, they generally vulcanise quickly (Bull. Imp. Inst., 1918, **16**, 435). It is evident from the above experiments that the resin constituents of slab rubber are responsible for its quick curing properties. This is confirmed by the fact that the acetone-extracted sample of slab required 90 minutes to vulcanise. It seems probable that part of the protein portion of raw rubber during the process of maturing is rendered soluble in acetone and this acts as a strong accelerator.

Spence (J. Ind. Eng. Chem., 1918, **10**, 116) states that Para rubber contains an "active principle," soluble in acetone, nitrogenous, and feebly basic in character, and acting essentially as a catalyst of vulcanisation. On the other hand, Stevens found that on one occasion the removal of resin had very little effect on the rate of combination of rubber and sulphur (Kolloid-Zeits., 1915, **14**,

91) while on another occasion the rate of combination was decreased by 25% (J., 1916, 874). In Spence's published experiments (Kolloid-Zeits., 1912, 11, 28) the "resins" were more completely removed than in those of Stevens, and it is possible that the last traces of "resin" may play an important part in vulcanisation. It seems probable, however, that the "resin" of Para rubber prepared in different ways and from different groups of trees will differ in quality as it does in quantity, and will have different effects on vulcanisation.

The increase in the vulcanisation coefficient at the standard cure on the addition of 2% of either slab resin or sheet resin is remarkable. In a preliminary investigation on the combination of crêpe resin with sulphur at 150° C. in a sealed tube in the presence of air, the resin was found to combine with 11·5% of its weight of sulphur in 2 hours. About half of this was insoluble in acetone. A fuller investigation of the combination of different rubbers with sulphur following the procedure advocated by Kelly might yield important results (J. Ind. Eng. Chem., 1922, 14, 196—197). For the present it should be borne in mind that the addition of 2% of either slab or sheet resin to crêpe rubber increased the vulcanisation coefficient by approximately 1% of combined sulphur. If the whole of this increase were due to a combination of resin and sulphur to form an acetone-insoluble compound, it would involve the conversion of the whole of the substances soluble in acetone into insoluble substances, and even then would give compounds containing on an average as much as 30% of sulphur. The increase in vulcanisation coefficient is so large that the combination of sulphur and resin to form an insoluble compound is unlikely to be the sole explanation.

Chemical and physical methods of determining time of vulcanisation.



Time of vulcanisation determined from the amount of combined sulphur x———x

Time of vulcanisation determined from the standard stress-strain curve o- - - - -o

FIG. 3.

The physical characteristics of the resins previous to vulcanisation are also unlikely to provide an explanation of this increased vulcanisation coefficient, since the crêpe resin was the softest and slab resin the hardest. The explanation may lie partly in the combination of resin with sulphur to form an insoluble product, partly in the physical properties of the compounds so formed, and partly in obscure physical and chemical relationships.

The influence of the resin constituents of rubber on the coefficient of vulcanisation at the standard cure raises the query as to whether the estimation of the correct time of cure by the determination of combined sulphur gives results similar to those obtained by physical methods. The average vulcanisation coefficient for the whole of the 24 samples described in the first part of this paper is 5·26. Assuming that a rubber which has been cured to a coefficient of 5·25 is correctly cured for the purpose of these experiments, the time of cure of each sample can be calculated and the results compared with those obtained by physical methods. The details are shown in Fig. 3. These results are in agreement with those of other workers and indicate that the chemical method of determining the time of cure does not give results materially different from the physical method (Eaton, *loc. cit.*; de Vries, *loc. cit.*). Rubbers from the same latx and prepared in the same way differ in cure roughly by the same amount whether their time of cure is estimated physically or chemically. There is not the same agreement between th physical and chemical methods of estimating the time of cure when rubbers of different form, such as crêpe and sheet, are concerned. These two types of rubber, however, differ in time of cure by an amount so large that these discrepancies are of little importance. We may definitely conclude that the relative times of cure of rubber-sulphur (90:10) mixes are approximately the same whether we adopt the chemical or physical method of determining the time of cure.

Conclusions.

(1) The amount of combined sulphur at the standard cure depends upon the way in which the rubber is prepared, upon the trees from which the latex is obtained, and also to a less extent upon unexplained variations in the finished rubber from time to time. In the samples tested the maximum variation did not reach 1% of combined sulphur.

(2) For a series of rubbers, as the average time of cure increases so the average amount of combined sulphur at the standard cure decreases.

(3) The amount of combined sulphur at the standard cure for rubber of the same form, and from the same trees, varies approximately as the amount of resin constituents of the rubber varies.

(4) The resin of crêpe rubber has little influence on the rate of combination of rubber with sulphur. The resin of sheet rubber acts as a mild accelerator, while the resin of slab rubber contains a strong accelerator. The resins of slab and sheet rubber increase the vulcanisation coefficient of crêpe rubber at the standard cure more than does the resin of crêpe rubber.

(5) Whether the time of cure of the rubber-sulphur mix (90:10) is estimated by chemical or physical means, the results are approximately the same, as long as similar forms of rubber are compared. The differences are larger when dissimilar forms such as sheet and crêpe are compared.

The experiments described in this paper have been carried out at the Imperial Institute in the course of investigations conducted in connexion with the Ceylon Rubber Research Scheme.

CHEMICAL ENGINEERING GROUP.

The papers by Messrs. Parrish and Hinchley, read before the sessions of the Chemical Engineering Group at Glasgow on July 6th, are printed below in abridged form. An account of Mr. Walmsley's paper will appear later. An abstract of the paper read by Mr. T. H. Gray will be found in the July 15th issue, p. 281 R. The full papers will appear in the Proceedings of the Group in due course.

OBSERVATIONS ON THE DESIGN AND WORKING OF AMMONIACAL LIQUOR STILLS.

BY P. PARRISH, A.I.C.

[*Abridged.*]

The quantity of gas liquor produced and distilled in the United Kingdom must be of the order of 1250 million gallons of 8 oz. (1·73 per cent.) NH_3 per annum. This quantity chiefly arises in the purification of crude coal gas derived from the carbonisation of coal at gas works and coke ovens, from blast-furnace gases, and the carbonisation of shale as conducted largely at the shale oil works in Scotland.

The following analyses give an indication of the average composition of ammoniacal liquors arising at various works:—

	Gas works. % w/v.	Coke oven. % w/v.	Blast furnace. % w/v.	Shale works. % w/v.
Volatile ammonia..	1·4 to 2·5	0·68 to 0·85	0·4	0·9
Fixed ammonia ..	0·1 to 0·4	0·3 to 0·10	0·01	0·3
Total ammonia ..	1·5 to 2·9	0·98 to 0·95	0·41	0·93
$(NH_4)_2S$	0·8 to 0·9	0·40	—	0·10
$(NH_4)_2CO_3$ ..	5·0 to 8·5	1·90	1·1	2·90
NH_4Cl.	0·5 to 1·0	0·20	0·006	0·015
NH_4CN	0·07 to 0·3	0·04	—	—

Broadly speaking, the arrangement of the stills and liming chamber can be divided into three categories, viz., (A) free still superposed on liming chamber, fixed still separate; (B) free still superposed on liming chamber and fixed still; (C) free still superposed on fixed still, liming chamber separate.

As to the arrangement which the plant should take, much depends on the provision made for cleaning the stills, on the fixed ammonia content of the gas liquor to be distilled, and on its freedom from tarry matter. By far the greater number of stills operating in the United Kingdom are stills built up of double-flanged sections, each of which, generally speaking, constitutes a chamber. The joints between the corresponding flanges of the chambers are made with boiled linseed oil and Vulcan cement, or with red and white lead and lead wire. Obviously these sections have to be provided with such a number of manholes, and of such a size, as will afford facilities for the cleansing of the overflow pipe or pipes and the removal and/or cleaning of the hoods, frogs, crocodiles, or whatever steam-distributing device is provided.

In this form of still the joints between the several sections are potential sources for the leakage of ammonia, and as it is unusual to insulate the covers of the manholes with non-conducting material, the loss of heat by radiation is not inconsiderable. Complete dismantling may become necessary owing to accumulations of lime sludge, either causing blockages which are difficult, if not impossible, to remove *in situ*, or the lime may form laminations on the bottom of the chambers to such an extent as seriously to impair the thermal efficiency and capacity of the plant.

Another arrangement of still which largely overcomes the disabilities to which reference has been made above comprises an outside shell free from a multiplicity of flanges, and without cleaning manholes. This design of still, for which Dr. Carpenter was responsible, contemplates the withdrawal of the internal elements, which comprise a hood, tray, and bubbler, as constituting a complete chamber for cleaning purposes.

These hoods, trays, and bubblers are provided with machined faces so that there is no possibility of the by-passing of steam on the outer part of the trays. Suitable lifting tackle is provided for facilitating the removal of the internal elements, which, in turn, are all provided with suitable lifting lugs.

It has been found in practice that, provided the accumulations of lime sludge at the foot of the liming chamber are removed every fortnight, and the top cover of the fixed still is lifted monthly for the cleaning of the perforations of the anti-priming device, the still will operate continuously for six months before cleaning is necessary. During this time approximately 5,000,000 galls. of gas liquor will have been distilled, still cleaning representing a charge of about 2d. per ton of sulphate made. With the shell type of still, involving as it does the withdrawal of the internal elements for cleaning purposes, it would be obviously unwise to arrange the plant according to category B. (*cf. supra*), as this would necessitate the removal of the liming chamber in order to afford access to the anti-priming arrangement, or first tray, of the fixed still.

Manifestly with gas liquor having a high content of fixed ammonia, particularly if such fixed ammonia is due to ammonium sulphate, the difficulty of keeping the distilling sections of the fixed still free from sludge, particularly the first and second fixed sections, is great. Special consideration should be given to the design of the liming chambers or the elements of large liming chambers, which admit of considerable time contact, in order to ensure active agitation. Easy means of a periodic discharge of the sludge from the foot of the liming chambers should also be provided. Failing this, an arrangement of plant with outside liming section specially designed as represented in category C. is necessary.

It is the author's view that mechanical considerations, such as facilities for cleaning, provision for the removal of bubbling hoods and initial capital cost, have been the factors largely governing the design and arrangement of gas liquor stills in the past. Had designers and makers of gas liquor stills been in a position to visualise the items which contribute to the cost of ammonium sulphate in so far as the still itself is concerned, it is not improbable that less attention would have been directed to this somewhat circumscribed aspect of design, and more attention given to the possibilities of designing a still which would be economic as regards steam consumption. In saying this, it is not overlooked that the ideals of the chemist and physicist have not infrequently to be compromised in order to ensure mechanical strength and practicability in the matter of production.

The data given below relative to the characteristics of several types of present-day stills lead to the conclusion that standardisation based on experimental data under varying conditions, and with due regard to the fundamental laws governing the distillation of gas liquor, would be fully warranted.

Tho above figures show the heat expressed in terms of B.Th.U. entering and/or leaving the various parts of the plant constituting a complete sulphate of ammonia unit.

Not infrequently has the question been asked, What are the conditions governing the water balance of a saturator?

Owing to the heat of formation of ammonium sulphate by the combination of the ammonia with the acid of the saturator, the temperature of the bath is at least equal to the temperature of a boiling saturated solution of ammonium sulphate. A further increase of temperature accrues from the free sulphuric acid content of the bath. Indeed the temperature of the bath will be at least 15° C. higher than the temperature of the stream of steam and ammonia leaving the still. Hence there can be little possibility of the condensation of water in the saturator unless the heat of formation of ammonium sulphate is counterbalanced by heat losses *viâ* conduction, radiation, and the circulation of mother liquor outside the saturator.

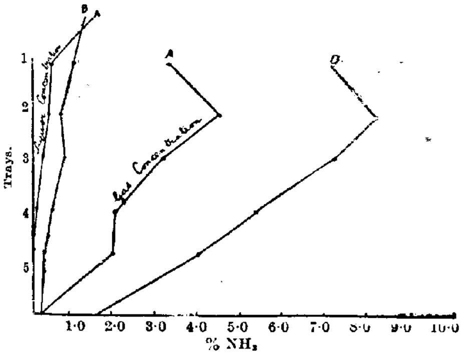

FIG. 1.

Diagram showing liquor and ammonia gas concentrations at two rates of speed.

3·7 *galls. per hour A* }
9·3 ,, ,, ,, *B* } *with identical steam consumption.*

The factors governing the water balance of a saturator are undoubtedly the strength of acid which is used and the quantity of extraneous water which is introduced thereto.

It is known that when using sulphuric acid of 70% H_2SO_4 content, 50 gallons of extraneous water can be introduced to the bath without creating redundant mother liquor.

From the thermal data afforded by the measurements under review a simple calculation will show that 55 gallons of water was being evaporated per ton of ammonium sulphate (of 25·74% strength) being made.

So far it will be seen that there is great uncertainty as to the form which the elements of an ammoniacal liquor still should take if the vital factor, namely, steam consumption within the still, is to be economised. Hitherto hypotheses have been deduced and indeed worked upon, but it is doubtful whether any satisfactory data have been arrived at, either experimentally or otherwise, to indicate the precise form which the elements should assume, and the conditions under which the stills should be operated if a minimum steam consumption is to be attained.

Having an experimental sulphate of ammonia plant available, experiments were conducted under varying conditions with a view of arriving at certain conclusions in the above connexion.

Fig. 1 is a diagram showing the liquor and gas concentrations at two rates of feed with identical steam consumption. It will be seen from this diagram that the rate of flow has been increased by about 250% at the sacrifice of 0·23% of free ammonia in the effluent. It is not inconceivable that an identical effluent to that of the lower rate of feed would have been obtained had the time contact been increased (say) to the extent represented by two additional trays. This experiment would appear to indicate that given a definite time contact, the steam consumption can be made to approach the theoretical minimum possible dependent upon the liquor feed concentration. The latter condition embodies the ideal at which designers of gas liquor stills should aim, and incidentally the one with which manufacturers should be conversant when contemplating the purchase of gas liquor stills.

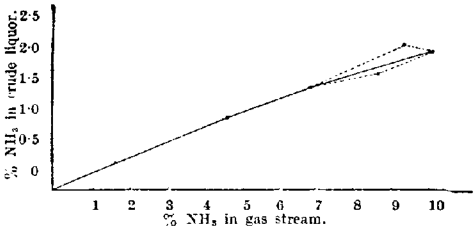

FIG. 2.

Diagram showing ammonia concentration of gas, with varying contents of ammonia.

A measure of the efficiency of the steam consumption of a gas liquor still is afforded by the concentration of the ammonia in the gas stream. A simple method of determining this factor under practical working conditions is to condense the stream of steam and ammonia leading to the saturator, and to make a determination for ammonia, carbonic acid, and hydrogen sulphide contents. From a series of analyses carried out in this manner, the graph shown in Fig. 2 has been prepared. By calculation from the foregoing graph the curve in Fig. 3, which affords an indication of the steam consumption per lb. of ammonia in relation to the ammonia concentration in the crude liquor, has been constructed.

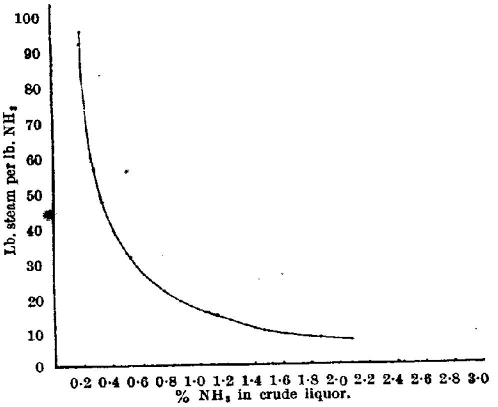

FIG. 3.

Curve showing steam consumption per pound of ammonia, with varying concentrations of ammonia in gas liquor.

Unfortunately little information appears to be available concerning the extent to which the concentration of ammonia in the gas stream is affected by varying concentrations of ammonia in the gas liquor. This obviously has an important bearing when fixing the price of gas liquor according to its ammonia content, and particularly so when purchasing concentrated gas liquor. As far as is known, the only recent work published on this aspect was an article appearing in *Chemical and Metallurgical Engineering* of February 15th last by Emil Piron, in which some of the fundamental laws governing the distillation of mixtures were discussed. This worker has shown the lines along which problems of this character can be studied, both experimentally and mathematically. Indeed the article is of such merit that diagrams, based on the experimental data furnished, have been embodied in this contribution. Fig. 4 is a graph which shows the relationship between the composition of the liquor being distilled and that of the distillate leaving the still. The particular experiment comes under the category of a discontinuous distillation, but the data so given can be correlated to the performance of a continuous still. This graph in conjunction with Fig. 5, which is compiled from data by the same author, is of importance as indicating the economic limit which should be looked for as representing the point at which further distillation is unprofitable. It also furnishes some idea as to the relative value of gas liquor of different concentrations from the point of view of the distiller.

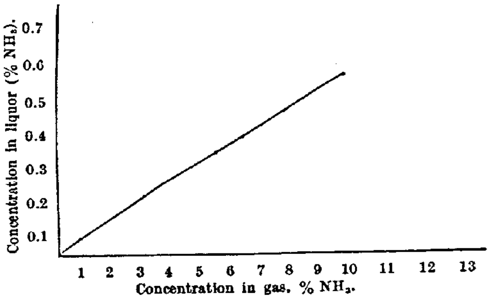

FIG. 4.

Diagram of Emil Piron's values, showing the variation of "K," with a variation of the strength of liquor.

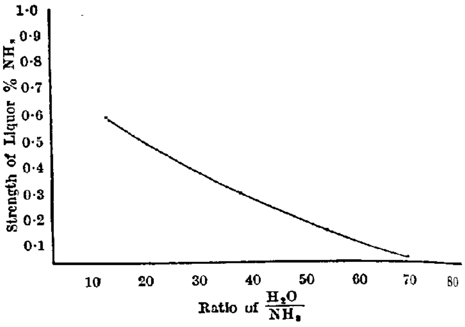

FIG. 5.

Steam consumption per unit of ammonia distilled from liquors of varying concentrations, plotted from data by Emil Piron (see Chem. and Met. Eng., Feb. 15, 1922).

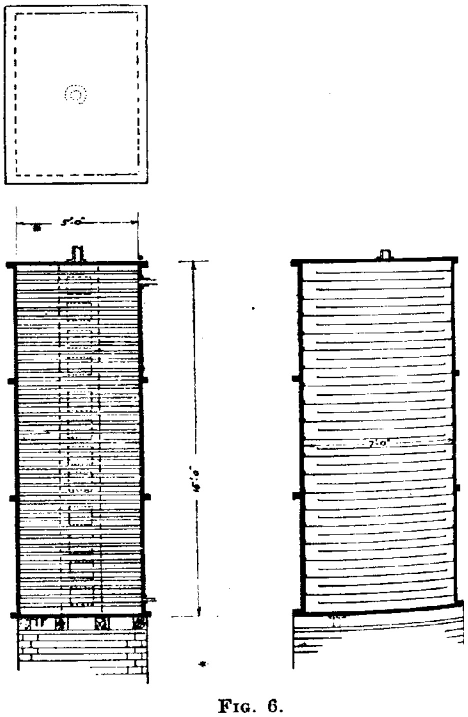

FIG. 6.

Hill's still.

It has been suspected by workers having technical and practical experience of gas liquor stills that there was no particular merit in the elements of the still being arranged with a deep seal, through which the ascending gases and steam were compelled to bubble. On the contrary, it has been suggested that the capacity of a gas liquor still can be fully maintained, and the steam consumption appreciably reduced, if the ascending gases and steam emerged on the liquor line in the trays.

Fig. 6 shows a continuous gas liquor still which was in operation in London in 1878, the design of which was based on the principle of a comparatively large surface area with a thin film of liquor, along which the gases and steam skirted by reason of the contiguity of the respective plates. It is known that a still 15 ft. high by 7 ft. x 5 ft. in section, having 38 plates, was capable of dealing with the free ammonia content of 10,000 galls. of gas liquor of 6—8 oz. strength per day.

It is clear from the experience afforded by the operation of the above still that heating surface is not alone the governing factor which should be aimed at in the design of gas liquor stills. Rather must attention be directed to ensuring the greatest intimacy of contact along with maximum time contact and heating surface. Attenuated bubbling of such a nature that maximum deformation and/or reformation of the bubbles is ensured, is the principal factor for promoting rapid equilibrium.

Experiments have been directed to the elucidation of the above view by varying the depth of seal for a given still design, and although the author is reluctant to draw premature conclusions, evidences are not wanting which support the theory advanced above.

It has to be remembered that the utilisation of exhaust steam is not confined to vacuum distillation plants alone. Many gas liquor stills operating under normal pressure conditions are worked to-day with exhaust steam. Moreover a consideration of the relative vapour pressure of ammonia and water in typical gas liquors at ranges of pressures between (say) 20 in. of mercury (absolute) and 35 in. (absolute) leads one to the conclusion that no great saving in steam consumption is likely to accrue, whereas an additional expenditure of steam will be required for the operation of the vacuum pump and the pump installed to withdraw the effluent liquor from the still.

Other considerations also operate when working a vacuum still. Some are advantageous, others have the contrary effect. The volume occupied by the steam at (say) 5·7 lb. per square inch (the absolute pressure at which the vacuum still at Hamilton is reported to have worked) is 68 cub. ft. per lb., as contrasted with 24·75 cub. ft. per lb. when operating under normal pressure distillation conditions. Thus, under vacuum conditions, the velocity of the steam through the still is appreciably increased and hence the time contact is reduced correspondingly for a given weight of steam. On the other hand, the greater volume of steam passing over, or bubbling through, the liquor on the several trays is clearly an advantage. Manifestly the elements constituting the chambers of a still operated under vacuum must have larger surface area provided for the ascent of the stream of steam and ammonia.

As uncertainty existed as to the intrinsic capacity of a still for dealing with gas liquor of varying concentrations, experiments were made to determine this aspect. Gas liquor of varying concentrations was fed to the experimental still under such conditions that the effluent liquor leaving the still had approximately a constant composition. From the rates of flow and the concentration, Fig. 7 has been constructed. In brief, this curve represents the amount of ammonia distilled in unit time expressed in relation to the concentration of the feed liquor.

Gas liquor storage tanks.

As to the form of the tanks and the general arrangement for the storage of gas liquor, practice varies considerably throughout the country. The shells of Lancashire boilers are used in many cases for the storage of gas liquor, and it is known that they have served quite well for this purpose. Experience suggests, however, that sectional plated cast-iron tanks are preferable, and are calculated to have a much longer life than second-hand steel boiler shells.

Preheaters and coolers.

With small units of plant it is usual to place the preheater inside the still house, where it is not subjected to extremes of temperature during operation. With larger units of plant the preheaters are almost invariably placed outside the still house building. This practice may be regarded as unsound from the point of view of heat conservation. The quantity of heat leaving the saturator, however, is appreciably greater than that required to raise the temperature of the feed liquor to boiling point. Indeed, cooling water has to be profusely used to reduce the waste gases at atmospheric temperature.

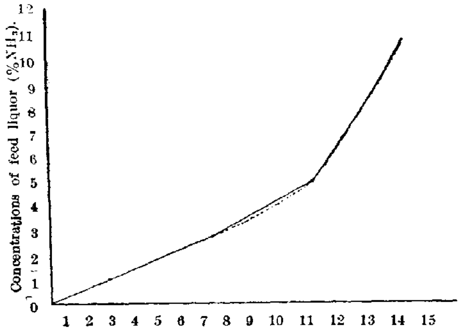

FIG. 7.

Diagram of the capacity of experimental still in relation to strength of feed liquor.

Devil liquor storage tank.

On account of the noxious character of the devil liquor, it is important that certain steps should be taken to ensure its collection and treatment. This is best effected in a sectional plated cast iron tank suitably lagged which will allow of 5 to 6 hours' accumulation. Opinions vary as to the best method of treatment. At many works the devil liquor is pumped along with the gas liquor and the mixed liquors are distilled. The only disadvantage is that expense is entailed in the matter of steam, and many of the impurities of the gas liquor which are arrested with the devil liquor, such as pyridine, creosote oil, naphthalene, etc., are again returned to the saturator. Obviously for the production of white salt it is essential that these impurities should be disposed of in another way, and not recirculated to the saturator.

Moreover, it must be remembered that the distillation of devil liquor represents approximately a 20% reduction of the capacity of the still, which is another important consideration.

Constituent parts of gas liquor stills.

Fig. 7 shows how the elements of the still designed by Dr. Carpenter (*v. supra*) are assembled. The bottom tray is supported on a circular webbed flange arranged within the still. Each succeeding tray is in turn supported by the one underneath. The first bubbler of the free still, placed immediately above the liming chamber, is supported by a vertical 9-in. cast iron pipe (which by a bend near the foot conducts the limed liquor to an outer annulus) placed centrally in the liming chamber and terminating with a suitable base. The first bubbler supports the hood which in turn supports the bubbler. Thus the whole weight of the bubblers and hoods is transmitted to the 9-in. pipe, and the complete weight of the trays is reflected on the webbed flange.

For the permanent machined joints a mixture of red and white lead is used. For the faced joints of the superimposed sections graphite paste is used. A packing of yarn is also employed between the trays and the outside shell of the still so as to prevent the admission of any rust which will interfere with the removal of the trays. The bubblers of the fixed section of this particular still are open, with serrated edges on the two circumferential peripheries.

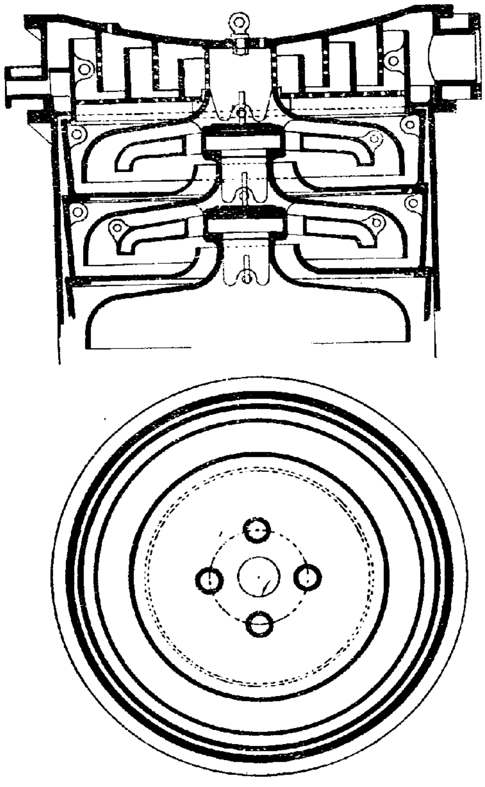

Fig. 7.

The merits of the design of this still are the size of the liquor overflows and the large area of wetted surface which the elements afford. Further, it is evident that the designer has appreciated two other important factors, viz., the great advantage of a high velocity of the vapours where they come in contact with the liquid, and the importance of time contact as between the vapour above the liquid and the liquid itself as aiding equilibrium.

Fig. 8 shows the elements of a still which was introduced to this country about 40 years ago. Some of the features of this still, particularly the liming section, possess definite merit, but it is believed that there are many directions in which the still can be improved, particularly in the matter of area of liquor overflows, time contact between the vapour and liquid, and velocity of the vapours through the liquid.

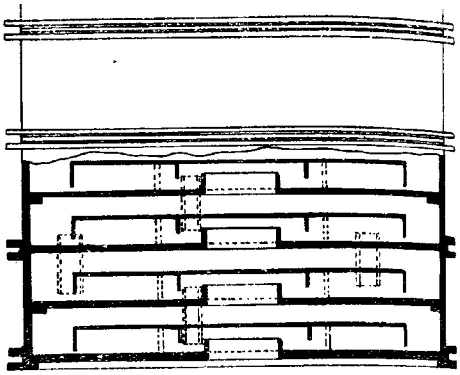

Fig. 8.

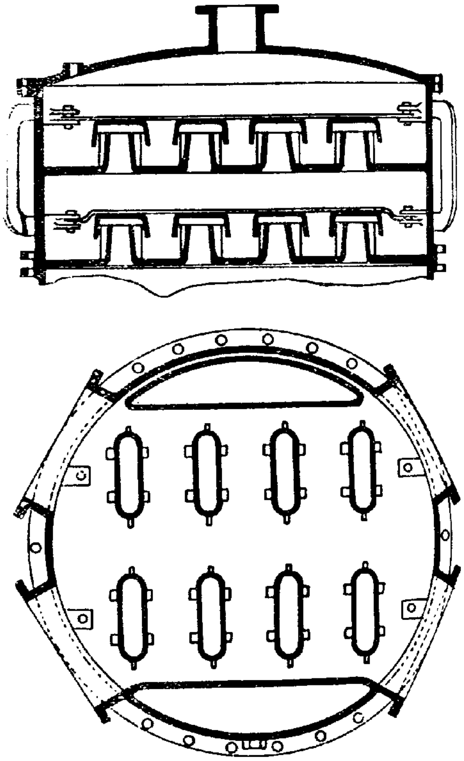

Fig. 9.

Fig. 9 represents the elements of a still of more recent design. Regard has obviously been paid to the removal of the hoods for cleaning purposes, and the possibility of blocked outlets would appear to be remote, in view of their size. The comparatively small diameter of the still in relation to the quantity of gas liquor with which it deals and the arrangement of hoods which clearly admit of the bubbles from one being thrown in contact with those created by the adjacent hood, must ensure considerable deformation, thus increasing the contact of liquid and vapour.

Fig. 10 represents a very simple form of element. If simplicity were the predominant factor in the efficiency of a gas liquor still, this particular design would certainly merit a premier place. The hoods in both the free and fixed stills are rectangular and the travel of the liquid is left to right and right to left alternately. The overflows are tolerably large and the designer has evidently had in mind the importance of avoiding blockages at this point. The hoods are capable of ready removal. One disadvantage appears to be that the arrangement of hood lends itself to localised bubbling. Moreover the area of the serrations is equal to, if not in excess of, the area of the gas slots, which area is too large for ensuring such a vapour velocity as to give anything approaching optimum bubbling.

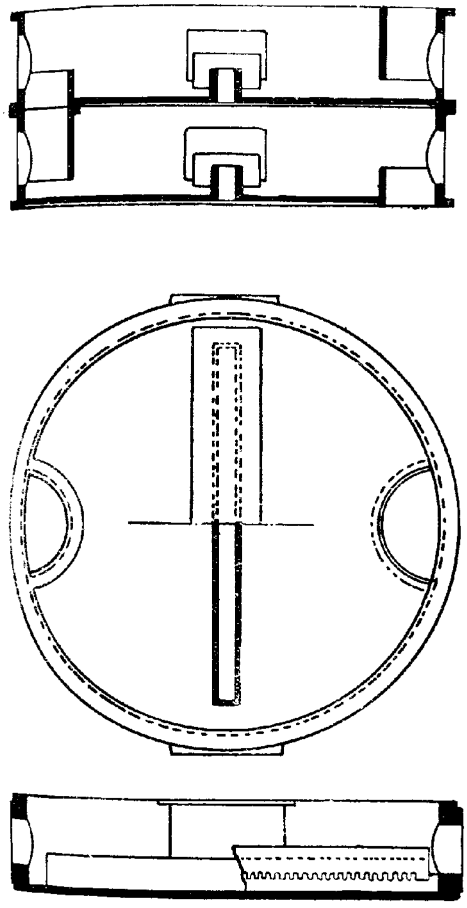

Fig. 10.

Fig. 11 represents the elements of a square still which by reason of its form must have the merit of cheapness as regards cost of production. The bubbling hoods are also readily accessible either for inspection or withdrawal. Whether the liquid will follow the path intended for it appears somewhat open to doubt. Whilst the arrangement of four hoods is a considerable advantage, it is feared that the area for the ascent of the gas is far too large for ensuring satisfactory bubbling, and the liquor overflows also appear to be unnecessarily restricted, although protruding as they do beyond the castings, they are without doubt easy of access.

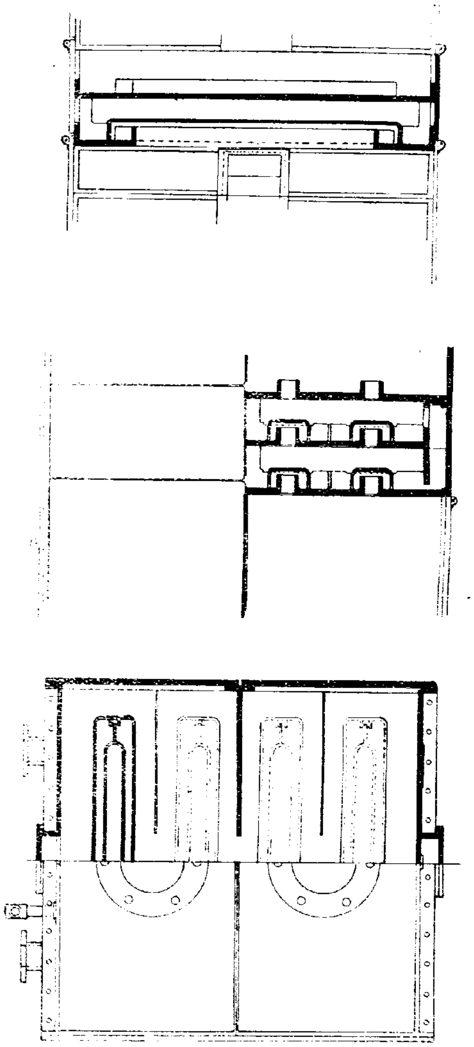

Fig. 11.

Fig. 12 represents the constituent parts of a still of recent design. This still has a very large capacity. The designers have recognised the importance of large overflows and the advantage attending the depth of chamber in relation to the liquor on the trays as increasing the factor of time contact. Moreover the weight of the still in relation to the capacity is certainly a chemical engineering achievement. The latter is largely due to the adoption of a small liming chamber, and of course introduces a subject on which there would be, no doubt, considerable divergence of views. It is believed that the design, by reason of the large area afforded by the serrations, militates against such a vapour velocity as is calculated to ensure satisfactory bubbling.

Fig. 13 represents the elements of a still possessing several merits, particularly the one of creating bubbling over a large surface area, and ensuring impact between the respective bubbles from the several hoods. It will be an advantage if the makers will in future increase the diameter of the overflow pipes, as it is not inconceivable that trouble may arise from this cause.

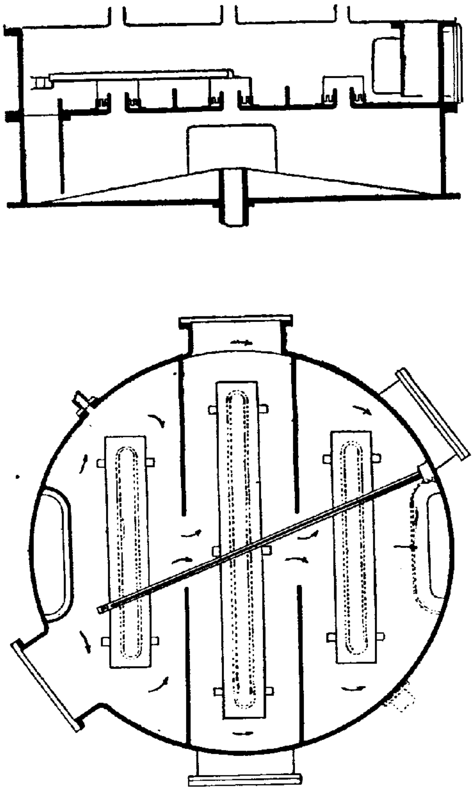

FIG 12.

Fig. 14 represents the chief constituent parts of a still which was designed nearly forty years ago. Whilst the designer has apparently recognised the importance of maximum agitation of the liquid, it is feared that the area of the serrations, which are largely in excess of the area of the gas outlet, will obviate this desideratum.

Fig. 15 represents the elements of a square still, certain advantages of which have already been named. Here the importance of vapour velocity appears to have been recognised, although impact of the bubbles appears impossible. The liquor overflow might with advantage be enlarged.

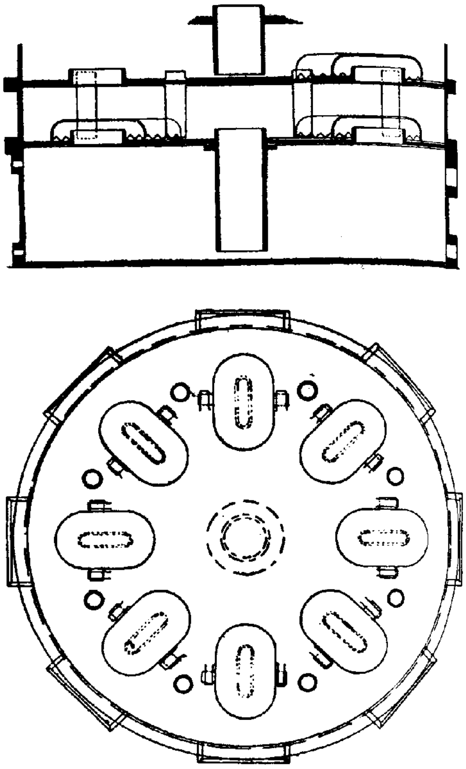

FIG. 13

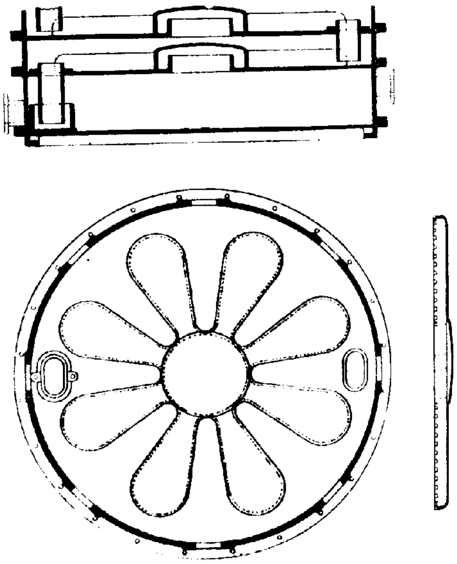

FIG. 14.

Fig. 16 represents the details of a still which it is understood is used to a considerable extent in connexion with ammoniacal liquor arising from the distillation of shale. The position in which the bubblers lie is varied alternately with each chamber. Thus they cross at right angles. Similarly the overflows are arranged alternately. This design, it is feared, does not allow of a suffi-

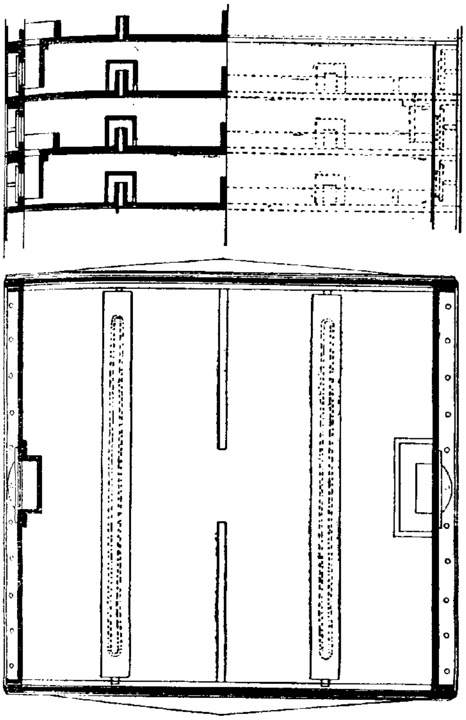

FIG. 15.

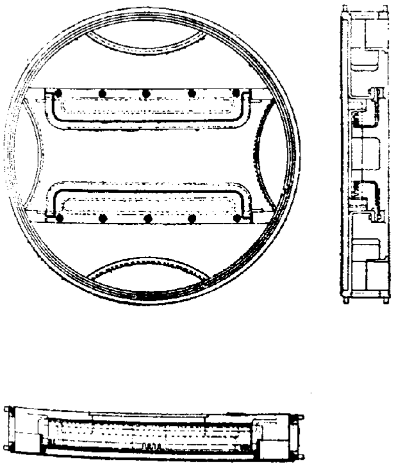

FIG. 16.

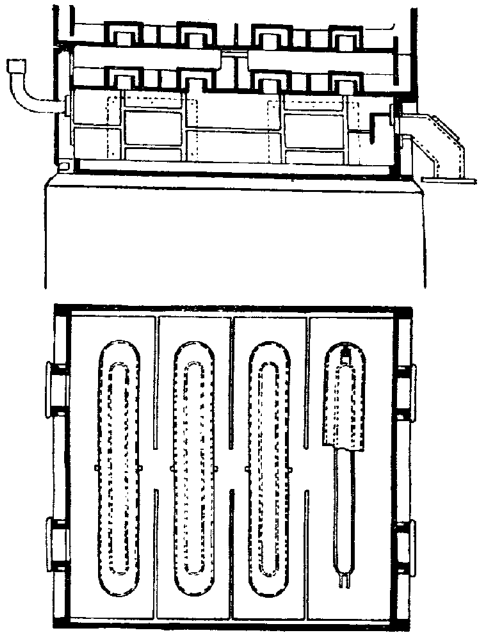

FIG. 17.

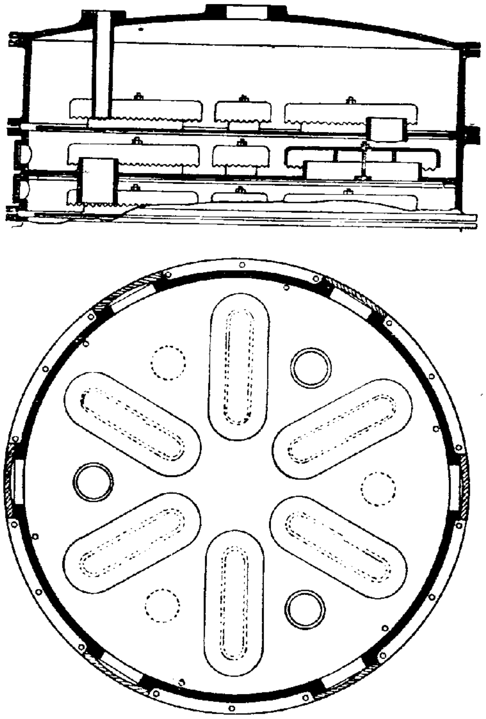

FIG. 18.

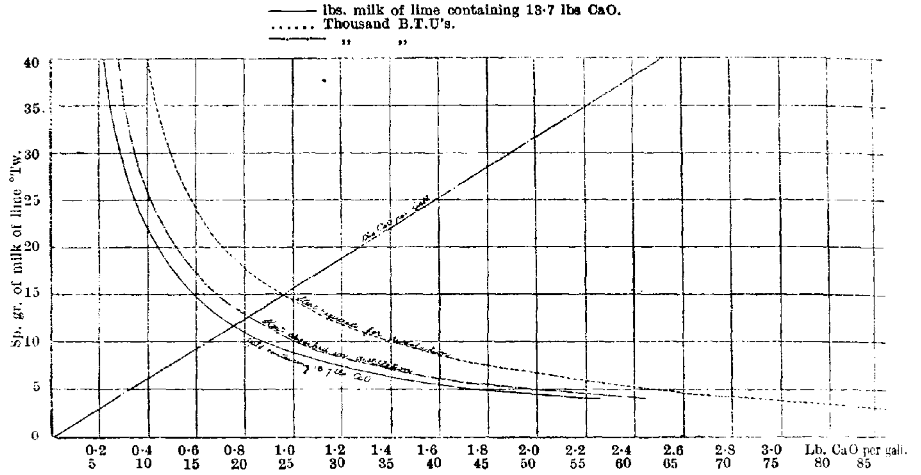
ciently rapid vapour velocity to ensure satisfactory bubbling, although the arrangement of the hoods and their camparative contiguity will doubtless assist in causing conflict between the respective bubbles.

Fig. 17 is similar in many respects to the elements of one of the other square stills to which reference has already been made.

Fig. 18 represents the sections of a still which has obviously been designed to ensure agitation over a large area, but unfortunately the low velocity of the gas is not calculated to assist to this end. The manholes appear to afford satisfactory access to the overflow pipes, but whether the serrations of the hoods can be as easily cleaned, or whether they can be readily withdrawn, is a matter of doubt. If there had been a larger vapour space above the liquid level in the trays, this would have ensured a greater time contact which obviously is a decided advantage.

"Liming" and liming chambers.

The most economical way of liming the gas liquor, which has been deprived of its volatile ammonia, is to introduce powdered lime by a positive method to the liming chamber. By pursuing this method steam and water are economised, and in addition advantage can be taken of the heat generated by the formation of calcium hydroxide. The importance of this aspect is made evident by the graphs and data furnished in Fig. 19.



Sp. gr. (°Tw.)	4	8	12	16	18	20	22	24	26	28	30	32	34	38	40

NOTES.—1. The above figures are calculated for the distillation of 100 galls. of 8-oz. liquor having a fixed ammonia content of 0·346% w/v (20% of the total ammonia).

2. An excess of 20% above theoretical lime quantity is allowed.

3. The milk of lime enters the still at 110° F. and has therefore to be raised through 106·5° to 216·5° (the temp. of distillation).

4. The heat required for the dissolution of the lime is taken as 151 B.Th.U. per lb. of solution.

FIG. 19.

Diagram having reference to the thermal aspect of the application of lime.

Unfortunately lime containing 96% CaO and free from ashes is very difficult to obtain, and no doubt this has been one of the deterring factors to the adoption of such a method as the one indicated. It is found in practice that cream of lime cannot be pumped satisfactorily, and that if pumping is resorted to milk of lime of about 16° Twaddell at 70°—75° C. has to be used. The lime mixer must obviously be placed in such a position that the cream of lime (say) of 30° Tw. can be gravitated direct to the liming chamber. When regard is had to the fact that lime is with difficulty soluble in water (only a 0·17% solution at 15° C. being possible) the importance of maintaining the cream of lime in agitation with the liquor need not be unduly emphasised.

The introduction of cream or milk of lime to the still chills the liquor at the foot of the liming chamber momentarily, but sufficient steam, usually about 10% of the total, has to be added to ensure the necessary agitation and to maintain the mixed liquor at boiling temperature.

Coming to the question of the size of a liming chamber, it would appear evident that if agitation is to be efficient, there must be a limit to the size of the liming chamber in relation to a given volume of limed-liquor treated. Undoubtedly one of the faults of design of many liming chambers is that they are too large and allow calcium salts to settle out, instead of being retained in a state of suspension. This is a matter to which increasing attention could be very profitably devoted.

Not infrequently has the question been asked, by managers in charge of small and medium sized sulphate of ammonia plants, whether any formulæ were known relative to the quantity of milk of lime required per unit volume of gas liquor containing a certain percentage of fixed ammonia in relation to the total ammonia.

Fig. 19 is of interest in this connexion. It is clear that a formula of the kind referred to can be readily calculated from analytical data. One such formula (based on the milk of lime required per hundred gallons of gas liquor) of which the writer has knowledge is expressed thus:—

$$V = 65 F \div L,$$

where V represents the volume of milk of lime in gallons, F the fixed ammonia content of the gas liquor in ounce strength, and L the strength of lime in degrees Twaddell.

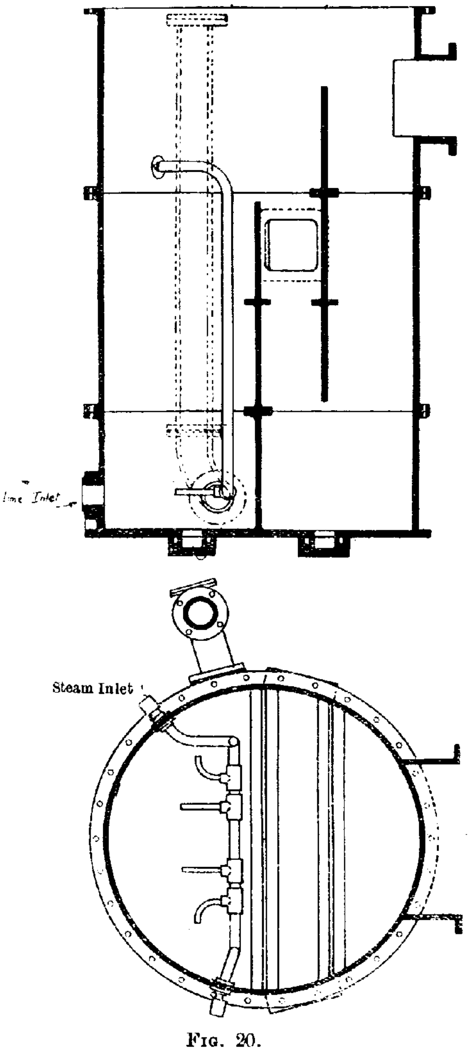

FIG. 20.

The following calculation will afford an indication as to how the above formula has been arrived at, and incidentally gives an idea of the excess milk of lime solution which it contemplates:—

1 oz. strength = 0·3469 oz. NH_3.
1° Tw. milk of lime = 0·845% CaO at 70° C.;
or, in 100 oz. ditto there is 0·845 oz. CaO
in 1 gallon ditto ,, ,, 1·352 ,, ,,
$2 NH_3$: CaO as 34 : 56

1 oz. fixed ammonia requires $\frac{0·3469 \times 56}{34}$
= 0·5712 oz. CaO.

The factor per gallon of gas liquor on the above given data is 0·5712 ÷ 1·352 = 0·42, or a factor per 100 gallons of 42.

Presumably the formula cited contemplates about a 50% excess of milk of lime. This is rather excessive as extended experience suggests that the whole of the fixed ammonia can be eliminated, given reasonable control with a surplus of milk of lime of 10—20% of the theoretical.

Coming now to the question of typical liming chambers, Fig. 20 shows a pipe bringing the gas liquor to be limed to the foot of the still, at which point the milk of lime is added. The steam inlet pipe is provided with four outlets two of which are placed tangentially, the other two being at right angles to the pipe. The baffle plates admit of considerable travel for ensuring uniformity of admixture.

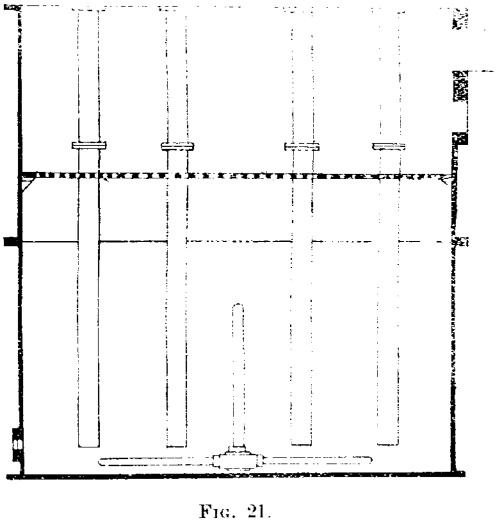

FIG. 21.

Fig. 21 represents another form of liming chamber. The liquor to be limed is brought to the foot of the still by four pipes and the milk of lime is admitted at the foot of the still, a suitable agitating steam pipe with radial arms being provided. The limed liquor ascends the liming chamber and is filtered through a perforated plate prior to being discharged to the fixed still. Whether blockages arise on the perforated plate is not known, but except the agitation is tolerably effective, it is feared that this may prove a possible source of difficulty, particularly so as the perforated plate is not too readily accessible.

Fig. 22 shows a simple form of liming chamber which intervenes between the free and fixed stills. The liquor to be limed enters almost at the foot of the chamber, at which point the milk of lime is

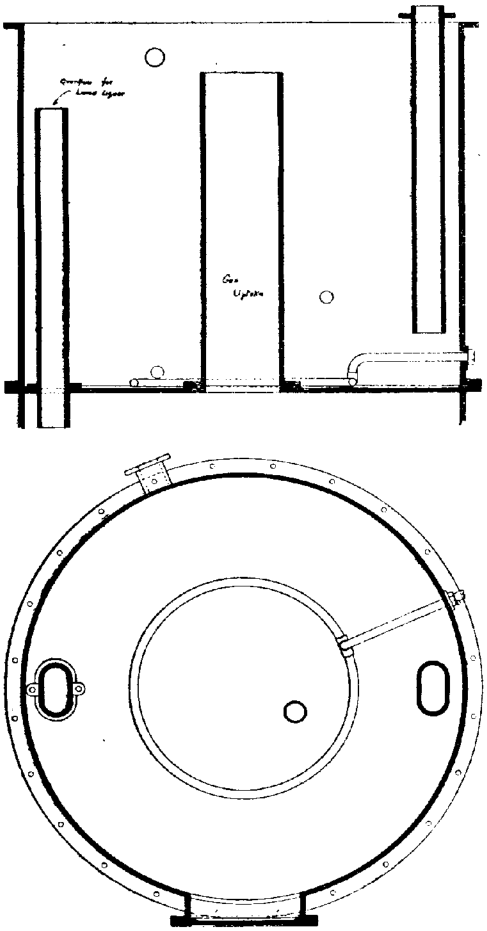

FIG. 22.

introduced. Agitation is created by a circular perforated pipe, the limed liquor leaving by the overflow pipe shown in the sectional elevation.

Fig. 23 represents another typical liming chamber having many features in common with those already described. It will be seen that this arrangement provides for the limed liquor passing to a chamber at the foot of the column before being led to the fixed still.

It is important that the gas liquor should be thoroughly decarbonated before entering the liming chamber, otherwise the ammonium carbonate will react with the milk of lime forming calcium carbonate, which becomes hard in the still and renders cleaning much more frequent and difficult.

Where the liming chambers are of tolerable size, provision should always be made for the periodic emptying of the liming chamber in order to remove the accumulations of lime sludge which settle out. Indeed, it has been found advantageous in the operation of many stills to run off part of the limed liquor from the liming chamber direct to the waste liquor main once or twice each day.

Manholes should also be provided in connexion with all liming chambers in order to afford access for cleaning purposes.

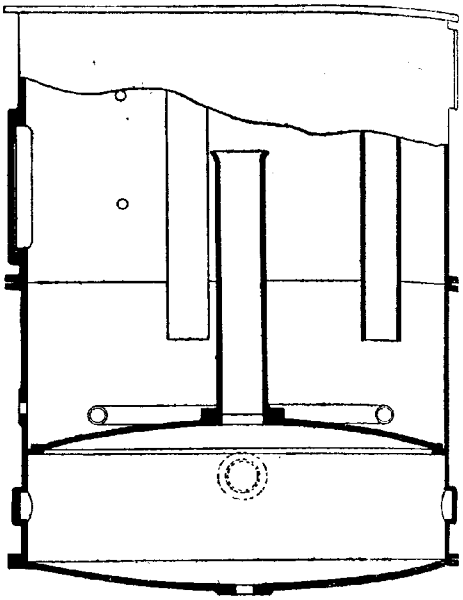

FIG. 23.

Seal pots.

To prevent the escape of steam etc. from the foot of the fixed still or fixed segment, it is necessary to provide some suitable seal pot or equivalent arrangement in order to ensure that the steam admitted to the fixed still will proceed through the several chambers and not by-pass the apparatus.

Constant steam supply.

The pressure against which the steam has to work in the fixed still, where usually 90% of the total steam is admitted, is the pressure of the combined seals in the several trays, plus the seal of the cracker pipes of the saturator, and the skin friction of the preheaters, coolers and pipe lines. This pressure will obviously vary with different stills, but usually does not exceed 3½ lb. per sq. in.

In the case of the steam admitted to the liming chamber, the pressure against which this will have to work will be of the order of 5–6 lb. per sq. in. It is clear, therefore, that some form of reducing valve must be used, in order to reduce the pressure at which the steam boilers normally work to a pressure compatible with the requirements of the stills.

Constant feed of liquor.

Many arrangements for ensuring a constant feed of liquor to ammoniacal liquor stills have been devised. Generally speaking, those having a float or suitable steel ball valve placed inside a small tank are the ones in operation in connexion with small and moderate sized distillation units. On the whole this type of constant feed arrangement has been found fairly satisfactory in operation. Some makers provide a graduated sight feed arrangement, consisting of a globe inside which is placed a pipe having a series of vertical stepped holes, graduated to represent varying rates of flow.

The only disadvantage of either of the above arrangements is the fact that the pressure against which the liquor is discharged is a slightly varying one, dependent on the depth of the acid seal in the saturator.

An arrangement for ensuring satisfactory and uniform feed in connexion with large units of plant provides for direct pumping of the liquor to the still, the rate of feed being governed by a cock to which is fitted a graduated quadrant and pointer. As a means of governing the delivery of liquor from the pump a connection is made from the delivery line to the suction, and inserted in this line is a spring-type of by-pass valve. The principle of this by-pass valve is that the liquor floats the mushroom valve against the pressure of the spring which can be adjusted.

Constant discharge.

This is dependent almost wholly on the maintenance of the two conditions to which reference has just been made. It has been found in practice that the setting of the outlet cock can best be adjusted by providing it with a graduated quadrant and pointer.

Prior to the admission of steam to the still for heating purposes it is important that all the trays should be sealed as well as the steam pipe or jets in the liming chamber and the fixed still. The heaters and coolers should also be filled with gas liquor and water respectively so as to prevent possible fracture of the pipes when the cold liquor is first introduced. Provision should be made for venting the air from the still. A suitable arrangement is to take a 1¼in. wrought iron pipe from the cast iron pipe leading from the still to the saturator, and provide this with a cock, allowing the discharged foul air to be emitted to the atmosphere.

The practice of venting a still inside the still-house is a dangerous one and should be discountenanced.

The gradual admission of steam to the still is important, particularly with the types of distillation apparatus which consist of a series of double-flanged pieces which are heavy in character. Such stills must be cautiously heated, otherwise the irregularities of expansion will cause fracture.

With a new still of tolerably large capacity at least twelve hours should be allowed for raising the temperature to the requisite degree for the admission of the gas liquor.

Thermometers should be provided, preferably fixed in suitable oil pockets, on the liquor inlet to the preheaters and on the outlet to the still, and similarly thermometers should be fixed on the waste gas inlet to the coolers and on the outlet.

It is also desirable to arrange a centrally situated gauge board so that the various pressures can be observed without difficulty by the operator of the plant.

It is equally important that each of the stills in the case of category A type of plant, and the columns in the case of categories B and C should be provided with an efficient safety valve, one form of which is of a simple spring type and can be easily adjusted and set to relieve at any predetermined pressure.

The heating of a still after temporary stoppage need not occupy more than four hours. After the top portion of the still has become warm, the cock of the vent pipe can be closed and the steam sent forward through the saturator, the cracker pipes in which have been sealed with mother liquor. It is important that the devil liquor outlet cocks should be opened immediately the heaters become warm in order to allow of the automatic withdrawal of condensation which must arise, due to the cooling influence of the gas liquor and water with which the heaters and coolers are filled.

Prior to feeding the still with gas liquor it is wise to pump, or gravitate, milk or cream of lime to the still, so that by the time the gas liquor is introduced, there is a complement of boiling milk or cream of lime in the liming chamber.

The raising of the temperature of the apparatus to this point is usually done with steam at boiler pressure, but immediately the liquor feed is commenced the reducing valve should be brought into operation by removing one or more of the weights on the spindle. The next step is to direct attention to the passage of the limed liquor to the fixed still, the connecting pipe to which is usually provided with a cock so that samples can be drawn from time to time. As soon as the limed liquor enters the fixed still a further and final adjustment of the steam reducing valve and the steam inlet valves to the stills is necessary.

Temperatures at the essential parts of the plant should be taken at regular intervals and should be recorded. Equally the liquor feed gauge board should be watched very carefully so as to make certain that a uniform feed is being obtained. Records of the liquor fed to the still should be made half-hourly.

It is usual to connect a cast iron pot to the fixed still, and to provide such pot with two vertical pipes, one of which is carried almost to the foot of the pot and which is provided above the pot with a glass tube suitably connected to give an indication of the working level of the still, the other pipe being attached to the cover of the pot in order to serve as a safety valve.

One other point of importance as affecting the operation of gas liquor stills has reference to the necessity for a uniform feed of devil liquor along with the gas liquor. It has been found that an indication of the uniformity of conditions is furnished by taking a continuous temperature record of the waste liquor leaving the still.

A continuous sample of the waste liquor leaving the still should be taken and a definite standard adhered to in this connexion. Experience suggests that 0·015% NH_3 in the waste liquor is an economic strength, as working below this limit simply resolves itself into the recovery of an exiguous amount of ammonia at the expense of labour in the operation of the plant. The devil liquor should be tested periodically from the points of view of its freedom or otherwise from ammonia and its volume. The presence of ammonia indicates that leakages are occurring, and these should be arrested at the very outset. An unduly large volume of devil liquor suggests a high consumption of steam in the distillation of the liquor, or otherwise the leakage of water in the coolers.

Early indications are furnished of the fouling of the stills by the necessity for reducing the volume of steam being introduced thereto, and it will be found, other things being equal, that the effluent liquor gradually increases in point of ammonia content. If tar accidentally becomes mixed with the liquor, in order to prevent this adversely affecting the working of the still, the preheaters and pipe lines to the still should be discharged, such discharged liquor being returned to a tank for separation or other suitable treatment.

In concluding these observations the author desires to summarise his views as to the direction in which progress in the design of ammoniacal liquor stills is likely to proceed in the future.

Designers must concentrate their attention and energies to the evolution of the elements of a still which will be economical as regards steam consumption. Data must be arrived at as to the relative value of attenuated bubbling, as compared with time contact of the liquid and the vapours as a factor in aiding equilibrium. Obviously distillation cannot proceed until the vapour pressure of the ammonia in solution in the trays is in excess of the vapour pressure of the ammonia in the vapours.

It should be possible to design such a form of bubbling device as will not only assist in promoting optimum bubbling, with maximum impact between the respective series of bubbles so formed, but that such an arrangement need not necessarily appreciably reduce the factor of time contact of the liquid and vapour. Such time contact can obviously be increased by allowing a tolerably large vapour space above the liquid in the trays.

Optimum bubbling is a function of a definite vapour velocity, which, when exceeded, will hold up the liquid and prevent contact between the vapour and liquid—in other words, will defeat its own object. This definite vapour velocity will differ in each compartment of the still, by reason of the varying vapour volumes, and instead of as at present the serrations, or perforations, of the bubblers being uniform in size, these must be modified in accordance with the varying volumes indicated.

As regards the utilisation of the surplus heat leaving the saturator, it is evident that the present arrangement of plant as generally known must be improved in order that more satisfactory conservation of the heat available can be ensured. There are several possibilities in this direction which must occur to one on careful consideration of the conditions obtaining.

Finally the author wishes to express his thanks to those chemical plant manufacturers and gas engineers who have kindly placed drawings and photographs of their stills and accessory plant at his disposal, without which the paper must obviously have been less comprehensive in its scope and data.

He also wishes to express his thanks to Dr. Carpenter and Mr. E. V. Evans, F.I.C. (the Chief of the Chemical Department), for their permission to publish certain experimental and other data embodied in the paper, and for their helpful guidance at all times.

His thanks are likewise due to Messrs. O. W. Weight, F. C. Snelling, and C. E. Parr for their assistance in the preparation of several of the drawings and diagrams, and for their helpful suggestions.

THE GENERAL PROBLEM OF EVAPORATION.

BY PROF. J. W. HINCHLEY, A.R.S.M., F.I.C.

[Abridged.]

The common meaning of the term "Evaporation" is the vaporisation of a liquid at some temperature below its boiling point, but in the technical sense the word may be considered to be synonymous with vaporisation.

The subject is a very difficult one and challenges the chemical engineer at every turn. It may be considered under two heads:—

(*a*) Evaporation below the boiling point of the liquid evaporated and

(*b*) Evaporation at the boiling point.

The study of the former has occupied the attention of meteorologists, physiologists and physicists to an extraordinary extent for many years, but unfortunately the work has rarely had any chemical engineering aspect, and its utility for this purpose is generally lost sight of.

Dalton, Apjohn, Maxwell and Stephan are the most celebrated of the host of workers who have studied this subject. Stephan showed that the rate of evaporation from a circular flush tank of radius a is given by the expression:—

$$4\ a\ k\ \log \frac{P - p_0}{P - p_1}$$

where

k is the coefficient of diffusion of the vapour,
P is the total barometric pressure,
p_0 is the partial pressure in mm. of Hg. of the vapour of the air,
p_1 is the partial pressure of water vapour at the temperature of the water surface.

If p_0 and p_1 are small in respect to P this formula becomes—

$$4\ a\ k \left(\frac{p_1 - p_0}{P}\right)$$

Such a formula is useless to the chemical engineer, since it is almost impossible of application. It states that the rate of evaporation is proportional to the linear dimensions of the tank.

A short experience with figures derived from industrial work rapidly proves that the rate of evaporation may be taken to be proportional to the area of the surface without serious error, provided that other factors such as the size, the ventilation and other points with respect to the factory are taken into consideration.

The urgent necessity some years ago of estimating the outputs of crystallising plant compelled the author to determine the rate of evaporation from water surfaces under ordinary factory conditions. The ordinary statement that the rate of evaporation in still air was proportional to the difference between the vapour pressure of the liquid and the vapour pressure in the air was found to be untrue, but a simple and reliable formula, at any rate for chemical engineering purposes, was found and adopted. The formula may be subject to criticism on account of its dimensions, but its utility justifies its existence. Since that date hundreds of experiments with simple apparatus have been carried out by the students of the Imperial College in the course of their training, and it is found that the rate of evaporation may be expressed by a simple formula:—

$$\text{Rate of evaporation in kilograms per sq. metre per hour from water surfaces} = \left(\frac{p_e - p_d}{50}\right)^{1 \cdot 2}$$

where

p_d = vapour pressure of the liquid in mm. Hg.
p_e = vapour pressure of the water vapour in the air in the same units.

This equation has been drawn in the form of a curve (Fig. 1), and as an alinement chart by Mr. Umanski (a former student of the Imperial College). Knowing the temperature of the water and the hygrometric state of the air, the formula enables one to determine at any instant the rate of evaporation from tanks of water in still air. With salt solutions it is obvious that the formula should give accurate results provided that the reduction of the vapour pressure of the solution through the presence of the salt be taken into account. These experiments have been made both with water and with salt solutions and compared with factory results. In general the agreement is good, but for estimating purposes the formula may be assumed to be 10% high.

When calculating the value of p for a salt solution using Raoult's law (the lowering of vapour pressure is proportional to the mol perunitage of the dissolved salt present), any dissociation of the salt should be taken into account.

Above 60° C. the experimental results are lower than those indicated by the formula owing to the fact that p_d is not the true vapour pressure in the air in immediate contact with the liquid. On the other hand the margin conditions modify the effect as between large vessels and small vessels to a small extent.

It may be remarked that since from a theoretical point of view the rate of evaporation in a still atmosphere should be proportional to the vapour pressure difference, some explanation of the index is desirable. The explanation seems to be that absolutely still air is impossible under the conditions, for moist air is lighter than dry air, so that convection must be a normal accompaniment of evaporation. Again, when there is a difference of temperature between the liquid and the atmosphere the convection effect must be still more evident.

Leonard Hill, in approaching the subject from a physiological standpoint, obtained a slightly different formula. He used a simple and ingenious instrument called a "Kata-thermometer," simply an alcohol thermometer with a large bulb which measures its own rate of cooling. By covering the bulb with a "muslin glove," after dipping the whole instrument in hot water, its rate of loss of heat could be determined in any air conditions imposed. He referred all his results to the temperature of the human body. It will be obvious that the area of surface of a "muslin glove" could not be a very accurate figure for our purpose, although it is remarkably valuable and satisfactory for physiological purposes. He obtained the formula—

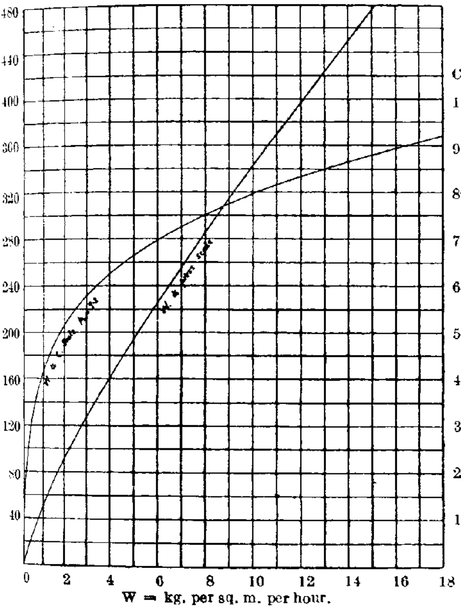

Fig 1.

$$E = 0{\cdot}085\left(p_e - p_d\right)$$

where E is the rate of evaporation loss in heat units—millicalories per sq. centimeter per second. It will be noticed that the index is $\frac{4}{3}$, not 1·2.

The work of Carrier in America calls for special mention, since he has approached the subject from a chemical engineering point of view and has obtained extremely useful results. His formula for evaporation in still air is—

$$R = 0{\cdot}093\ (e^1 - e)$$

where R is the number of pounds of water evaporated per sq. foot of surface per hour and e^1 and e are the vapour pressures of the liquid and in the air respectively in inches of mercury. Converted into metric units and using the same notation as before we get—

$$W = 0{\cdot}0178\ (p_e - p_d)$$

It will be noticed that 0·0178 is nearly $\frac{1}{56}$.

Effect of velocity.—The effect of a draught on the rate of evaporation from the surfaces of liquids has been investigated by many observers. There is a difference of opinion as to whether the rate of evaporation is increased in proportion to the velocity or in proportion to the sq. root of the velocity of the current of air.

Jeffries in 1918 discussed the subject mathematically and found that:—

(1) The rate of evaporation is proportional to the sq. root of the velocity.

(2) The total evaporation from surfaces of the same shape and orientation to the wind are as the $\frac{3}{4}$ powers of the respective areas.

The difficulties of ensuring that the current of air is parallel to the surface, that its velocity is uniform and is measured accurately, apart from the presence of disturbances and convection effects, make the problem extremely difficult.

Leonard Hill's experiment first led him to a formula involving the sq. root of the velocity, but he has now added to his "still air" formula the factor $0{\cdot}102V^{0{\cdot}3}$, where V is the velocity of the wind in metres per second. This would indicate that the rate of evaporation is doubled in a wind velocity of 0·55 metre per second.

It is obvious that the rate of evaporation will be greater for a wind impinging on a surface than for a wind parallel to a surface, and it is usually found that the rate is nearly doubled when the wind strikes the surface at a right angle. This would explain the high rate given by Hill's formula, since his "Kata-thermometer" exposes a large area of vertical surface.

Carrier states that the rate of evaporation is $3\frac{1}{2}$ times as great in a wind of 4000 ft. per minute velocity as in a wind of 1000 ft. per minute velocity, and the formula he adopts indicates that the increase in evaporation is proportional to the velocity. Converted into metric units his equation becomes—

$$W = 0{\cdot}0178\left(1 + \frac{v}{1{\cdot}17}\right)(p_e - p_d)$$

It will be seen that in a current of air parallel to the surface the evaporation is increased to twice that in still air at a velocity of 1·17 metres per second—almost exactly half that given by Hill's formula. The effect of changes in barometric pressure on the rate of evaporation may be allowed for by modifying the formula as follows:—

$$W = 26{\cdot}2\left(\frac{p_e - p_d}{P}\right)^{1{\cdot}2}$$

and if we adopt Carrier's figure for the effect of velocity on evaporation we obtain the following formula:—

$$W = 26{\cdot}2\left(1 + \frac{v}{1{\cdot}17}\right)\left(\frac{p_e - p_d}{P}\right)^{1{\cdot}2}$$

where, as before, W is the number of kilos of water evaporated per sq. metre of surface per hour, v is the velocity of air in metres per second, p_e and

p_d are the vapour pressures of the liquid and in the air respectively in mm. Hg. P is the barometric pressure in mm. Hg.

This formula can be approximate only, but under ordinary practical conditions where the temperature of the liquid is less than 60° C. the error should not be more than 10%.

The experimental work at the Imperial College has not reached the stage when this formula can be thoroughly criticised.

It is obvious that the formula must fail with high velocities of air current because saturation of the air will impose a limit—in fact, the straight line law suggested cannot be strictly true.

There are many applications of the fact that the rate of evaporation from a vertical surface is practically twice that for a horizontal surface—the conditions under which direct impingement of the current of air may readily take place.

In drying cakes of wet material the rate of drying is increased greatly by placing them on edge. One of the most successful air-drying peat processes depends largely on that fact.

With respect to the evaporation of liquids other than water, the rate of evaporation appears to be proportional to the molecular weight, and for liquids which are not associated the law may be stated—

$$W = 0{\cdot}48\,M\left(\frac{p_e}{P}\right)^{1\cdot2} \text{ (approximately)}$$

where

M is the molecular weight of the substance
p_e is the vapour pressure of the liquid
P is the barometric pressure.
W is the weight of liquid evaporated in kg. per sq. metre per hour.

Measurement of vapour pressure.—The accurate determination of the vapour pressure in the air is becoming more and more important as the effect of air-conditioning on the output of factories is becoming appreciated. The determination of the dew point directly is often in error through the temperature or heat gradient in the instrument being comparatively great. Fig. 2 shows a convenient dew point hygrometer designed by the author. The thin silver chamber is charged with ether and air drawn through it by means of a water pump or rubber bulb. The cooling produced by the evaporation of the ether lowers the temperature of the surface until dew appears. The flow of the pump is then reduced until the dew just disappears. The mean of the temperatures at which these phenomena occur is taken to be the dew point. Unfortunately, even if the experiment is performed very slowly, and although a reading of less than one-fifth of a degree can be obtained, the temperature gradient may produce an error of twice or three times that amount. This fact is due to the high surface resistance of even such a conductor as silver, so that the temperature of the thermometer for both readings may be as much as half a degree different from that of the surface upon which the dew is formed. By making the bulb of the thermometer the container for the cooling agent as well as the surface for the deposition of dew the effect of the temperature gradient may be eliminated and a very accurate result obtained.

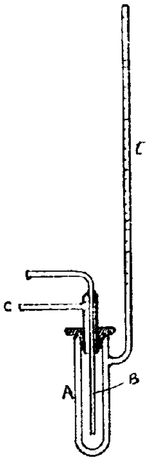

FIG. 2.

The dry and wet bulb thermometer appears to be the universal instrument of the factory for the determination of the hygrometic state of the air. A discussion of the instrument would be too long for this paper, but it may be stated that although it is nearly always inaccurate it is rarely misleading. In instruments where the bulbs are shielded and the air is drawn past the wet bulb by mechanical means most satisfactory results are obtained, but the ordinary stationary instrument is very unreliable.

The more recent electrical methods give excellent results, but if used without a complete knowledge of the principles involved may be very misleading.

Drying.—While the evaporation formula given are devised for use in cooling, crystallising, and concentrating operations, they may also be applied to drying operations in air dryers.

If the rate of drying does not exceed the rate of liquid diffusion through the material the rate of drying is nearly proportional to the perúnitage of "free" moisture present in the material. The texture and plasticity of the material affect this rate to an extent which cannot generally be estimated, and experimental tests for the determination of drying factors (the relation of the rate of drying of the material to the rate of drying of a water surface under the same conditions) are always necessary.

Knowing the maximum and minimum drying factors for the material in question and therefore the maximum and minimum rates of drying the logarithmic mean of these rates will give the average rate of drying. Since the determination of a logarithmic mean is one of the commonest calculations the chemical engineer must make I have ventured to submit a graphical method of determining it. If the smaller number be divided by the larger number and the fraction obtained be called "j," the logarithmic mean will be given by multiplying the larger number by the fraction:—

$$(1-j) \div \log_e 1/j$$

The values of this fraction are given by the curve (Fig. 3).

Boiling point evaporation.—In considering the subject of evaporation at the boiling point we meet with many new conditions and limitations to the rate of evaporation possible or desirable. A successful evaporating plant is one in which for a given quantity of heat supply the maximum rate of evaporation is produced at the minimum cost. On this account it is necessary to employ heating surfaces at their highest rates of working, to use sizes of vessels and pipe work so that for a given expenditure in capital, fuel and labour, the maximum amount of profit is obtained.

There is no question that the efficiency of chemical plant is capable of enormous improvement by the application of sound chemical engineering science both in design and operation. Few are aware to what a considerable extent this improvement may be carried.

The rate of heat transmission in evaporating plant from steam to water solutions may vary in the same kind of plant from 300 to over 3000 calories per sq. metre of surface per hour per 1° C.

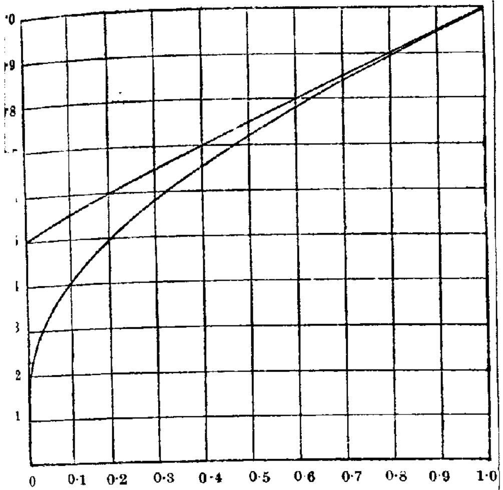

Fig. 3.

temperature difference. This simple fact illustrates the possibilities of sound chemical engineering.

In plant in which evaporation takes place from the surface it is obvious that the area of that surface should bear some relation to the amount of evaporation. The equation we have already discussed fails when $p_e = P$ (*i.e.*, at the boiling point), but it suggests that at the boiling point of water the rate of evaporation in still air would be about 26 kg. per sq. metre per hour and that such an evaporation would be produced from water without any disturbance of its surface, that is, without any boiling. This figure seems to indicate the rate of evaporation from any water solution at which no difficulties from frothing, entrainment, or other troubles could occur.

The maximum rate at which evaporation might take place from an evaporator is not easy to determine, but everyone who has had charge of evaporators or stills will have experienced the effect of projection of the liquid from the still, either as a whole or by frothing or by ordinary entrainment. The designer of the plant, however, must fix a limit to the rate of evaporation from the surface in his particular apparatus, and it has been the author's practice to suggest the figure of 250 kg. per sq. metre per hour. In rectifying plant, where entrainment must be avoided at all costs, this rate should not exceed 100 kg. per sq. metre per hour. These figures do not represent the maximum rate at which any apparatus may be worked, but they do give a convenient design figure.

In that type of evaporator in which the liquid is forced through tubes and the contents of the tube are projected into the chamber in which separation of liquid and vapour may take place, this limitation of area does not arise. In this type we obtain a more or less fine spray in which the convex surfaces of the drop present a maximum area and the best conditions for vaporisation. On the other hand, however, frothing of the liquor may impose a working limit.

An interesing feature about frothing is the fact that there is generally a critical rate above and below which the plant may be worked without any trouble from this source.

An effective "save-all" or arrangement for the separation of spray from vapour makes the question of area of pan of less importance, but it is always desirable to measure the amount of entrainment, which is occasionally excessive.

In most commercial plants it is obvious that the limitation of the rate of evaporation is mainly a question of heat transmission. On this subject it is quite easy to produce observations which are mutually contradictory, unless one takes into account secondary effects which are neglected and generally misunderstood.

It is generally assumed that the rate of heat transmission through any given surface is proportional to the temperature drop, and this assumption enables the chemical engineer to make calculations for design purposes which are usually satisfactory in practice.

It has been stated by many observers that the rate of heat transmission per degree Centigrade of temperature difference per unit of surface increases with the temperature drop. On the other hand, there are quite a number of observations which would suggest that the rate of heat transmission is greater with small temperature drops.

In many experimental results the figures obtained are simply measures of the rate of supply of heating agent to the apparatus, the capacity of the pipe-work to supply steam, etc.

Contradictory results may be explained by simple physical facts that have been overlooked, errors in determination of mean temperature and temperature differences etc.

A few preliminary experiments at the Imperial College gave curves of heat transmission which could only be expressed by a cubic equation. It is obvious that contradictory conclusions could easily be drawn from such experimental results if they had not been carried far enough to reveal their character.

A slight consideration of heating by steam is all that is possible in this paper.

The rate of heat transmission from steam to boiling liquids is determined mainly by :—

(a) temperature drop and temperature level.

(b) the velocity of the liquid and of the heating steam.

(c) the density and viscosity of the liquid.

(d) the resistance of the surfaces and scale.

(e) the resistivity of the material of which the heating surface is made.

The work of Badger and others in American Universities is very valuable on these points.

Temperature drop.—There is little doubt that the rate of heat transmission is not strictly proportional to the temperature drop; but since the amount of mechanical disturbance bears some relation to temperature drop and temperature level, and is limited by the construction of the plant, no mathematical relation is possible except for a particular design. It is found that with a particular type of plant or at a particular temperature level, a certain temperature drop will give a maximum rate of heat transmission. At high temperature levels this drop will be greater than at low temperature levels and with high hydrostatic heads greater than with low hydrostatic heads. With film evaporation this drop is smallest.

Velocity effect.—The effect of temperature drop and temperature level is bound up with (b) the effect of the velocity of the liquid and of the heating steam.

The effect of velocity on increasing the rate of heat transmission is well known, but full scientific knowledge is not available.

Scale.—The effect of density and viscosity of the liquid on the heat transmission will be obvious without discussion, but much experimental work is needed on this point. The resistance of the metallic surfaces and of any scale formed is perhaps more important to the user than any other point. To keep clean the heat transmitting surfaces of a plant is not a question for the chemical engineer only, but for the chemist as well. The chemist can often prevent the formation of a hard scale by slight modifications of the process. The chemical engineer in charge is often powerless, and can only stop for cleaning at definite intervals—with most plants the best solution of the problem is only obtained by the assistance of the chemist.

Where the circulation is high and the heating surfaces are well submerged scale to a minimum is produced. It may be mentioned that the presence of fine solids in a well circulating evaporator will often keep the surfaces clean.

Material.—Although the effect of the heat resistivity and thickness of the material of the heating surface is much smaller than the other factors, it must not be neglected. Rates of heat transmission of over 3000 are not possible except with good heat conductors.

Multiple evaporation.—It will be realised that owing to the high latent heat of water the cost of evaporating water is very high. By using the evaporated steam as the heating agent in another apparatus a large portion of this latent heat may be recovered and a further evaporation obtained, and so on. This is the well-known system of multiple effect evaporation.

The heat pump.—Early in the last century, it was suggested that by compressing the evaporated steam, its temperature could be raised and it could be used in the same evaporator as heating steam. Siemens tried this plan in 1868, but on account of the low efficiency of compressors of his day the experiment was a failure. To-day four or five firms are making plant on this principle.

On account of the immense improvement in efficiency of electrically-driven turbo-compressors, and also by the use of high pressure steam injector compressors, a considerable amount of success has been obtained

It will be realised that in this form of evaporation the condenser is the heating surface itself and is at a higher temperature than the liquid in the evaporator. Of course, the condensed water from the heating surface is used in a heat-exchanger for heating the in-coming liquid.

Provided that the temperature rise is small, about 5° C., the efficiency of the "heat pump" is sufficiently good. By the turbo-compressor, about 10% heat efficiency is obtained and by the injector probably over twice this amount.

It is obvious that on account of the small temperature difference (3° C. or 4° C.) the method cannot be used efficiently for concentrated salt solutions and that in any case special methods must be used for obtaining a high coefficient of heat transmission. In the Söderlund and Boberg evaporator the liquid is allowed to flow in a thin film down vertical tubes. In the Prache and Bouillon evaporator, mechanical means are adopted to move the liquid at a high speed and a very high coefficient is obtained.

Communications.

THE HEAT DEVELOPED ON MIXING SULPHURIC ACID, NITRIC ACID, AND WATER.

BY J. W. McDAVID, D.SC., F.I.C.

It is well known that when sulphuric acid or nitric acid and water are mixed heat is developed, and that the actual amount of heat depends on the initial and final concentrations of the acid solution. The quantity of heat generated has been determined in the case of mixtures of sulphuric acid and water and of nitric acid and water by Thomsen (Thomsen's "Thermochemistry," translated by K. A. Burke, p. 76). Thomsen's results put in slightly different form, are given in Tables 1 and 2, while they are shown graphically in Fig. 1.

Similar data for mixtures of sulphuric acid, nitric acid, and water are very often required in connexion with the designing of cooling plant employed in acid mixing, but hitherto, with the exception of results determined for a few special cases, such information has not been available. It was evident, however, that, with the assistance of the figures given in Tables I. and II., a very few series of experiments would give a sufficient number of results to enable a diagram to be constructed which would be of considerable assistance in heat problems dealing with acid mixing or acid distillation.

As a triangular diagram is the most suitable method of representing results for mixed acids, the data given on the H_2SO_4—H_2O and HNO_3—H_2O graphs in Fig. 1 were first of all transferred to the triangle in Fig. 2. For this purpose the percentages of sulphuric acid in 1 g. of solution, which hen produced from pure acid and water give 10, 20,), etc. g.-calories of heat, were read off from the aph and plotted along the side H_2SO_4—H_2O of ie triangle in Fig. 2. Similarly the results refer- g to mixtures of nitric acid and water were read ff from Fig. 1 and plotted along the side HNO_3—$_2O$ of the diagram in Fig. 2. The points repre- enting 10, 20, etc. calories were marked with the ppropriate number.

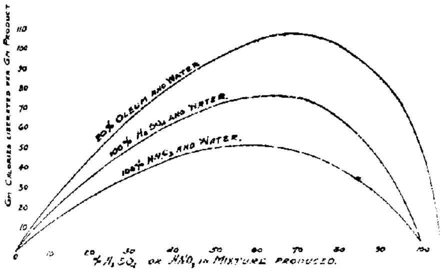

Fig. 1.

Graphs showing heat developed on mixing pure sulphuric id, or 20% oleum, or nitric acid with water. Calculated from ta given by Thomsen (Thermo-Chemistry, p. 76) and Porter rans. Faraday Soc., **13**, 373).

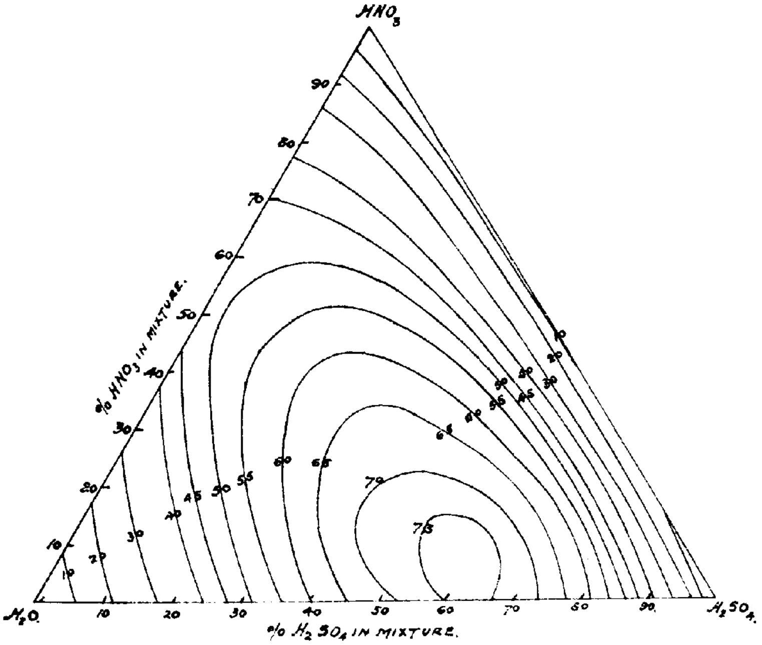

Fig. 2.

Heat developed in g.-calories per g. of product when mixed acid is produced from 100% H_2SO_4, 100% HNO_3, and H_2O.

Next, in order to obtain similar points inside the riangle, it was necessary to determine the heat leveloped in producing mixed acids of various com- ositions, and for this purpose mixtures of the fol- owing acids were employed:—(1) 49·2% HNO_3 and 6·16% H_2SO_4. (2) 20·0% HNO_3 and 96·16% H_2SO_4. 3) 96·8% HNO_3 and 60·0% H_2SO_4. (4) 96·8% HNO_3 nd 99·5% H_2SO_4. (5) Mixed acid containing 9·8% H_2SO_4, 48·4% HNO_3, 1·8% H_2O, and water.

The experiments were carried out in the silvered glass vessel of an ordinary vacuum flask. In each experiment 400 g. of mixed acid was prepared by placing one of the constituents in the flask, noting its temperature, bringing the other constituent to the same temperature, then adding it to the liquid in the flask and noting the rise in temperature.

In order to calculate the heat developed, a knowledge of the specific heats of the mixtures, over the temperature range employed, is necessary, but such data are not available. The specific heats of mixtures of sulphuric acid, nitric acid, and water at 20° C. have, however, been determined by Pascal and Garnier (Bull. Soc. Chim., 1920, 18) and the results obtained by them have been used in calculating the quantity of heat liberated. From one or two isolated specific heat determinations carried out at higher temperatures it is evident that the error introduced in this manner is negligible for all practical purposes.

The method of calculating the amount of heat developed can be best explained by means of an actual example. When 250 g. of 49·2% nitric acid and 150 g. of 96·16% sulphuric acid were mixed there was a rise in temperature of 49·2° C. The water equivalent of the calorimeter was 17 g. and the specific heat of the resulting mixed acid was 0·573. The heat actually evolved was therefore $(400\times0{\cdot}573+17)\times49{\cdot}2=12113$ g. calories. But this is only the heat evolved in producing the mixed acid in question from 49·2% nitric acid and 96·16% sulphuric acid, and to obtain the total heat evolved in producing the mixed acid from 100% sulphuric acid, 100% nitric acid, and water, it is necessary to add to the above figure the heat already developed in producing 250 g. of 49·2% nitric acid and 150 g. of 96·16% sulphuric acid.

Now from Fig. 1 the heat developed in producing 1 g. of 96·16% sulphuric acid from H_2SO_4 and water is 19·5 calories. Hence the heat developed in producing 150 g. of 96·16% sulphuric acid is 2925 g.-calories.

Again, from Fig. 1 the heat developed in producing 1 g. of 49·2% nitric acid from the 100% acid and water is 47·8 g.-calories, and therefore the heat emitted in producing 250 g. of 49·2% nitric acid is 11,950 g.-cals. Hence the total heat emitted in producing 400 g. of the mixed acid in question from 100% H_2SO_4, 100% HNO_3, and water is 12113+2925+11950=26988 g.-calories or 67·5 g.-calories per g. of mixed acid produced.

All the results given below were calculated in this manner.

The details of the experiments carried out and the results obtained are given in Tables III.—VII.

If the figures in the last column of Table III. are plotted against the percentage of sulphuric acid given in column 3, a graph will be obtained from which the mixed acids corresponding to 10, 20, 30, etc. calories can be read off. These points can then be marked on Fig. 2. The results in Tables IV.—VII. can be treated in the same manner and when the points are plotted on Fig. 2, curves can readily be drawn through corresponding points. Fig. 2 shows the completed diagram. The curves in most cases pass through all the corresponding points which were determined by experiment and interpolation. Each curve in the diagram is marked with a number, which denotes the number of g.-calories evolved when 1 g. of any acid situated on the curve is produced from 100% sulphuric acid, 100% nitric acid, and water. The heat evolved in the production of 1 g. of any acid which is situated between two of the curves can, of course, be obtained by interpolation.

The diagram in Fig. 2 can be employed for solving many problems in connexion with acid mixing, but a great many problems, for which Fig. 2 is of no assistance, are connected with the mixing of oleum with other acids. It is therefore convenient to construct from the data already obtained curves showing the heat developed when 1 g. of mixed acid of any composition is produced from, say, 20% oleum, 100% nitric acid, and water. In order to do this it is necessary to know in the first place the heat developed in making any strength of sulphuric acid from 20% oleum. Porter (Trans. Faraday Soc., 13, 373) has dealt exhaustively with the heats of dilution of oleum and sulphuric acid, and the oleum-water graph in Fig. 1 has been compiled by combining his figure for the dilution of 20% oleum to 100% H_2SO_4 with Thomsen's results in Table I. From this graph the percentages of sulphuric acid in 1 g. of solution which when produced from 20% oleum and water will generate 10, 20, 30, etc. g.-calories can be read off and plotted along the H_2SO_4—H_2O side of a triangular diagram. The figures on the HNO_3—H_2O side of the diagram are exactly the same as in Fig. 2 and the points within the triangle can all be obtained by calculation from the data given in Tables III—VII. The finished diagram is given in Fig. 3 and will be found to give the same results as Fig. 2 in such problems for which either can be employed.

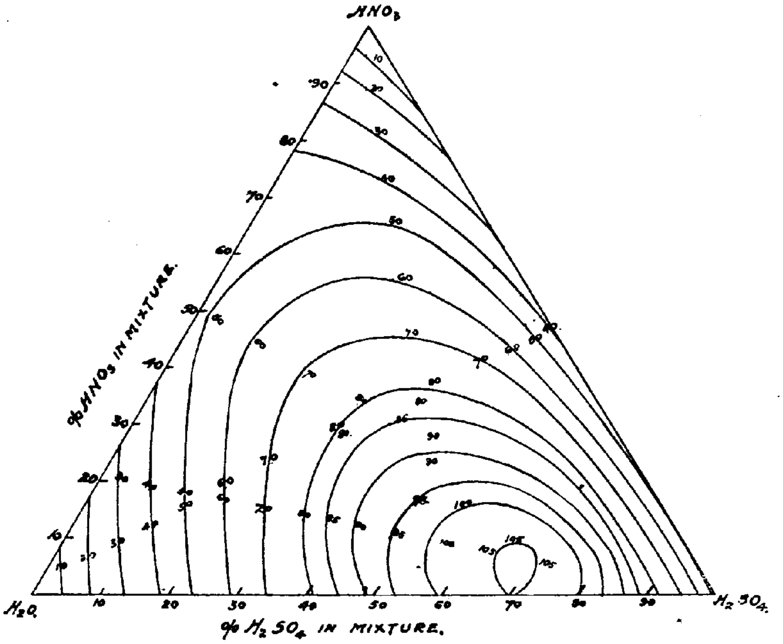

Fig. 3.

Heat developed in g.-calories per g. of product when mixed acid is produced from 20% oleum, 100% HNO_3, and H_2O.

Similar diagrams can be constructed starting with any strengths of oleum or nitric acid.

Use of the diagrams in Figures 2 and 3.

The diagrams in Figs. 2 and 3, especially the latter, are necessary for the solution of all heat problems in connexion with acid mixing. Suppose, for example, that weak nitric acid is to be added to C.O.V. to form mixed acid, and it is desired to know the quantity of heat that will be generated, the result can be obtained with little trouble from either Fig. 2 or Fig. 3. As one illustration of the use of the diagrams this problem is worked out in detail below.

Again, the heat generated in the production of nitroglycerin mixed acid from oleum and nitric acid can be determined without difficulty. The diagrams can also be employed to solve thermal problems in connexion with acid distillation or denitration.

Two examples of the use of the diagrams are given below.

Determination of heat generated in mixing 96% sulphuric acid and 65% nitric acid to produce mixed acid containing 64% H_2SO_4, 21·7% nitric acid, and 14·3% H_2O.

Calculation shows that to make 100 parts of mixed acid of the above composition 66·7 parts of 96% sulphuric acid and 33·3 parts of 65% nitric acid are required.

Now in the production of 100 parts of the mixed acid from sulphuric acid, nitric acid, and water the heat generated = 100×57 g.-calories (see Fig. 2) = 5700 g.-calories. But the heat generated in making 66·7 parts of 96% sulphuric acid from H_2SO_4 and water = 66·7×20 g.-calories (see Fig. 1) = 1334 g.-calories. Also heat generated in making 33·3 parts of 65% nitric acid from HNO_3 and water = (33·3×47·5) g.-calories (from Fig. 1) = 1583 g.-calories. Hence heat generated in producing 100 g. of mixed acid from 66·7 g. of 96% sulphuric acid and 33·3 g. of 65% nitric acid = (5700 − 1334 − 1583) = 2783 g.-calories = 27·8 g.-calories per g. mixed acid.

The above problem can also be solved by using Fig. 3 instead of Fig. 2, as follows:—

In the production of 100 parts of mixed acid from oleum, nitric acid and water the heat generated = 100×88·0 (Fig. 3) = 8800 g.-calories. But heat generated in making 66·7 parts of 96% sulphuric acid from oleum and water = 66·7×66·5 = 4435 g.-calories (Fig. 1), and heat generated in making 33·3 parts of 65% nitric acid from HNO_3 and water = 33·3×47·5 = 1583 g.-calories. Hence heat generated in producing 100 g. of mixed acid from 66·7 g. of 96% sulphuric acid and 33·3 g. of 65% nitric acid = 8800 − 4435 − 1583 = 2782 calories = 27·8 calories per g. of mixed acid.

In order to calculate the temperature rise it is only necessary to divide the result obtained above by the specific heat, which is 0·45. Hence temperature rise in this case = 27·8 ÷ 0·45 = 62° C.

Determination of heat liberated in the production of mixed acid containing 58% H_2SO_4, 40% HNO_3, and 2% H_2O from 20% oleum and 90% nitric acid.

Calculation shows that 55·5 parts of oleum and 44·5 parts of 90% nitric acid are required to produce

100 parts of mixed acid of the above composition. Now, from Fig. 3, in the production of 100 g. of the mixed acid from 20% oleum, anhydrous nitric acid, and water, the heat generated = (100 × 49) = 4900 calories. But from Fig. 1 the heat developed in producing 44·5 g. of 90% nitric acid from anhydrous nitric acid and water = 44·5 × 23·3 = 1037 calories. Hence heat liberated in producing 100 g. of mixed acid from 20% oleum and 90% nitric acid = 4900 − 1037 = 3863 = 38·6 calories per g. of mixed acid.

In conclusion, the author desires to thank the management of Messrs. Nobel's Explosives Co., Ltd., for permission to publish these results.

Stevenston, Ayrshire.

ELECTRIC HEATING AND CONTROLLING APPARATUS FOR A SMALL THERMOSTAT.

BY S. O. RAWLING, B.SC., A.I.C.

(*Communication No. 23 from the British Photographic Research Laboratory.*)

In working with automatically regulated, constant-temperature baths, it is frequently found that to change from one temperature to another involves troublesome readjustments of heat supply and regulating gear. The apparatus to be described has been devised with a view of overcoming this difficulty, within the temperature range from 25° to 40° C.

Electrical heating and controlling is employed, and the general principle of the apparatus is illustrated diagrammatically in Fig. 1. Current is supplied from the direct current power mains.

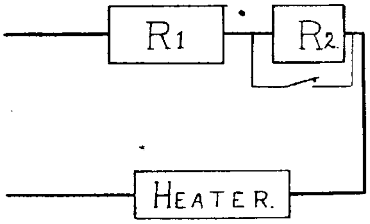

FIG. 1.

A thermo-regulator controls a device whereby the resistance, R_2, is short-circuited when the temperature of the bath falls below its working level. The resistance, R_1, is adjusted so that when current is passed through it and the heater alone, more heat is supplied by the heater than is necessary to keep up the temperature of the bath. The second resistance, R_2, is of such a value that when the short-circuit is broken, the total resistance causes the rate of heat supply to become too small to keep the temperature up to its working degree.

The thermo-regulator (Fig. 2) consists of a large bulb, A, from the neck of which a side arm, B, slopes downwards and connects it with the middle of the U-tube, C. The U-tube itself is divided into two parts by a seal, D, through which a platinum wire is fused. The arm, F, of the U-tube is provided with a short length of capillary tubing of about 1 mm. bore. A side tube, G, is fitted above the top of the capillary and a rubber stopper, H, fitted in the widened end of the U-tube, carries a platinum electrode mounted in a glass tube. The end of the electrode projects about 1·5 cm. into the capillary tube. The upper end of the tube leading from the top of the main bulb is closed by a glass tap, K, with a fairly wide bore. It is essential that the plug of this tap should be very well fitted.

To fill the regulator, clean mercury is poured into the U-tube so that its level is about halfway up the capillary tube; G is then closed by a rubber tube and clip. The working fluid—saturated calcium chloride solution or toluene—is next poured into the main bulb by means of a funnel of which the neck has been drawn out so that it can be passed through the bore of the tap.

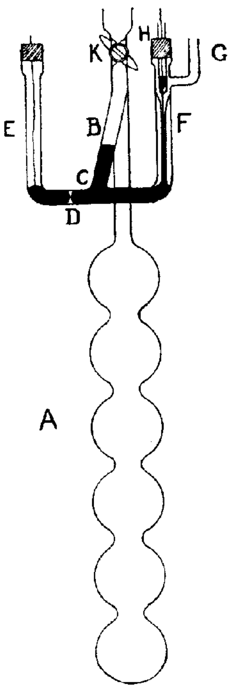

FIG 2.

Electrical terminals are provided on one side by a copper wire dipping into mercury placed in the arm, E, of the U-tube and on the other by a wire dipping into mercury in the electrode tube fitted through the stopper, H.

Adjustment is effected by heating the bath to its working temperature with the tap, K, open. Towards the end of the heating, the rate of supply of heat is reduced to ensure that the liquid in the bulb has attained the temperature of the bath. The tap is then turned off and the electrode tip is adjusted to the surface of the mercury* in the capillary with the arm, G, open. This regulator works well, and for a working temperature of 25° C. is capable of keeping the temperature of a bath containing about 27 litres of water constant to ±0·02° C.

The arrangement of the short-circuiting relay, resistances, and switchboard is shown in Fig. 3.

Carbon-filament lamps are used as resistances. Provision is made for varying these resistances by placing two bayonet sockets in parallel for each resistance. By using different combinations of lamps, a considerable range of resistances may be covered. The relay itself is part of an electric bell, and consists of the electromagnet, A, armature and spring, C, and the contact point, B. When no current is passing through the magnet coils the spring of the armature makes contact at B and so the resistance, R_2, is short-circuited through the spring to B and the small resistance, R_4, which is a toy resistance of 7 ohms placed in series with the principal circuit. When the temperature of the bath rises so as to make contact between the mercury and platinum in the thermo-regulator, current will flow round the magnet coils and the contact at B will be broken. The main current must then flow through R_1 and R_2 in series and in this way the current through the heater is diminished.

---

* In cases where the temperature need not be adjusted nearer than 0·1° C. it is unnecessary to make a fine adjustment of the electrode point.

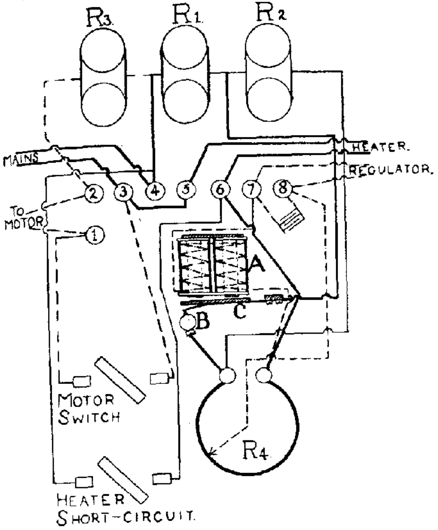

FIG. 3.

The terminal board is made up of fibre, and the variable resistance, R_4, is mounted on a block of the same material. In making up this board it is advisable to number the terminals as shown in Fig. 3. The wiring is then an easy matter.

Efficient stirring is provided in the thermostat bath by means of a centrifugal stirrer driven by a small motor. A switch is provided on the terminal board to control the motor, which takes its current from the mains through a lamp resistance, R_3.

In order to heat the bath quickly from room temperature a switch is arranged to short-circuit both resistances, R_1 and R_2, and so allow the heater to develop its full power.

The heater actually in use at present is a nickel "hot point" immersion heater capable of supplying 300 watts; it has a resistance of about 160 ohms, and works on the 210-volt circuit.

As an example of the method of calculating the resistances necessary for R_1 and R_2 the following case may be taken:—

The thermostat consists of a tank of copper,† 30 cm. cube, lagged round the bottom and sides with thick felt. A glass window 20 cm. by 22·5 cm. in each of the opposite faces is left uncovered. The top of the tank is open. A cooling curve was plotted to find roughly how much heat per second must be supplied in order to keep the temperature up to any desired degree. The volume of water in the tank is about 27 litres. With the room at about 15° C. and the bath at 25° C. the heat lost per second is about 12·4 calories. This is equivalent to 52 watts. It is then necessary to choose R_1 and R_2 so that with the voltage across the mains (in this case 210 volts) the power developed in the heater when R_2 is short-circuited is about 70 watts and when R_1 and R_2 are in series, about 30 watts.

As already stated, the resistance of the heater is about 160 ohms. Thus the current required to develop the necessary power in the heater can be calculated. Heat developed per second in a conductor of resistance R ohms carrying current C amps. $= C^2R$ watts. When R_2 is short-circuited, $C_1^2 \times 160 = 70$, where C_1 is the current in ampères necessary to give 70 watts in the heater. Hence $C_1 = 0{\cdot}665$ amp. When R_1 and R_2 are acting in series, $C_2^2 \times 160 = 30$, where C_2 is the current necessary to give 30 watts in the heater, whence $C_2 = 0{\cdot}434$ amp.

The values of R_1 and R_2 can now be calculated. $0{\cdot}665 = 210 \div (160 + R_1)$ whence $R_1 = 157$ ohms (approx.), $0{\cdot}434 = 210 \div (160 + 157 + R_2)$ or $R_2 = 167$ ohms (approx.).

The resistances chosen were as follows:—R_1: two 32-candle-power 200-volt carbon-filament lamps in parallel; net resistance about 150 ohms. R_2: a single 16-candle-power 105-volt carbon-filament lamp; resistance about 160 ohms.

The lamps used for the various resistances must be able to withstand the voltages which occur across them. The conditions obtaining in the present arrangement are as follows:—When R_2 is short-circuited, the voltage across R_1 is 100 volts, across the heater 110 volts, and across R_2 nil. When R_1 and R_2 are in series the voltage across R_1 is 67 volts, across the heater 73 volts, and across R_2 70 volts.

The use of lamps for resistances in circuits that are made and broken frequently has the advantage that very little sparking occurs at the contacts. As has been shown, the voltage drop across the short-circuiting device and its contact breaker amounts only to about 70 volts in the particular case given. The sparking occurring is hardly perceptible. The only part of this apparatus having large self-inductance is the electro-magnet of the relay. In order to cut out the sparking at the platinum and mercury contact in the regulator, a small induction coil condenser has been placed across the regulator terminals, 7 and 8 (Fig. 3).

To estimate the resistances of carbon filament lamps the catalogue values of nominal candle-power and voltage are used. The consumption per nominal candle-power may be taken as about 4·3 watts for these lamps. From this the watts consumed by any lamp working at its correct voltage may be calculated and the resistance of the lamp is then calculated from the formula $R = E^2/W$, where R = resistance in ohms, E = voltage (catalogue value), and W = watts consumed.

The apparatus has worked very well for six months. The lamp combinations for R_1 and R_2 necessary for various temperatures have been worked out, and so to change from one temperature to another takes only as long as is necessary actually to bring the temperature of the bath itself to the new one required.

In conclusion the author wishes to express his thanks to Dr. T. Slater Price and to Dr. G. I. Higson for much help and advice in the working out of the details of this apparatus.

THE DETERMINATION OF SULPHUR IN VULCANISED RUBBER.

BY J. W. W. DYER, M.SC. (LOND.), AND AMY R. WATSON, B.SC. (LOND.).

In the course of endurance tests on a large number of rubber-proofed balloon fabrics it was necessary to make chemical analyses of the proofings.

The methods which will be described have been tried only on vulcanised rubbers suitable for this kind of material, *i.e.*, on mixings containing usually little more than 5% of ingredients other than rubber, of which 1—3% may be sulphur, but there is no reason for supposing the usefulness of the method is limited in application to such mixings. For the purpose in view, a knowledge of the amounts of free and combined sulphur was desired. It was always preferable, and often necessary, to work on the proofed textile itself, and not on scraped-off proofing, and the oxidation of a large amount of organic matter with a very small weight of sulphur was thus involved. This necessity limits the agreement obtainable with repeat tests, because of slight uncertainty as to the weight of the textile components. It does not, however, affect the figures given in this paper.

---

† With electrical heating, a glass battery jar, inverted bell jar, or even a large beaker might be used instead of a metal tank.

A review of available methods, and some preliminary experiments led to adoption of a modified form of the nitric acid process.

Method for combined sulphur.—The modification of the simple nitric acid treatment consists in the addition, in the later stages, of small amounts of potassium permanganate, to complete the oxidation in a shorter time. From 0·5 to 3·0 g. of material (depending on whether rubber alone, or rubber on textile is being used) is added to 30—40 c.c. of nitric acid, sp. gr. 1·42, in a suitable open flask. Gentle heat starts the reaction, which may at first need restraint by cooling. Subsequently the mixture is heated to gentle boiling, with a funnel in the mouth of the flask, and the boiling continued till the liquid is clear. Powdered pure potassium permanganate is now added to the slightly cooled liquid, about 0·25—0·5 g. at a time, and the heating continued between the additions. The first rapid disappearance of the permanganate soon slackens, and finally a permanent black precipitate is obtained on further addition of a little permanganate: usually about 2 g. in all is required. The contents of the flask are transferred to a basin, and evaporated to dryness once, and then again after addition of about 10 c.c. of concentrated hydrochloric acid and a little water. The residue is treated with water, brought to a bulk of 100 c.c., and made just acid to methyl orange at boiling point. Since small amounts, usually less than 0·1 g., of barium sulphate are involved, great attention to the conditions of precipitation is necessary; particularly the free acidity and bulk of liquid should be kept low. It is usually necessary to filter from a few specks of insoluble matter before precipitation, but perfectly clear, colourless solutions, filtering quickly, are always obtained.

Although, as stated, the method is intended, and is normally used for combined sulphur only, we have found it satisfactory for total sulphur where the amount of free sulphur is not large. The following figures exemplify results obtainable by this and other methods:—

Example 1.—Total sulphur in a proofed fabric. Nitric acid only, 2·05% S; bromine plus nitric acid plus potassium permanganate to finish, 2·09% S; nitric acid plus potassium permanganate to finish, 2·15% S.

Example 2.—Total sulphur in a proofed fabric. (*a*) Two tests by nitric acid—permanganate method on the whole fabric gave 2·49, 2·55%—mean 2·52%. (*b*) Two tests by Carius' method on peeled-off proofing gave 2·17, 2·25%—mean 2·21%. (*c*) A considerable amount of free sulphur is present in the textile of new proofed fabrics. A determination of this in the cotton enclosing 100 g. of rubber gave 0·35 g. Adding this to result (*b*) the figure 2·56% is obtained, in good agreement with direct determination (*a*), viz., 2·52.

Example 3.—On a vulcanised mixing, rubber 100, litharge 3, sulphur 3 (total sulphur content 2·83%) the results obtained were:—With nitric acid alone, 2·38, 2·54—mean 2·46%; nitric acid plus permanganate, 2·90, 2·96—mean 2·93%.

Example 4.—On a mixing made as Example 3, but with double the quantity of litharge, the Carius method gave 0·1030 g. $BaSO_4$, and the nitric acid and permanganate method 0·1021, 0·1024 g.

Method for free sulphur.—By the term "free sulphur" is meant that extracted by acetone at or near its boiling point. It is determined by oxidation with neutral potassium permanganate in the acetone solution. If the weight of the acetone extract is required, either the acetone is distilled off, the dry extract weighed and redissolved for oxidation of the sulphur, or else two separate extractions are made, one for oxidation direct, and one for drying and weighing. In the case of normal new fabrics, an amount equivalent to 1—2 g. of proofing is used. In the apparatus employed, about 50—60 c.c. of acetone is required, and to this acetone extract 0·5—1 g. of pure potassium permanganate is added all at once in powder form, the mixture shaken round for a minute or two, and allowed to stand for half an hour or so at room temperature. If the deep purple colour disappears on this treatment a little more permanganate is added, but this has only been found necessary where much oxidation resin is present, as in perished proofings, and then the determination of free sulphur is largely meaningless. Following this the acetone is distilled off from a water bath. To prevent bumping, which may cause serious loss, a glass bead is put in. The brown residue is heated in an oven for a short time at 100°—110° C. to remove every trace of acetone.

Concentrated hydrochloric acid is then added in amount* only slightly in excess of that required to bring the residue to a clear dark greenish solution, becoming colourless on heating for a short time in the water bath. This solution is diluted a little, and filtered from a very slight insoluble residue. The filtrate is brought to near 100 c.c., ammonia cautiously added till the clear nearly colourless solution becomes yellowish and slightly turbid, the solution made just acid and precipitated at boiling with 4 or 5 c.c. of $N/2$ barium chloride.

The following results indicate the sufficiency of the method.

Example 1.—A quantity of proofed fabric was extracted with acetone, and five equal volumes of the extract, each representing 1·5 g. of the original fabric, were taken.

	Method of oxidation.	$BaSO_4$ g.
1.	Carius	0·0421
2.	Cold neutral potassium permanganate in acetone solution	0·0418
3.		0·0413
4.	As 3 and 4 but heated under reflux condenser	0·0416
5.		0·0425

Example 2.—A different fabric treated as above.

	Method.	$BaSO_4$ g.
1.	Carius	0·0338
2.	1 g. potass. permanganate in acetone half an hour	0·0338
3.	1 g. potass. permanganate in acetone 24 hours	0·0341
4.	1 g. potass. permanganate heated under reflux condenser half an hour	0·0340

It is clear that the method is rapid, simple, and accurate. Blank tests on all reagents are necessary. Results given above are corrected for blanks, which were never more than 1 or 2 mg., and frequently nil.

* From 3 to 5 c.c. of acid of 1·16 sp. gr. for each gram of permanganate used.

Annual General Meeting.

Wednesday, July 5th.

The **President**, in calling upon Professor H. E. Armstrong to deliver the first of the Messel Memorial Lectures, said that Dr. Rudolph Messel had been one of the original members of the Society, and on his death, in 1920, he had bequeathed upwards of £20,000 to the Society of Chemical Industry. A part of this the Council had decided to use for the first of a series of lectures, to be known as the Messel Memorial Lectures, and to prepare a medal, which would be known as the Messel Medal, to be given, by vote of the Council, to the most distinguished chemist of the time in England. Dr. Messel had been President of the Society of Chemical Industry in 1911–12, and during his visit in that year to America and Canada he had done more, probably, than any other individual in popularising the Society in North America. Dr. Messel might be described as a typical chemical engineer. At first he had been a chemist, and carried out research work in Germany for many years. He had also done research work in this country, and had then devoted himself to chemical engineering and made the contact or catalytic process for the manufacture of sulphuric anhydride a commercial process. After a few years of work he had turned out no less than 10,000 tons of sulphuric anhydride by the process. Before calling upon Professor Armstrong to give the ecture, the President, on behalf of the Society of Chemical Industry, presented to him the Messel Medal in recognition of his distinguished career as an educationist and his outstanding work as a chemist and as a scientist.

The Medal was then presented to Professor Armstrong amid applause.

Sir **William Pope** said that the late Dr. Messel had been one of the great pioneers of technical chemistry in the British Empire; he had cultivated close friendships amongst the select few who had been worthy of his friendship. The fact that Professor Armstrong had been an intimate friend of Dr. Messel would alone make the choice of the first Messel Medallist an appropriate one, but the Medallist had many other qualifications. Just as Dr. Messel had been a pioneer in technical chemistry, so Professor Armstrong had been a pioneer in technical education; the great schemes for bringing a scientific technical education within the reach of all who were capable of profiting by such a training—schemes which had become realities some 40 years ago—had been carried into execution by Professor Armstrong and a small band of similarly far-sighted enthusiasts. It was certain that such co-operation as now existed between chemical scientists and chemical technologists in the British Empire and in America—a co-operation from which both pure and applied chemistry had greatly benefited—had originated in the great campaigns for technical education which Professor Armstrong and his few brother enthusiasts had initiated nearly half a century ago. Closely identified with Professor Armstrong's conceptions of scientific educational method was the idea that the student should early become imbued with that spirit of inquiry which was the source of all progress in either pure or applied science. Their Medallist had been himself a keen investigator; his name was permanently associated with the discovery of those facts and with the enunciation of those speculations which now formed the basis of our modern knowledge of the several branches—inorganic, organic, physical, and biological—into which the complex chemistry of to-day was divided. This breadth of interest had been perpetuated throughout a long and laborious life, and he had no doubt that it would be reflected in the vigour and scope of the Memorial Lecture which they were about to hear; it could be seen reflected in the fact that the audience that morning included a large number of men who had been trained by Professor Armstrong. In conclusion, he wished to express very keenly his own appreciation of the honour which they had done to one of Professor Armstrong's former students in calling upon him to make a few remarks introductory to the Messel Memorial Lecture.

Professor **Armstrong** then delivered the Messel Memorial Lecture.

First Messel Memorial Lecture

RHAPSODIES CULLED FROM THE THIONIC EPOS
CHEMICAL CHANGE AND CATALYSIS

BY HENRY E. ARMSTRONG

(Delivered at the Forty-first Annual Meeting of the Society at Glasgow, J[illegible] 4th, 1922)

Semper aliquid certi proponendum est.

When this Address was undertaken—

> What did we do but make a vow
> To do we knew not what nor how?[1]

What should be my theme? I could not well round upon you, as I might have done upon the Brewers when addressing them last year, with the lines—

> Thou that with ale or viler liquors
> Didst inspire Withers, Pryn and Vicars
> And force them, tho' it was in spite
> Of Nature and their stars, to write,

unless, indeed, sulphuric acid were counted among "viler liquors," a course I would not advocate: in fact, I shall plead for it the place of Prince among them and ask that once more due honour be given to its might and solidarity.

Fortunately, you inspired me by a flashed vision of platinum. No tip more appropriate to the occasion could be imagined, as you had charged me with the duty of lighting the torch that is to be kept burning, in future, to illumine the memory of the man who, learning from Döbereiner, Edmund Davy and Wöhler, was the first to use, as a catalyst, the metal now valued so highly, which is an aid to man in so many ways and the most prized among metals by woman. Indeed, platinum may well become the bond of union between the sexes, a bond that the fair ladies now in revolt may perchance hereafter admit, when the force of "some tonic" they "have drunk" is spent and the spell of Meredith's admonition is fully felt—

> Ah! madam, were they puppets who withstood
> Youth's cravings for adventure, to preserve
> The dedicated ways of womanhood?
> The light which leads us from the paths of rue,
> That light above us, never seen to swerve,
> Should be the home-lamp trimmed by you.

Mayhap platinum, fit symbol of stability, will be used to light that lamp, for as gold has led woman to minister to man in the past, why not platinum in the future, especially as our gold is now reduced to paper which cannot be worn with effect as jewellery?

---

[1] American readers please note, the citations when not identified are from sources at least two centuries old.

Saying this, however, I must not pass the chance to appraise the greatness of our art. Confided to a thionic embrace, even paper, in the chemic hands of the Courtauld firm, is now forced into the state of colloid and spun into a simulacrum of the butterfly's activity. The physicist but dreams of changing the atoms: we are facultative alchemists and transmute trees grown on the cold heights of Scandinavia into stockings fit for the fair in the most heated climes. What can men of letters set against these achievements? On account of his works the chemist should be highly honoured of men in all the pathways of the world; woman has still to appreciate the part he plays in providing her not only with platinum and stockings but also with the complete series of rainbow tints which permit her to outrival not merely the peacock but even the lilies of the field: she little knows the extent to which in this and other ways she is his unconscious debtor. Still the claim, nay the right, of chemistry to rank as fundamental, not only to other sciences but to all human activity, has yet to be made clear: those historic lovers of ale, Wither, Pryn and Vicars, if with us to-day, could but agree that we have the right to think no small beer of ourselves. Is not this a point worth making on such [illegible] occasion, in this drab town which is so nee[illegible] of beauty? Think what we could make of it if we had our way; at least we could rid it of its chronic murky atmosphere, if not of its heritage of rickets.

To leave the serious, my task is to lay a foundation and set an example. Those who follow, with less opportunity to indulge in panegyric, will doubtless be moved to develop some special theme and carry Thionism to greater heights. Hence the propriety of my text,

Semper aliquid certi proponendum est,

which appears to have been Matthew Arnold's favourite maxim, as he cites it more frequently than any other in his *Note Books*. At least, it is a good one for a scientific essayist and Arnold is an honourable example to follow, as he was both critic and thoughtful, exact writer. The chemist *should be* all these: is he either, in any sufficient way? If not, why not? To take rank in the world he must not only hold his own against the best of his competitors but force his way ahead of them. To save the world from a Russian fate science must be made as constructively effective in commanding human nature as it has been hitherto in hurrying the nations to their ultimate destruction. To-day, *you* are only thinking of speeding up the process of wasting Nature's resources and are giving little or no thought to their conservation. The chemist alone, through his thionic influence, has made the Northcliffe press possible, the destruction of forests certain: think what that means! How will you counteract the evil work?

Our word-spinning literary friends—rather might we characterise them as enemies, so narrowly have they led the world, if we could think of them as other than thoughtless offenders—infer that we cannot express ourselves properly and Goths upbraid us from Cambridge that we are Greekless! Themselves, they have little regard for truth and realities, worshipping form rather than substance. It is difficult not to believe that they are consciously seeking to prevent us from coming to expression in the public service: how otherwise are we to account for the rare appearance in the Press of the scientific writer? He would be there, if in the least encouraged: is he perhaps feared and kept out because it is felt that he might show up the futility of the hack writer or is it because journalism is now a close ring? Blame is often cast upon public taste but this is the herring across the trail: the public is not so simple as it is often made out to be and is willing to learn.

The man of words, in some degree conscious of their music, is more or less careful in their arrangement; he would not be paid for them if he did not place them with fair effect. The scientific writer, who, be it noted, has usually had the same early schooling as the literary writer, has his attention so fully directed to realities and is so occupied in thinking out the consequences of his acts and in placing his work on record, that he is apt to give too little attention to style and rhythm. Too frequently, therefore, he is verbose and lacking in lucidity; mere tricks of speech pass muster which should be avoided. To think every way at once is a little difficult, as those who have tried are aware. Yet not a few compare more than favourably with their literary colleagues—because they have something real to say. Darwin's *Origin* has often been cited as a model of clear statement: Huxley's studied style may be set against Ruskin's perfervid oratory: both were founded upon the Bible; Huxley's was not merely the product of genius but due to the exercise of thought and his sense of proportion, yet his utterances, at times, border on the sententious and if not less convincing, are certainly less alluring, than the sentimentalist's spontaneous ravings. Let us, however, be mindful of Milton's lines:—

Thus they in mutual accusation spent
The fruitless hours but neither self-condemning;
And of their vain content appeared no end.

Each of us has sufficient task in clearing the motes from his own eyes: we should seek to work together.

Unfortunately, the pages of our chemical journals are full of examples of careless writing—of careless writing due to careless thinking. Little is done to overcome the influence of habit; self-criticism is rarely practised. We have no school of criticism to impose discipline in our ranks. I well remember the effect on myself of a [*sic*] appended by that old Etonian warrior, Dr. Warre, to a quotation he gave from a letter of mine, to which he was replying in *The Times*; though he could not parry my argument, he caught me out over a split infinitive. Since then I have not repeated the heinous literary offence consciously and shall ever hold him in pious memory for his act of grace in curing me of the habit. It may comfort some if I say that I was once a dire offender. The current rumour that a free-lance journal may be established in connexion with the Chemical Societies is an augury of a happier future—if only the pedantry of a publication committee of superior, elderly intolerants, without imagination, can be avoided. Free exchange of opinion, free criticism, is much needed among us; we are far too narrow in our outlook, too sensitive to remark; Professor Patterson's famous tilt over " But " is an amusing extreme example of the intolerance of the hard editorial mind, worth remembering as an indication of the difficulties to be overcome and the danger we run in limiting freedom of expression.

Is't not enough to make one strange
That some men's fancies should n'er change
But make all people do and say
The same things still the self-same way?

Our position as chemists, the position of science in the community, will depend far more upon words than upon works—upon the use we make of our English tongue. We must not only learn to weigh our words and use them effectively but use clear words, words that can be understood. Far from eing Greekless, we are overfond of using an ffected Attic terminology. Striking examples of l-directed zeal are to be found in the pretentious ıanuals of so-called colloid chemistry. The bee in he bonnets of the dreamers in this field is the ərminal *oid*. After wading through much colloid ıire of late, I am wondering whether the 15,000 ld members of Dr. Parsons' happy and obedient ock of chemists in the land of Wilder D. Bancroft o not consider suspenders a vulgar term for races and wear their pants adsorbed by suspendids. If I be not misinformed, the younger ladies ow wear corsoids and chemiseoids, no longer the eal thing; in fact, I believe all feminine garments re *oids* in these days, except hose, perhaps—and his because chemists have made them of an ttractive *sericoid* material. Everything seems to e now a shortened, sort-of-a-kind-of what it used) be; canned goods have captured the world and npudent advertisement counteracts conscience.

I trust what has been said will suffice to

Force you by right ratiocination
To leave your vitilitigation.
And make you keep to the question close
And argue dialecticos.

The need of care has been specially impressed pon us of late owing to the attitude adopted by he Official Referee of the Board of Trade ppointed under the Safeguarding of Industries ct, 1921. Nothing could be more humiliating ıan the manner in which, sitting as a Delphic racle in Whitehall or the Law Courts, this gentlean has created chaos in Chemistry by his pronouncements upon our vocabulary. The discussions n the subject in various Sections of this Society ıve been far from illuminating; the lack of agreeent among speakers, in fact, is sufficient proof at clear thinking is not yet our characteristic.

Mr. Edmund Gosse tells us, on the authority of e Marquis de Racan, that the leader of the ssical reaction in France, M. de Malherbe, one ur before he died, woke with a start out of a ep slumber to rebuke his hostess, who was also s nurse, for using an expression which he did not nsider to be correct French. When his Confessor ntured to chide him, he replied that he could t help it and that he wished to preserve up to e moment of his death the purity of the French guage.

My exhortation is, in like manner, that we should content only to play upon

. . . the lyre of language clear
Love's tongue and source,

of the most perfect of Meredithian couplets.

'o return to platinum, to mention it is to excite imagination in many ways. Its attributes are such perfection that the metal must have been ture's first care had due forethought been rcised at the Creation: it is clear that little as re is now, in the beginning there was no scious science, otherwise platinum would be as n in quantity and much more oxygen free in the ld. The electrons, however, seem to have been -willed and proportions may well have been ermined merely by their affinities as influenced transcendental temperatures, just as is the comxity of benzenoid hydrocarbons at ordinary ts.

ron has many attractive qualities: without it haps the world would have been colourless and r; without it perhaps we could not have been with air; yet it has many imperfections:

Ah me, what perils do environ
The man that meddles with cold iron.

er were we so mindful as now of its misuse and re striving to minimise this to the utmost; but as usual are lacking in outlook, leaving chemistry out of account and failing to take proper measure of human nature and its structural stability, failing to realise that the problem is chemical at bottom, living Nature being but one huge laboratory, in which structure is the main determinant of function, its operations largely catalytic.

If platinum could be used as iron much trouble and loss would be avoided: polish and paint would be far less in request; of no knight's pistol could the mock-heroic have been written—

But Pallas came in shape of rust
And 'twixt the spring and hammer thrust
Her gorgon-shield, which made the cock
Stand stiff, as if 'twere turn'd t' a stock.

Think of the chemist's generations-old struggle to decipher the mysteries of rust: what it will eventually be worth to us if all iron be made rustless!

Helmholtz's complaint against Nature of the imperfectness of the eye is a small matter in comparison with the lament the chemist may utter as to the scarcity of platinum: the uses to which he could put it are so many and so important. The man whose mentality it is my allotted task to picture, a task of exceeding difficulty, was the first to give it to full industrial use: this was his great achievement.

We often spoke of its wonderful activity; I more than once said to him, "Whe[illegible] have done with using it, we will set to work together to find out, if possible, how it does its work." That day never came and seemingly we drifted away from our purpose: he stuck to sulphuric acid and kept his platinum in technical use; whilst occasionally taking a sip at the acid I began to play with organic catalysts, not uninfluenced by the thought of his disease; there was no money in them but they gave what I believe to be the final clue to the behaviour of platinum. I little thought that I should be called upon and privileged to display my knowledge in his honour.

RUDOLPH MESSEL

I first met him in my initial year of office as a Secretary of the Chemical Society, in April 1876, on the evening when Dr. Squire and he described and demonstrated the process they had developed of manufacturing sulphuric anhydride, already in operation at Silvertown. He was elected a Fellow of the Chemical Society that same evening. I was the only speaker to break the harmony of the meeting by suggesting that Nordhausen sulphuric acid was not a mere solution of the anhydride but mainly a definite acid, a compound of the anhydride with sulphuric acid, anhydrosulphuric acid, then unrecognised except by Schützenberger. I trod on Messel's heels with a paper on "Systematic Nomenclature": this, too, shadows me to-day.

I was greatly attracted to him from the beginning and we soon became fast, I may say affectionate, friends. Perhaps I surprised him by knowing the work he had done as a student on strychnine and maleic acid: I would here emphasise the fact that he started his career as a chemist on the organic side. Moreover, I had been ahead of him in cultivating the acquaintance of sulphuric anhydride—on German soil—as it was the subject of my Ph.D. thesis, published in English in the *Proceedings of the Royal Society*, under Frankland's patronage, in May, 1870, under the modest title "Contributions to the history of the acids of the sulphur series. I. On the action of Sulphuric Anhydride on several chlorine and sulphur compounds." This was my introduction to the Royal Society. A little later, in 1871, I made my first appearance, as an independent worker, at the Chemical Society, with a paper on the use of sulphuric chlorhydrol as a sulphonating agent. Messel was afterwards led to take an interest in this compound through preparing it for me.

I thus came under thionic fascination at an early stage of my career and was fully prepared to appreciate Messel's work and its value, the more as I had worked alongside Graebe in Leipzig and Perkin was my fellow secretary.

Messel was born January 14, 1847, in Darmstadt. He died April 18, 1920, at his chambers in Victoria Street, London. He was of Jewish extraction but professedly Lutheran.

To-day I will give only a brief survey of his history, sufficient to make clear his proclivities and the influences to which he was subject.

His father, Simon Messel, was not originally intended as his father's successor in the banking business but was apprenticed to a Parisian maker of artistic furniture, which accorded more with his own taste for art. The interest of this fact lies in the indication of the source of the highly developed artistic tastes which most of his children evinced. Before he had completed his training in Paris, however, Simon Messel was recalled to Darmstadt to take the place assigned to his elder brother, who had journeyed to America and there disappeared from the sight of his relatives. In consequence of this change, Rudolph Messel's early years were spent in what for those days ranked as affluence and his father was able to provide adequately for his education. He was the second of five children, of whom four were to make their homes in England; the fifth acquired great distinction as an architect in Berlin.

He received his elementary training at Schmidtz's Academy in his native city. Shortly after his father's death in 1859, he was sent to a Huguenot school at Friedrichsdorf in the Taunus, where he remained until early in 1863, that is to say, until he was fifteen years old. His early interest in science and his precocity are shown by the following reference he made to this period in his Presidential Address to this Society in New York in 1912.

> "In 1861, when I was at school at Friedrichsdorf, in Germany, my master, Philip Reis, invented the first telephone. I was present at its birth and assisted Reis in making the mechanical parts of some of his instruments and also repeatedly in his experiments, Reis being at one end of the circuit, speaking or singing, I listening at the other or *vice versa*."

While he was at school, the family circumstances had changed and it was clear that Messel would have to be self-supporting at an early date. His intention, formed during the last years at school, was to become an engineer, either civil or mechanical. In January, 1863, he discussed his future course of action with an old friend of his father's, Heribert Rau, an author of some distinction, then living in Frankfort. Rau wrote to him a letter strongly advising against this choice of a profession, basing himself upon the fact that the demand for engineers already fell short of the supply, whilst the boy's religion would, he said, militate against his receiving a State appointment. If the boy were father to the man, as all accounts indicated that he was, Rau knew well the love of independence and self reliance which were among this young friend's salient characteristics. After citing the reasons given above, he lays the greatest stress upon the fact that to become an engineer would entail many years of study preceded by years of practical work at the bench, so that the day when he would be able to support himself must be far distant. He then gives the young Rudolph positive advice, which it is clear determined all his future. He bids him devote himself to the study of commerce, which, he said, would rapidly lead to independence and to combine with this the study of Chemistry, Physics and Technology and so become a manufacturer. Rau seems to have felt that to become a manufacturer was a great falling away from grace for an ardent boy, because he goes at great length into the great future which lies before him and the noble examples of enlightened and well-spent lives which were to be found among the great manufacturers of the day. Finally, he advises Messel to move to Frankfort, to enter the business of some large merchant, to attend at the same time lectures in Chemistry, Physics and Technology and after completing his apprenticeship, to travel to France, Belgium and England, the lands of factories and industry, to keep his eyes open for this or that article the making of which was urgently needed and to become himself a factory owner.

That Messel's whole course of action was influenced by this letter is clear, not only from the fact that he kept it to the last amongst his rarest treasures but that he followed the advice it contained, almost verbally.

In April, 1863, he became apprenticed to E. Lucius, in his wholesale drug, chemical and pharmaceutical factory in Frankfort, where, according to a letter from Lucius, he obtained a thorough knowledge of the business in all its branches. He remained in Frankfort until September, 1866. Although there is no definite evidence that he attended lectures at the same time or who his teachers were, there can be little doubt that in this respect also he followed the advice given him. In 1864 and 1865 he was a member of the "Physikalischer Verein," which was then and later a teaching institution; the teacher in chemistry was Prof. Rudolph Boettger and in Physics first Prof. Oppel and later Prof. Friedrich Kohlrausch.

On leaving Lucius, Messel entered the Federal Polytechnic in Zürich, where he followed the regular first year course. Among the subjects taken were organic and inorganic chemistry (taught by Städeler); technical experimental physics (taught by Bolley); mechanics, mineralogy, botany and technical drawing. Messel completed his year in Zürich. The following winter he spent at Heidelberg studying organic chemistry under Erlenmeyer. According to a letter from Bunsen, he worked with the utmost zeal on analytical subjects in the laboratory of that great teacher, then in his prime. Bunsen, who wrote two years later, especially mentions Messel's manual dexterity, which he says was clearly shown in his later published researches on strychnine-oxyethylene compounds and sulphomaleic acid.

From Heidelberg Messel moved in the spring of 1868 to Tübingen, where he finished his education. Here he spent a year attending the course of experimental physics of Prof. Reusch and courses in organic, inorganic and analytical chemistry by Prof. Strecker. From the spring of 1869 onward he appears to have been engaged in various inquiries under Strecker. A description of those referred to by Bunsen in the letter noted above formed the thesis he presented for his degree. Messel left Tübingen for England in April, 1870.

I believe he came to England originally to act as private assistant to Roscoe. During the short period he spent in Manchester, he worked both with Roscoe and Grace Calvert. The outbreak of the Franco-Prussian war, however, led to his recall to Germany. Owing to some physical defect, he did not serve in the army but was relegated to the Ambulance Corps; he was wounded while on service. When recovered, he returned to England, where he remained during the rest of his life and ultimately became an Englishman. He entered the service of

Dun, Squire and Co. at Stratford, as assistant to Dr. Squire and here he became a thionist; but the virus was already in his veins.

In his Presidential Address, he tells of a conversation in the beginning of the 70's with his former teacher Strecker, of Tübingen—who was the first to discover the relationship of alizarin with anthracene —and Brüning, of Höchst, on the importance of fuming sulphuric acid in the synthetic alizarin industry, then rising into importance. To his question, how the acid should best be made, Strecker gave the prescient reply: "That is a problem for you to solve." A few experiments convinced him, he says, that given pure gases, the catalytic action of platinum was the rational solution of the problem. On April 8, 1875, a telegram came to him at the laboratory, from Squire, asking him to read up that night about Nordhausen acid, as it was wanted by an alizarin works. The response was Messelian and immediate: no reading was necessary. Next day he showed how simple a matter it was to marry sulphur dioxide with oxygen by means of platinum. However, Squire was conventional and thought that the decomposition of an acid sulphate would be a simpler method. Experiments were made as requested but eventually Messel was told "to try his dodge."

With Messel to try what he had once conceived as practicable was to succeed. He was there already; he had seen and he conquered forthwith. A patent was taken out by Squire in 1875 and the process was described at the Chemical Society early in 1876. Meanwhile, Squire had established as a new firm Squire, Chapman and Co., with Messel as factotum; he would have objected to my calling him chemical-engineer, as he had no belief in half-breeds, also he was an entire disbeliever in the attempt to bring the works into the laboratory.

The process was established at Silvertown and in 1878 he succeeded Squire as manager of the works, which he only quitted in 1915, when his health gave way under the excessive strain of the times.

The paper Messel and Squire read at the Chemical Society was never published: even I cannot say why; probably because of patents; from a remark made by Messel, I gather that it was not sent in by Squire. The record of the meeting on April 20 in the *Chemical News* runs simply as follows:—

> "The speaker (Messel), after giving a sketch of the history of the manufacture of sulphuric acid, described the process for preparing the anhydride. The vapour of ordinary sulphuric acid is passed through a white-hot platinum tube, whereby it is almost completely decomposed into water, oxygen and sulphurous anhydride: the mixed gases, after passing through a leaden worm to condense the greater portion of the water, are completely dehydrated in a leaden tower filled with coke, over which a stream of concentrated sulphuric acid is allowed to trickle. The dry mixture of oxygen and sulphurous anhydride is now passed through platinum tubes heated to low redness and containing fragments of platinum pumice, when the gases recombine to form sulphuric anhydride which is condensed in a series of Woulffe's bottles."

In early days, I was a frequent visitor at Silverown, where Messel not only worked but also lived n the modest quarters of a small house attached to he works, until he removed to chambers in Ebury treet and afterwards to Victoria Street. Characeristic of the man throughout his career was his npretentious, simple mode of life. I only knew im to be vain in one connexion—as President of is Society; but he was very proud of the F.R.S. d not a few of us were proud of him as a colleague. enerous and ever thoughtful of others, unselfish to a degree, he had little thought for himself and a hatred of all display; the artist came out, first in his extreme devotion to his own art—for chemistry, technical chemistry in particular, is an art—then in his love of the company of artists and other bohemians: he was a great admirer and friend of Gilbert—of Gilbert and Sullivan fame—and a constant frequenter of the Savage Club; may I add, as a judge of quality in Champagne; in Weib and Gesang he had no estate, though he was musical. Living among them, he knew his work-people and was in sympathy with them: hence his popularity and power.

One understood his success when one followed his work. A man of astounding vigour and full of feeling, he burnt the candle at both ends and all over its surface. That he lasted so long always surprised me. When about sixty he was overtaken by diabetes. He was everything—not only chemist, engineer and business man; he also took care to cultivate the social side of his life; he was the only manufacturer of my acquaintance who attended regularly at scientific gatherings and showed real interest in the proceedings. He was thorough in everything he did. Probably he did far too much himself but he could not suffer fools gladly, though not often impatient outwardly and always considerate. He had no hobby outside his business and science. During many years, his one way of recuperating was a weekly visit to Brighton on Sundays. He went down by the early train, walked out to the Devil's Dyke, had lunch and then returned to town, usually to spend the evening with friends. In those days he was a real walker, as I found when occasionally his joyful companion.

Those who knew him, especially in the early days, will remember his vigorous frame, his black hair and sparkling eyes, his smiling face, his hearty bass staccato laugh, his peculiar gutteral accent. If his portrait were to be painted, I think we should ask the artist to depict just that smile alone, following Tenniel's living presentation of the Cheshire Cat up in the tree by its grin. We can fancy him to-day, smiling at King Ruttan and his crowd and at me the executioner, chuckling at my use of the axe of criticism. He never mastered English properly, though he spoke it fluently. He was very fond of young people, many of whom rejoiced in his generosity. We who knew him all think of him as one of the most loveable men we have met. His outlook on life was always cheerful and optimistic but he was a close observer and critic; always broad, clear and careful in his judgments but deliberate in forming them. The example he set in leaving his fortune to science is a remarkable one and best proof of his considerate outlook. Honest and sincere himself, he hated insincerity and all meanness of spirit. He combined in his person all the best of German good qualities, fired and softened by Jewish imagination.

Nordhausen or Fuming Oil of Vitriol was the only kind of sulphuric acid known to the early chemists. Even in comparatively recent times, not more than a hundred years ago, the manufacture of Vitriolic acid, by burning sulphur, was so imperfect a process, that the old method, troublesome and crude as it was, still held its ground.

The production of the anhydride, by decomposition of a sulphate, appears to have been known in very early times, indeed up to the year 1736 the only way of preparing sulphuric acid was to evolve vapours of the anhydride by destructive distillation of a sulphate and to pass these into water.

When Messel and Squire began their work, Baron Stark, in Bohemia, was sole maker of the fuming acid, the process he used being substantially that of Basil Valentine, born 1394. A particular kind of Pyrite was weathered (oxidised) by exposure to the air. The copperas (ferrous sulphate) so formed was dissolved out and the solution concentrated. The sulphate crystals which separated were usually sold; the mother liquor, containing much ferric sulphate, was then evaporated to dryness and the residue slightly roasted, so as to dry it. The vitriol-stone, as it was called, so produced, was broken up and charged into small bottle-shaped retorts arranged in a gallery furnace, in such a way that they could be heated to a high temperature. Instead of receiving the vapours in water, as in making sulphuric acid, they were condensed in oil of vitriol, a small vessel containing the acid being luted to each retort. The distillation lasted about 36 hours and as the quantity put into each retort was small, the product was also small. The consumption of fuel was great and much labour was involved in charging and discharging the retorts, many of which were broken. The process required great skill on the part of the workers. All attempts to manufacture the acid in larger apparatus appear to have ended in failure.

At the outset, when the attempt was made, to produce the anhydride by passing the vapour of burning sulphur mixed with air over heated pumice coated with spongy platinum, the chief difficulty met with was in condensing the anhydride. As Messel and Squire remark—the manner in which sulphuric anhydride will evade condensation from a gaseous mixture is something quite marvellous. When pure gases were used, the condensation was easily effected; on this account, in the early days of the industry, when the value of the fuming acid was much greater than that of oil of vitriol, a suitable mixture of sulphur dioxide with oxygen was obtained by decomposing the latter. In their experiments referred to in the paper, a small platinum still about 4 inches in diameter was so arranged in a Hofmann Gas Furnace that it could conveniently be maintained very nearly at a white heat. Ordinary oil of vitriol was slowly fed into the still and kept strongly boiling; the vapour was almost completely decomposed, the condensed water containing but little acid. After the mixture of gases had been dried by means of sulphuric acid, it was passed over pumice stone prepared with platinum, enclosed in a large tube made of thick platinum foil, heated to a dull-red heat by the waste heat of the gas furnace. Little or no sulphur dioxide passed away when the heat was properly managed, the process was continuous and the condensation perfect. Nearly 70 parts of anhydride were obtained from 100 parts of white sulphuric acid, the theoretical amount being 80 or thereabout.

In the early days, the demand was limited by the requirements of the dyestuff industry, especially that of the madder colours. When the use of the fuming acid was introduced into the Cordite industry, in connexion with the displacement nitration process, the demand became much greater. At the close of his industrial career, Messel was producing from 250 to 300 tons of Oleum per week, containing 20% of anhydride in admixture with sulphuric acid.

As experience was gained and the difficulty of condensing the anhydride was overcome, sulphur dioxide prepared by burning sulphur and ordinary air were used. In this case also exact proportions were at first adhered to. I remember Messel telling me that he was first led to use excess of air and therefore to abandon the use of special appliances for the supply of the gases in due proportion by having his attention called, by his workman-foreman, to the fact that the plant worked better when air was supplied in excess.

In early days, to reduce the cost of carriage, acid was sent abroad of 80% anhydride strength and diluted with 'monohydrate.' Where this was done I forget but that this was his practice I know, as when I once asked him if he had any knowledge of the process of making sulphuric acid (H_2SO_4) by freezing it out from oil of vitriol, he told me that he had at one time so made it for the purpose stated above.

Over and over again he told me that he aimed at making vitriolic acid by his process as cheaply as by the chamber process and I well remember the joy with which he told me that he had at last succeeded.

Messel's claim to distinction does not rest upon the discovery of a chemical process but upon his initial success in building up from the foundation, unaided and almost alone, a novel industry of great importance and in having solved a variety of technical problems of extreme difficulty. His success was due not only to his great mechanical ability and clear understanding of the task before him but particularly to his high moral standard and his absolute devotion to work.

'The strongest weapon one can see
In mortal hands is Constancy.'

Doubtless, in later days, as we all do, he derived assistance from outside but this was only when his primary work was accomplished and it became necessary largely to extend the plant. We have been accustomed to admire the systematic manner in which the German chemical works are conducted with the aid of a considerable staff of trained, disciplined workers: what always appealed to me was the fact that he, a German working under our English conditions, with scarcely any technical staff, was long far in advance of his countrymen. His success was due, in the first place, to his thorough scientific training and to his scientific outlook but, to an exceptional degree, to his moral attitude towards his work. The lesson to be learnt from his life should be of no small value to us.

CHEMICAL ACTION *AND* CATALYSIS

AN ESSAY ON CLEANNESS

"*A Satyrical Allusion to the Heathen Gods, who are supposed all of them to have been Kings or famous Men in their Time and fabl'd into Deities by the Error and Ignorance of those Days; concluding with a list of Great but Vicious Princes in our Modern Times fit to make Gods of in the next Promotion.*"

Chemical Action *and* Catalysis: if not these words, καταλύω should be graven at the base of the monument to my friend.

The industry which Rudolph Messel had so large a share in developing, more than any other perhaps, is commonly thought of as one in which "*catalysis*" has a leading part: every budding student during generations past has been taught to regard nitric oxide as the catalytic agent in the *chamber process* and platinum as similarly effective in the later *contact process*. No two less similar processes could well be imagined; yet if choice were to be made between them, I imagine the latter would be regarded as the "typically" catalytic process.

Berzelius, in first communicating his conception in 1835, included a long list of interactions under the influence of agents which appeared to take no permanent part, even if included, in the change, as they were ultimately recovered unaltered.

Whilst in the interval attention has been more and more concentrated upon platinum, nickel and the enzymes as catalytic agents *pur sang*, of late years there has been a growing tendency to extend the conception to all agents determining change—in other words, to chemical change in general.

A strange confusion of thought prevails, in fact: rather, may it be said, perhaps, a strange lack of thought. Francis Bacon three hundred years ago could point out, that "the ill and unfit choice of words wonderfully obstructs the understanding." The term catalysis would seem to be one of those "Idols of the Theatre," as he terms them, "which have immigrated into men's minds from the various dogmas of philosophies and also from wrong laws of demonstration."

If, as Bacon insisted, "words force and overrule the understanding and throw all into confusion and lead men away into numberless empty controversies and idle fancies," it behoves us to be most careful in our choice of words and concise in our definitions, remembering that "even definitions cannot cure this evil in dealing with natural and material things, since the definitions themselves consist of words and those words beget others, so that it is necessary to recur to individual instances and those in due series and order."

It is a strange fact that whilst the "criteria of catalysis" are more or less fully discussed in recent works, there is practically no reference to the broader problem of chemical change or action; even Mellor, in his two encyclopœdic volumes, makes no attempt to consider the conditions which determine it. This is equally true of the lengthy dissertation compiled by the pillar of American Physical Chemistry, Wilder D. Bancroft and his adsorbed body of assistants. The recent discussion at the Faraday Society, apart from Langmuir's experimental contribution, appears to have been in a "greenery-yallery, Grosvenor-Gallery" Valhalla to which chemists can never hope to attain—only Dr. Lowry spoke from a foundation of fact, in earthly but shattering terms.[*] The main lesson to be drawn from the two documents is that Dr. Miall should continue his efforts to found an Association for the Discouragement of the Integral Calculus of which he has given notice in the U.S.A.

Students, we know, have been taught of late years to worship Idols of the Theatre, to lisp certain Teutonic shibboleths; but the inner mysteries of chemical change have never been confided to them. The state of ignorance induced by our text-books is astounding: a vast burden of facts is laid upon us but processes are rarely considered: the manuals mark no advance in methodical treatment, and are best described in Shelley's words as—

> . . . . tomes
> Of reasoned wrong, glozed on by ignorance.

We physicians have a long way to go in healing ourselves before we prate of scientific method to the public. As to text-books, let us Scrap the lot![*]

In R. L. Stevenson's apposite words: "Culture is not measured by the greatness of the field which is covered but by the nicety with which we can perceive relations in that field, whether great or small."

Thus defined, where is the cultured chemist to be found to-day? Recent hearings before the Board of Trade Official Referee show that the witnesses —I will not call them chemists—were not even agreed as to what is "A Chemical"; the innocent lawyer was trapped into the belief that it was something manufactured.[†] Doubtless this definition was paid for—nothing else could explain and excuse its absurdity.

Chemical Change

All single things dealt with by the chemist are chemicals. A chemical can only be defined as a material which can take part in a chemical change; combustion undeniably involves chemical change: argle—Oxygen is a Chemical! Who manufactured oxygen? We can only say—It is!

What is involved in the process of Combustion— to take the simplest possible case, that of the formation of *hydrone* (water) from hydrogen and oxygen? Every text-book we have *lies* in telling the student that hydrogen and oxygen interact to form "water." We *know* they do not. The effect of drought upon the country is patent to everyone —especially of late years—yet no notice is taken of its effect in chemistry. The remarkable work of Wanklyn, Cowper, Dixon and especially of H. B. Baker may be just mentioned occasionally but its entirely fundamental value is in no way appreciated; Lowry's work may be seen but it is not heard.

It is as Bacon said three hundred years ago: "The Idols and false notions which are now in possession of the human understanding and have taken deep root therein not only so beset men's minds that truth can hardly find entrance but, even after entrance obtained, they will again in the very instauration of the sciences meet and trouble us, unless men, being forewarned of the danger, fortify themselves as far as may be against their assaults."

Surely it were time that we fortified ourselves; that we sought to deserve the title of scientific workers and thinkers? Human understanding *is* frail and limited but not so limited as we make it appear. There is no conscious effort made by us to be impartial and logical; and our difficulties arise from lack of culture—from the gross specialisation of the day, which is largely conditioned by our satanic system of competitive examinations: a system more calculated to kill genius and prevent progress could not possibly be devised.

---

[*] Bancroft's essay is written with child-like innocency of purpose. He meanders through three numbers of the Journal of Industrial and Engineering Chemistry (April to June) without ever stating what he thinks he means by catalysis, without making the slightest attempt to overlook the process of chemical change in general. Like most chemists of the time, he seems to be clad in little more than a chemical loin cloth: that a whole suit is necessary for a change seems never to have occurred to him. Such be your Gods, Oh Israel!

The same sense of disappointment is left on turning over the pages of the monographs on the subject. Jumble sales of facts, vastly interesting and valuable as catalogues of observations, they lead nowhere in particular:—

> When they cry, "Steer to starboard but keep her head larboard,"
> What on earth is the Helmsman to do?

The mind is reduced to the condition of the map so vividly described by the Bellman in *The Hunting of the Snark*—"A perfect and absolute blank."

The statement made by Samuel Butler, under the heading "First Principles," is worthy of quotation in this connexion:—

> "When we are impressed by a few only or perhaps only one of a number of ideas which are bonded pleasantly together, there is hope; when we see a good many, there is expectation; when we have had so many presented to us that we have expected confidently and the remaining ideas have not turned up, there is disappointment. So the sailor says in the play: 'Here are my arms, here is my manly bosom but where's my Mary?'"

Indeed, "Where's my Mary?" must be the general cry of those who read of catalysis in the journals; we miss her dear form everywhere.

[*] It is estimated that new books will be "Homeless" at the Chemical Society five years hence. It is clear that a "Palace" must be found in which the united Chemical Societies can foregather with the books of the future and those of the past which are worth preserving: no other Catalyst will serve the purpose. Meanwhile let selection be made of the few text books worth preserving and the rest publicly burnt, as a warning to budding authors: there will then be sufficient room on the shelves to meet passing needs while the Palace is building.

[†] Judgment upon the Act was pronounced by the author of *Robinson Crusoe* when he said:—

> Reason is the Test of the Law; for Laws which are contradictory to Reason are void in their own Nature; and ought not either to be made or regarded.

Yet hope is in the offing. To me it seems, I am glad to say, that, in upper scientific circles, there are clear signs of a return to chemistry and reason—that the attention paid to pseudo-physical aspects having outworn its welcome is giving place to the desire to consider the inner meaning of chemical phenomena, to be eclectic, to recognise the insufficiency, if not the emptiness, of the treatment to which they have been subjected by the Syncretists. The work done by Hardy in correlating lubricating power with chemical structure and that of Jacques Loeb, following that of Hardy, on proteins, may be referred to by way of example. We are returning to the sane vision before the early workers that molecular structure is the key to function; let us hope that the change will be marked by the rejection of the pedantic jargon which has so long marred the fair field of our science.

From morning to night we must impress upon our students that they must learn to think for themselves but that thinking rightly is an outcome of experience, no easy thing; that they must therefore give due heed to experience but have no belief in authority—above all, be wary of the journalist and propagandist and of the text-book.

The experimental evidence put forward by H. B. Baker is of such cogency that it may now be asserted, that hydrogen and oxygen *cannot interact* and that to determine interaction *a third component must be introduced into the system.* What is the nature of the third component? Whilst affording proof that moisture promotes the change, Baker's observation that liquid water might be present and yet no explosion take place apparently is proof that water alone cannot act as third component. By using the hardest glass and gases liberated from a solution of baryta, Baker eliminated acid impurity as far as was practicable; as interaction takes place when these precautions are not observed the legitimate inference is that water becomes the determinant only when it is rendered conducting by the presence of impurity, usually acid. The interaction is an electrolytic process, in fact. One Faraday taught this doctrine in early days (1833). By his study of the power of metals and other solids to induce the combination of gaseous bodies and of electro-chemical decomposition in general, he laid the foundation, for all time, of the theory of chemical change; and yet, whilst honouring it in its transcendental aspects—for we recognise that Faraday foreshadowed the electron—we pay no attention to the ordinary applications of his work. Why is it that we so rarely read in order that we may mark, learn and inwardly digest? Whatever of logic I have in my composition, whatever unfortunate tendency to be critical, I owe it, in some measure, to Trench's *Study of Words* but mainly to reading Faraday. An early purchase of his collected works was the most fortunate I ever made. The exquisite lucidity of his logic at once impressed me. The Electro-chemical Researches are in *Everyman's Library* and every youthful student who wishes to gain the scientific habit of mind should acquire and master this volume—if only as a literary exercise. All the essayists may well be put aside for it, if the desire be to cultivate style and to escape from the tyranny of the literary plagiarists who eternally harp upon one theme and make no attempt at progress.

To-day, I but take up the position I took with reference to Baker's work in March, 1885, when he was only beginning his chemical studies—merely telling us that the combustibility of phosphorus and charcoal had been overrated and misinterpreted. Influenced by a Faradic current of thought, intensified by my association with two pioneer workers in electricity, Ayrton and Perry, I dared to project my mind into the future and say that some day it would be found that a mixture of pure hydrogen with pure oxygen would be inexplosive. The position, I assumed, was perfectly simple—that action always takes place and only takes place in a conducting or electrolytic circuit. Neither gas was a conductor nor did either make water conducting. Following Ayrton and Perry, I argued that Ohm's well-known electrolytic law, $C=E/R$, was equally the law of chemical change. My forecast was verified by Baker in 1902 and he has since given not a few other proofs of the validity of my thesis.*

I venture to think that the discussion we had on the occasion referred to at the Chemical Society is the most important in its history and yet how little real recognition it has received. Who reads such literature, any real literature to-day.† The Tit-bits miscalled abstracts and illiterate text-books alone hold the field. Very few remain mindful of Liebig's counsel to Kekulé: "No one who does not ruin his health with study (he meant reading) will ever do anything in chemistry nowadays." Some excuse, perhaps, is to be found in the quality of too many modern memoirs.

Altars have been set up everywhere for the worship of a narrow doctrine mislabelled Physical Chemistry; the chief Ikon has been St. Arrhenius, a divinity of Scandinavian origin; Teutonic priests, the Ostwalds especially, have ministered faithfully at his shrine; latterly they have gradually changed the material of his effigy and have formed it in glue. The fashion set has not only stuck in many places but has assumed epidemic proportions. The ritual the school has developed is as vague, as wordy and as mystical as that of any of the Churches. Leipzig for a time was a veritable Lourdes and full of pilgrims; everyone knows the miraculous curves that were issued from the temple there. The prominent symptom of the disease is that it renders the mind semi-permeable to ideas; if any, only those of one kind get through. However, we all have partially permeable intellects—not semi only but some much smaller fraction. The Americans, as was to be expected. have been worst hit; we come next; the French have displayed their characteristic immunity towards external influences and have shown a sense of proportion which has enabled them to preserve their sanity. No cult can last for ever; some free men there still are in the world; the war has made people think a little; shortly we shall realise how silly we have been in adopting clerical methods and substituting faith for evidence, particularly in putting faith in any one hypnotist and allowing him and his lieutenants to dogmatise us into belief. Science is a human occupation like others; we are all prone to hero-worship and seekers after praise and position, making pleasurable statements, are always taken too much at their own valuation; when followed by the trail of Nobelism they are irresistible.

---

* As the Proceedings of the Chemical Society are not generally available, I venture to reproduce my prophecy:—

> "He (Dr. Armstrong) had even ventured to affirm to Mr. Dixon that some day it would be ascertained that a mixture of pure oxygen with pure hydrogen was not explosive."
>
> "Dr. Armstrong said that the view which he now held was best stated by defining chemical action as *reversed electrolysis*, *i.e.*, in any case in which chemical action was to take place it was essential that the system operated upon should contain a material of the nature of an electrolyte. Neither oxygen nor hydrogen was an electrolyte, therefore a mixture of only these two gases should not be explosive; a mixture of pure oxygen and pure carbonic oxide for like reasons should not explode. There was, however, a tendency perhaps to exaggerate the importance of water and to overlook the possible presence in minute quantity, and influence of, other bodies. Water not being an electrolyte, as it was scarcely probable that water and oxygen or hydrogen would form an electrolyte, it was difficult to understand that the presence of water pure and simple should be of influence in the case of a mixture of oxygen and hydrogen."

† The Americans, almost more than the French and Germans, now pay scant attention to outside literature and are on the way to give a new meaning to the term Monograph—not the graph of a subject but that of a notion. Falk disregards the whole of my work, including that on enzymes, in his monographs.

There is nothing dogmatic in the assertion that all chemical change is an electro-chemical, *i.e.*, an electrolytic process—facts prove it to be such: let those who doubt study Faraday. Modern discovery only serves to deepen the conviction. The nature of the electro-chemical process, however, is still open to argument.

To the pure all things are pure, it is said; but none of us dare claim to be otherwise than impure and so we may reverse the proverb and say that to us, the impure, all things are impure. Strange to say, the physicist is still affecting to love the simple life and has not yet learnt to take things impurely: he has yet to recognise the value of chemical soap-and-water, the need of attaching importance to cleanliness, perhaps it should rather be said, to dirt; his interpretation of the phenomena of electric discharge has yet to be justified under dry conditions. The intermediary is difficult to find. Langmuir seems to be the most likely holder of the office, if he can but come down to earth and be proportionate in his judgments—in Faraday's sense; if he will work at the open window.

The Determinant

Most will now admit that the interaction of hydrogen and oxygen is *determined*—please mark the word—by conducting water. What is conducting water? The Arrhenists claim that water itself is a conductor—though only a very feeble one at best. I need not remind that the plea, " It's only a wee one," is not admitted in law. The assumption that water is a conductor *per se* is purely gratuitous. The value accepted is that arrived at by Kohlrausch—but he worked in prehistoric times and used prehistoric methods; he cannot conceivably have dealt with pure water. Pure water is impossible in mortal hands. Some minute impurity must ever be present. Knowing as we do that impurity is present and that conductivity falls rapidly as impurity is removed, it is only logical to assume that ideal, .pure water would be a non-conductor, at least to all ordinary potentials. The situation is one which cannot well be resolved by experiment. We must proceed by way of hypothesis, as in the case of gravitation.

Let our hypothesis be this—that the interaction of two diverse molecular systems is determined by the presence of a third system, itself an electrolytic system and compatible with them, in the sense that the three can be associated into a single conducting system. I would call this third system the *Determinant* and say that every chemical change involves the presence of a Determinant. Please mark the word *Determinant* and note that the Determinant is always an electrolyte.

Sauce for the goose being sauce for the gander, all that I have said may be read backwards. If hydrone cannot be formed by the direct interaction of hydrogen and oxygen, it cannot be directly resolved into these; some determinant must intervene to bring about the decomposition. H. B. Baker has given proof of this thesis by showing, to take only a single case, that the stability of ammonium chloride is greater the more carefully it is dried.

Recognising this, let us give effect to our belated conversion to a true faith by including in every equation the symbol of the determinant, E or Ed, a small one, if you will; better an epsilon, ϵ, if not $\epsilon\delta$, as these foreign signs will have greater appearance of learning. Let us not be ashamed of acknowledging the determinant, especially in Grecian dress, as a necessary member of any family party of chemical agents we may call together, *e.g.*, in expressing the formation of hydrone empirically, in order to show what factors are involved, let us write:—

$$(O_2+\epsilon\delta+2H_2)=2H_2O+\epsilon\delta;$$

or if we wish to represent the operation as a reversible change

$$(O_2+\epsilon\delta+2H_2)\rightleftarrows(2H_2O+\epsilon\delta).$$

The brackets are added to indicate that a complex system is involved in each case.

The argument may be extended even to explosives. We know from Gattermann's work that the stability of nitrogen chloride depends upon its purity. In firing Cordite—a mixture of cellulosic and glyceric nitrates—not a little of the unburnt material is often projected from the gun in the form of perfect rods much reduced in size. The explosive is not shaken to pieces molecularly but just burnt away at the surface and we have to picture to ourselves the long-despised little ee's or ed's bombarding this with incredible activity as the charge is slowly fired—slowly in comparison with the intra-molecular activities of the explosive system.

A horribly pedantic jargon has been piled up around ethylic aceto-acetate and other compounds which lead a double life, beginning with the word *tautomeric*: an unnecessary invention, Berzelius having rightly assigned *metameric* to such use. They were long represented as not knowing their own minds for two seconds together—strange to say, no Ostwald ever coined the term *Lunoids* for them—as ever undergoing an internal molecular change at their own sweet wills. It has always been clear that little $\epsilon\delta$ was at work. Groves and I took this view in several instances in writing our (Miller's) *Organic Chemistry* (1880); and Lowry, in my laboratory, has given the most complete proof of the thesis. Recently, it has been found that either of the two metameric (isodynamic) forms of the aceto-acetate may be obtained at will by observing certain precautions—mainly, be it noted, by using quartz instead of glass vessels.

I have not yet reached a terminus. If logical and we have faith in our prophetic powers, we may project our minds into the future and foresee the time when it is admitted that liquids and also solids are not as we see them. Baker is already leading the advance into this field. By drying benzene, he has raised its boiling point above that of water—if indeed the explosive behaviour at the higher temperature can be characterised as " boiling." He has obtained similar results with carbon bisulphide and other liquids. Carnelly's dream of hot ice was perhaps not the absurdity it was deemed to be at the time! Benzene boiling at 107° or mercury at about 450° would have been scoffed at equally. Benzene and similar liquids which are not miscible with water are not easily dried but once dried they are not easily wetted. Baker being a veritable wizard has been able to boil off water through dried benzene. Modest in manner and modest in statement, he has made far too little impression upon our cloth; no Teutonic Boswell has log-rolled his progress, no special Journal has been founded to acclaim the peculiar joys or drawbacks of the dry state in chemistry, no Act of Congress has been passed to provide for its operation. The main reason probably why the prophet has been insufficiently honoured even in his own country is the fact that we chemists are educated into being the dullest of drones—without imagination. We cannot remain dry ourselves, even in the U.S.A., therefore, apparently, we have neither belief nor interest in the dry state, except as one to be avoided; we only subconsciously realise perhaps that you cannot get on in it; presumably it is one involving the death of chemical change, as it is of all artistry, because of the inanimate life the molecules enjoy during drought.

The Catalyst

Having considered the conditions which determine the occurrence of chemical change, let us now pass to those which hasten its progress. The interaction of hydrogen and oxygen is promoted by platinum in any state of division but more especially when it is very finely sub-divided, as in the spongy platinum first used for the purpose by Döbereiner in 1823, although Humphry Davy had previously (1817) noted the inductive effect of the metal in the massive state.

Döbereiner, as Faraday wrote in 1833,

> "refers the effect entirely to an electrolytic action. He considers the platina and hydrogen as forming a voltaic element of the ordinary kind, in which the hydrogen, being very highly positive, represent the zinc of the usual arrangement and like it, therefore, attracts oxygen and combines with it."

The only essential condition, as Faraday insists, is a clean metallic surface. As he recognised,

> "The effect is evidently produced by most, if not all, solid bodies, weakly perhaps by many of them but rising to a high degree in platina. Dulong and Thénard have very philosophically extended our knowledge of the property to its possession by all the metals and by earths, glass, stones, etc.; and every idea of its being a known and recognised electric action is in this way removed."

What could be better, too, than the following?—

> "All the phenomena connected with this subject press upon my mind the conviction that the effects in question are entirely incidental and of a secondary nature; that they are dependent upon the *natural conditions* of gaseous elasticity, combined with the exertion of that attractive force possessed by many bodies, especially those which are solid, in an eminent degree and probably belonging to all; by which they are drawn into association more or less close, without at the same time undergoing chemical combination, though often assuming the condition of adhesion; and which occasionally leads under very favourable circumstances, as in the present instance, to the combination of bodies simultaneously subjected to this attraction."

The modern work of Hardy, Langmuir and others is justification of the view that condensation at solid surfaces is the outcome, not of a mere mechanical cohesion but of an attraction due to residual chemical affinity and therefore selective—in fact, a function of structure. The peculiar activity of platinum seems to be due to the fact that it is highly attractive of both hydrogen and oxygen—whether and to what extent it combines with them to form an "oxide" when exposed to the two gases is open to question. Willstätter has argued that the presence of some oxygen in platinum sponge is essential to its activity as a hydrogenating agent and he assumes that an unstable compound with both elements is formed. Faraday's observation that, although the plate is less readily cleansed when made the negative pole in diluted sulphuric acid, a platinum plate at which hydrogen has been evolved, when clean, is equally active in promoting the interaction, would seem to preclude the presence and need of oxygen, unless it be that the formation of the oxide postulated by Willstätter takes place immediately, by partial displacement of hydrogen, on presentation of the clean metal to the gas; also the fact that most if not all solid bodies are in some degree active, is against the oxide view; but the gradual corrugation of the solid metal and the expansion of palladium as it is charged must not be overlooked as favouring it.

For the present argument, this is a question of minor importance. The main function of the platinum surface would seem to be to capture and raise the concentration of the interacting substances; not to induce change but to hasten it by this increase of concentration. The determinant is as necessary as in the ordinary case of interaction of the gases in its absence, as without it no electrolyte would be present. The problem has not yet been submitted to any refined study but it is known that moisture favours the action.

I am thus brought to the definition of a Catalyst* as something different from a Determinant and to accept the statement, which is commonly stressed, that it is an agent which accelerates a change in being. Unlike the Determinant, however, the Catalyst is not an electrolyte but merely a solid superficies at which the interacting substances become condensed and therefore of increased concentration; hence the acceleration of the interaction and hence the value of its aid.

In the mind's eye, from Faraday's massive plate to the most minute speck of platinum mounted upon a Messelian asbestos support, the change in size and increase in activity is continuous and doubtless in correspondence with the increase in surface area; the greatest activity would be that of molecular fineness. The speck, however, must remain a speck: it must retain its particulate character; in solution, the molecules are too often married with the solvent, their distribution is too uniform, to permit of an excited rate of change.

The activity of the catalyst would seem to be due to the operation of the force of residual affinity; on no other assumption can we well understand the preferential activity of various catalysts. The work of Hardy and Langmuir especially has afforded proof that molecular structure is a determining factor and that a single layer of molecules can cover and effectively occupy a solid surface. The molecules in some way become ranged in accordance with their structure. Chemists have long thought of the carboxyl radicle in acids as the active part of the molecule and it is no surprise to have proof given that when a fatty acid is spread out upon water the molecules become ranged in the film in serried ranks, like porcupine-fishing-floats in a stream, only the carboxyl radicle dipping into the liquid; the argument may be extended to an oiled solid surface.

The character of the surface also plays its part. Hardy has definitely shown that glass, metal and various kinds of composite material of the ebonite class behave differently. We can but imagine that the structural character comes into play and that centres of attraction may be offered. No other explanation can well be given of the entirely selective activity of the colloid catalysts—the enzymes, the potent agents of change at the root of all vital activity. It is commonly stated that these fit their compatible hydrolytes as a key fits a lock; the hypothesis was put forward by the late Prof. Emil Fischer, long my venerated friend; as he has been regarded as a super-authirity, not only in

---

*I believe I introduced the term in 1885. *Catalyser* (*catalyser*) is a word without euphony to my ear and I would specially deprecate the use of the verb *to catalyse* or any verbal form of the term.

Germany where it is customary to worship the words of professors but by chemists generally, the suggestion has been made one of our chemical shibboleths. Infinitely gullible we are, as Carlyle has said. The suggestion does not bear thinking about, charming though it be as a literary parallel. A key is something entirely different from a lock—something which fits into its blanks. Blanks are unknown to us in our chemical locks. The fit cannot well be other than that of similarity: in some part the enzymic complex must be so like the compatible hydrolyte that the two fit together when superposed; we are therefore driven to think of this active centre as the hydrolyte itself gathered into the structure of the complex. My son and I have long advocated this view.

The influence of proteid colloids other than enzymes as catalysts has been little studied.* The production of hydrazine from ammonia and hypochlorite, according to Raschig, is promoted by the presence of a little glue; but it is found, I believe, that all glues do not equally serve the purpose. If so, is the difference due to some structural peculiarity? It is conceivable that the interaction may involve the intervention of a protein chloramine? If so, structure might tell.

In addition to directly active catalysts—catalysts which exert a definite attractive effect upon substances whose interaction they promote—there is conceivably a neutral class, effective through the agency of the specially active layer of simple hydrone molecules deposited at their surface.

Hydrone and Water

Progress has too long been stayed by the fiction that water is represented by the symbol OH_2—by the failure to recognise that it is a "mush" of molecules of several degrees of complexity.† Unfortunately, we can only distinguish one at present, the simplest, that of hydrone, OH_2, probably always a minor constituent of water. Bragg's recent work rather favours the view that ordinary ice is a benzenoid complex in which six hydrone molecules are conjoined. I have long been of the belief that water is to be thought of as a mixture of hydrone with several polyhydrones of the polymethylene type.

If we could be logical, we should only apply the term water to the liquid substance, never to that symbolised as H_2O. We have as little right to think of this as water as we have of the various polymethylenes as methylene.

The Pseudo-Physical School has been so impassive and impenetrable by ideas, so intellectually pachydermatous, that it has never given heed to the composition of water. The treatment of the problems of solutions by the school has therefore been purely empirical and of small value. The main object has been to force agreement with a formula; this satisfies the mathematical mind but not the free-spirited chemist striving to see within and to dissect out the active factors. We are often told that a return to the land is now our one hope of salvation as a people—in any case our ultimate fate. Let us chemists recognise that we can only abide in chemistry and let this be to us a word of real significance, of broad and intensive meaning. A chemist must be a chemist and not a mere bit of one, still less a formula-seeking mathematician, to do effective work.

To begin with, we must purify and simplify our nomenclature and use only words of clear import. We must arrive at an understanding as to the meaning to be given to the term solution. The term solid solution is a contradiction in terms; Colloid solution is equally bad; in a crystalline solid mixture there cannot be that evenness of distribution which is the characteristic of a solution; motion must be constrained and limited, not illimitable; there cannot be that exercise of affection between solute and solvent, that compatibility of temper due to oppositeness of character, which is at the root of solubility and dissolving power, which leads to short marrying long, to beauty mating with ugliness.

Determinant and Catalyst

This brings me to the final distinction I desire to make between Determinant (εδ) and Catalyst (κ).

The one is active in solution, the other in suspension; in the one case the distribution of the components is even; in the other it is uneven and local, the catalyst being a surface-centre towards which the interacting substances are attracted.

In the presence only of a determinant, the rate of change is in accordance with the sacred Law of Mass Action, which is ever subject to modification however, owing to changes in the medium conditioned by the alterations in molecular character and complexity which attend all interactions, just as human laws are always being modified by circumstances.

---

* The attempt has been made by the school that dubs itself "colloid" to read into the term the sense of particulate—of very finely divided matter in suspension in a fluid. Nothing was further from Graham's mind.

I would urge that the term colloid should be used only in its etymological sense and confined to substances such as Graham contemplated—substances opposite to the so-called crystalloids in the scale of solubility.

Then that a distinction be drawn between actions in solution and those at particulate surfaces.

The passage of the colloid from solution into the particulate state probably involves far more than meets the eye, even that of imagination, to-day. McBain's fascinating studies of soaps have brought to light the existence of a tendency similar to that apparent in compounds such as the cobaltammines and other complex salts, in which one or more of several negative radicles is lost to view. In the soaps, several primary molecules of the salt are merged into an aggregate in which the alkali is in large part hidden away. We have to remember that even acetates have a tendency to take on a more complex form than that of the simple molecule. It is possible to think of a wheel-like arrangement of the molecules, in which most of the carboxylated groups are at the hub, the hydrocarbon radicles ranging outwards like spokes. The coagulation of colloids may well involve the formation of aggregates, in like manner: and the production of a jelly is conceivably due to the interlocking of such polymerised molecules, water filling the waste spaces. As Wilder D.B. has the goodness to say: "For the moment it looks as though the organic chemist were the safe man to follow," rather than the adsorbist. Yet such an explanation can scarcely be given of the agglutination of micro-organisms under some special conditions which we cannot yet appreciate; the primary change, in these cases, may be in water.

† The rapid increase in the rate of chemical change as the temperature of a solution is raised, it may be suggested, is mainly due to the changes which water itself undergoes—to its increasing activity.

* When Mr. Walcot has exhausted his imaginative power in depicting Roman and Persian subjects, he will perhaps find a worthy stimulus to his needle in an allegorical presentment of the new Babylon science is building. I said much of our abuse of our language in 1894, in my first Presidential Address to the Chemical Society. As Secretary, I had had some influence in securing uniformity and clearness of expression. To-day, there seems to be no check to lawlessness—no clear understanding of law, no desire to arrive at and obey the law. Proceedings under the Safeguarding of Industries Act show that we must spring-clean our vocabulary and give thought to our words. Why do we so carelessly use Interaction and Reaction indifferently, when the former expresses our meaning and the latter does not? Why are we not satisfied to speak of chemical agents, instead of reagents? The medical man is content with "therapeutic agents." Why introduce "reactant"—an unnecessary and un-English word? Our object should be to use words as near as possible to those in popular use, if not those in actual use: our desire being to live on terms of intimacy with the public. Why coin new words when old ones will suffice? Adsorption would be a proper word to introduce, if a new word were necessary; but several popular words suffice to convey the idea underlying its use. It is strange to the common ear and to the novice. If we are to coin new words, they should suit the genius of our language; no language is so hospitable to foreign intruders, yet it cannot admit every stranger that may call in. To get over the difficulty arising from the alternative use of absorb and adsorb, it is proposed to omit the prefix; but sorb is a word without dignity, and the attempt to introduce it should not be countenanced. The introductory "But" is a mild offender compared with it. Then why so un-English a term as ionic *micell* when aggregate gives complete expression to the underlying idea: the word carries no crumb of comfort to the British ear: and what will it become in America—My-y-sell? Anything may happen to such a word. It is time some sense of eternal fitness, if not of the ridiculous, were infused into the scientific mind—if we wish to secure public sympathy. Still:

Oh ye who tread the Narrow Way
By Tophet-flare to Judgment Day,
Be gentle when the heathen pray
To Buddha at Kamâkura.

In the presence of a catalyst, the action is not in accordance with the nominal concentration but much more rapidly and nearly at a linear rate over the greater part of the period of change. Unfortunately, the action of catalysts, especially of enzymes, is often obscured by secondary actions and the assumption that all chemical change must be subject to the mass action law has gained such credence that almost everywhere the temptation to twist the results to this interpretation has been irresistible. There has, however, long been a suspicion that enzymic hydrolysis takes place mainly at linear rates, so long as disturbing influences are inoperative; it is permissible to say, I think, that the work done in my laboratory, especially that with urea and the enzyme urease, has raised this to a certainty, confirmed as it has been, in the most striking manner possible, by the observations made by Drs. E. F. Armstrong and Hilditch on the hydrogenation of oily fluids in presence of very finely divided metallic nickel.

Let me cross the t's in this section by saying that if we desire to give expression to the action of a catalyst in writing an explanatory equation, this may be done as in the following example:—

$$O_2+\epsilon\delta\kappa+2H_2=2H_2O+\epsilon\delta\kappa.$$

By associating the symbol of the electrolytic determinant with that of the catalyst, the fact is brought out that the former is necessary and that both factors are concerned in the operation.

Hydroxylation not Oxygenation

The formation of hydrone from hydrogen and oxygen is but imperfectly expressed even in the equation

$$O_2+\epsilon\delta+2H_2=2OH_2+\epsilon\delta;$$

it is true unusual attention is paid to the character of the process but this is not fully developed as an electrolytic event.

When writing my *Introduction to the Study of Inorganic Chemistry*, published in 1874, although I was grossly ignorant and inexperienced, I was beginning to think. Discussing the formation of acids by the oxidation of the corresponding aldehydes, having assimilated Avogadro's theorem and knowing the formula of oxygen, which few did at that time, I wrote (p. 241):—

$$2R'.COH+O_2=2R'.CO(OH).$$

In a footnote I added:—" Perhaps

$$R'.COH+O+OH_2=R'.CO(OH)+OH_2,$$

i.e., the reaction is one of double decomposition, H being replaced by OH and does not consist in the mere addition of oxygen." In Miller's *Organic Chemistry* (p. 417), published in 1880, this conception was logically extended to cases of oxidation generally.

I had not then consciously developed a consistent electrolytic conception of chemical change, yet I was approaching it and had foreseen that the oxidation process is to be interpreted as primarily one involving hydroxylation.

It may safely be asserted, taking the facts generally into account, that when acidified water is electrolysed, hydrone molecules are primarily resolved not into oxygen and hydrogen but into perhydrone (hydrogen peroxide) and hydrogen:—

$$\begin{array}{llll} H & \cdot\quad\cdot\quad\cdot & OH. & \\ H & \cdot\quad\cdot\quad\cdot & OH. & \end{array} = H_2 \quad \cdot\quad\cdot\quad\cdot \quad (O_2H_2)$$

The dots stand for the little $\epsilon\delta$'s, the electrolytic systems which carry H and OH at their terminals. The perhydrone, maybe a sulphonic-perhydrol, is decomposed at the electrode face. How? Not by mere contact with the chilly metal; the process resorted to is a warmer one, I believe, involving hydroxylation of the perhydrone:—

$$HO.OH+\epsilon\delta\kappa+HO.OH=HO.O.OH.+OH_2+\epsilon\delta\kappa$$

and when the hydroxyls are crowded together, as they are at certain strengths of sulphuric acid or when currents of relatively high density are applied to the solution, probably still higher perhydrones are produced by a similar process.

Oxygen and ozone appear to be the products of the breakdown of these perhydrones.

A wicked and perverse generation, to the present day, we teach the poor student that when water is electrolysed—acid is added, to make it conducting, we say—it is resolved into hydrogen and oxygen; occasionally a reference is made to by-products, never to the probability that the oxygen is a by- or secondary product. Endless talk about hydrogen and hydroxyl ions is probably indulged in and the student carries the scars of these through life, though nothing more; fiction is always preferred to fact, in reading.

What is true of electrolysis is true of oxidation phenomena generally.* Hydrogen is first burnt to perhydrone (hydrogen peroxide); the oxygen is merely hydrogenised. In turn, the perhydrone molecule serves as the oxidant, so that the oxygen molecule is broken down in two stages; there is no reason to think of atomic oxygen as ever engaged in the operation. Were it not that the mystic word " ionised " is now grafted into our being, we should think without difficulty in terms of molecules and be rational.

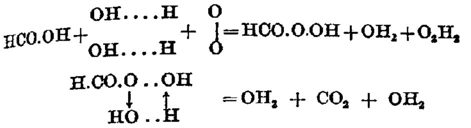
Hydrocarbons behave, in general, as hydrogen.

Carbonic oxide is peculiar in this as in most other respects. It is commonly recognised not only that this gas cannot be burnt dry but that the rate of combustion rises as the amount of hydrone in admixture with it is increased, up to a certain point; hydrone apparently plays a peculiarly active part in its combustion, primarily through incorporation into its being. In fact, it is difficult to think of hydrone as active in conjunction with carbonic oxide except by giving rise to formic acid; the two molecules cannot well grip each other at all with any other result. Carbonic oxide, under ordinary conditions, is an alert molecule which cannot easily be caught; tamed at the surface of a catalyst it is docile enough. A mixture of carbonic oxide and chlorine must be well sunburnt to induce interaction but an active charcoal will induce the immediate pairing of the gases. Faraday found that unheated clean platinum was without sensible action on a mixture of carbonic oxide with oxygen; further, that in presence of any considerable proportion of carbonic oxide, hydrogen and oxygen were indifferent to each other at the metallic surface. It is therefore to be supposed that the carbonic oxide molecules, having the greater affinity for platinum, cover up its surface against hydrogen. Faraday's observations were confirmed by Groves' later study of the gas battery. It is an unfortunate fact that carbonic oxide and oxygen cannot, as far as we know, be usefully associated in an electrolytic circuit; if the disability could be got over and economically, how golden might the future of industry be.

Given the initial production of formic acid, all else in the behaviour of carbonic oxide is clear. The oxidation of this acid presumably involves the formation in the first instance of a perhydrol (per-acid) which breaks down on hydrolysis into carbon dioxide and hydrone:—

---

* Compare my *Studies on Oxidation*, this Journal, 1913, 391.



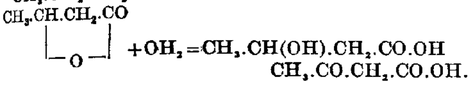
$$\mathrm{HCO.OH}+\begin{matrix}\mathrm{OH....H}\\ \mathrm{OH....H}\end{matrix}+\begin{matrix}\mathrm{O}\\ |\\ \mathrm{O}\end{matrix}=\mathrm{HCO.O.OH}+\mathrm{OH_2}+\mathrm{O_2H_2}$$

$$\begin{matrix}\mathrm{H.CO.O..OH}\\ \downarrow\quad\uparrow\\ \mathrm{HO..H}\end{matrix}=\mathrm{OH_2}+\mathrm{CO_2}+\mathrm{OH_2}$$

I call attention to these operations in order to make clear the point that the "Sweet to the Sweet" principle prevails in chemistry, as in life. Oxygen seeks oxygen but falls a prey to hydrogen by the way. Only on this assumption can we understand the manner—sometimes dubbed peculiar by the thoughtless—in which the oxidation of carbon compounds is effected. In the case of the fatty acids, the candle is mainly burnt not at both ends but at the carboxyl wick, which is necessarily attractive as an electrolytic centre. Apparently the perhydrol that is formed then proceeds to curl its hydroxylic-tail and, like the whiting, the CH_2 radicle next but one to the carboxyl group swallows the hydroxyl at its tip; then casting off hydrone, it is reduced to a weakened state, in which it soon falls a victim to further hydroxylic attack. In plain symbols—

$CH_3.CH_2.CH_2.CO.OH$

$CH_3.CH_2.CH_2.CO.O.OH$



$$\begin{matrix}\mathrm{CH_3.CH.CH_2.CO}\\ \lfloor\!-\mathrm{O}-\!\rfloor\end{matrix}+\mathrm{OH_2}=\begin{array}{r}\mathrm{CH_3.CH(OH).CH_2.CO.OH}\\ \mathrm{CH_3.CO.CH_2.CO.OH.}\end{array}$$

Dakin has written a special monograph on the subject—but without discussing the process: such is the advanced state of our chemistry. Ions to right of us, ions to left of us, onward we stumble: but look, let alone see, where we are going, rarely. Why the tail is swallowed at the third carbon atom history does not tell: the future historian will probably recognise that it is a consequence of a structural peculiarity innate in the carbon chain. The agent also at times is not without influence upon the result; probably it alters the length of lash of the tail.

I have yet to withdraw one reputed catalyst from your sight—the ferrous salt; to put it in its proper place, that of a mere determinant, a little εδ.

By hypothesis, perhydrone is not an oxidising agent: like water, it is not an electrolyte. When coupled with an iron salt, it becomes active, we may assume, in virtue of the formation of a perhydrol which is an electrolyte in solution:—

Ferrous sulphate.

Ferrous sulphate perhydrol.

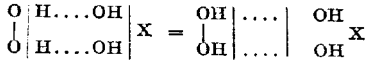
This compound may be produced, be it noted, starting with oxygen. The perhydrol, moreover, can not only serve as an "oxidase" but also as a "catalase": it can oxidise perhydrone itself and so determine the liberation of oxygen.

The idea that oxygen acts *directly* as an oxidising agent is so fixed in our minds that it is with difficulty put aside; yet it is one to be discarded.

Directed oxidation

We have also to realise that hydroxylation may take place in the absence of oxygen—under the influence of reducing agents. This process is one of special importance as playing a determining part in vital phenomena, in fermentation, for example. It is that which renders anaerobic life possible. A specially interesting case has been dealt with recently by Gowland Hopkins, Morgan and Stewart, who have studied the action of a peculiar agent in milk which induces the oxidation of both xanthin and hypoxanthin in presence of a reducible substance such as methylene-blue, for which oxygen may be substituted. The agent in question is not a mere determinant like ferrous sulphate but a catalyst, as change proceeds under its influence at linear rates. As its activity is confined to the two bases mentioned, the catalyst is to be regarded as an enzyme, the more as it is destroyed by heat.

The oxidising agent acts only indirectly as depolariser, the active hydrogenating agent in the oxidation process being the hydroxyl of hydrone liberated in an electrolytic circuit in the following manner:—

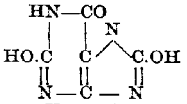


$$\begin{matrix}\mathrm{O}\\ |\\ \mathrm{O}\end{matrix}\left|\begin{matrix}\mathrm{H....OH}\\ \\ \mathrm{H....OH}\end{matrix}\right|\mathrm{X}=\begin{matrix}\mathrm{OH}\\ |\\ \mathrm{OH}\end{matrix}\left|\begin{matrix}....\\ \\ ....\end{matrix}\right|\begin{matrix}\mathrm{OH}\\ \\ \mathrm{OH}\end{matrix}\mathrm{X}$$

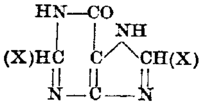
X is the oxidised material. Methylene-blue (or other reducible substance) may be set in the place of oxygen in this expression. The only distinction to be drawn between them is that oxygen has double the value of methylene blue as a reducible substance, the perhydrone produced at first being itself reducible to hydrone.

The remarkable fact has been established, by Hopkins and his fellow workers, that with the aid of methylene-blue the two bases are oxidised (to uric acid) at molecularly equal rates, twice the amount of work being done upon the one as upon the other: it is therefore necessary to conclude that the two oxidisable centres in hypoxanthin are in a single circuit.

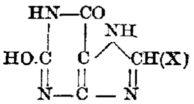
The striking similarity in the two bases and uric acid is brought out clearly when their formulæ are written in the following way, X being the centre at which hydroxylation takes place:—



Uric acid.



Hypoxanthin.



Xanthin.

As the oxidase can influence or direct attack at two centres simultaneously in hypoxanthin, it is probable that the enzyme fits upon a large section if not the whole of the molecule.

An enzyme which could thus act may be imagined, containing as active component uric acid itself; this might be compatible with both molecules, as the CH group to be oxidised would probably be no obstacle to its fit, whilst the presence of NH in place of O in adenine and guanine would certainly be an interference. It is possible to think of such an enzyme becoming perhydroxylised under the influence of the hydrogen acceptor and the product as inducing in turn the hydroxylation of one or both sensitive centres in the two bases. The effect on hypoxanthin would be like that of using two voltaic cells in series instead of a single cell of about half their joint electro-motive force.

In ordinary alcoholic fermentation, assuming that the glucose molecule be primarily resolved into two molecules of glyceraldehydrol,

$$CH_2(OH).CH(OH).CH(OH)_2$$

both a highly reducible and a highly oxidisable substance, the reduction of the one molecule may be supposed to take place, directly or indirectly, in virtue of the hydroxylation of the other.

The results obtained by Hopkins, Morgan and Stewart are also of special interest in connexion with the oxidases so frequently met with in plant and animal fluids; the evidence that these are enzymes has hitherto been inconclusive, though from their specific behaviour it appeared probable that at least most of them were.

Such enzymes should be distinguished from those which simply induce hydrolysis of a single molecule. These latter may be termed *homolytic*, whilst those which promote hydroxylation by the co-operative action of two distinct molecules, the one reducible and the other oxidisable, may well be termed *heterolytic*.

I thus end my discussion of chemical change upon a natural note and pass to

Sulphuric acid

yet only again to voice a conplaint of inattention, if not of ignorance. Over fifty years ago, when fellow students, Horace Brown and I were Frankland's "Versuchsthieren," used in imagining graphic formulæ, to test the application of the then new practice of such exercise; we played the game much as that of noughts and crosses is by children, in accordance with certain very elementary rules. To-day we cannot express the structure of sulphuric acid with any less uncertainty than Horace Brown and I did in those distant days of our early innocence.

What *is* the structure of sulphuric acid? We simply do not know. What indeed do we mean by sulphuric acid? It is premature to ask the question until we agree in our definition of an acid. To get this fat out of the fire will be no easy matter.

I ask you to face the facts. It matters little how much knowledge we have; it can avail us little if we are not alive to our ignorance of things fundamental.

The Acid Function

I have been much struck of late by the frequency with which in examination papers of schoolboys *oxygen* is referred to as a misnomer. In a French scheme for the reform of the nomenclature of inorganic compounds, brought forward at the Lyons Conference a few days ago, the compound formulated HCl is referred to as a hydracid and given the name "acide chlor-hydrique"; we often go one worse, calling it hydrochloric acid, seeing that there is no "chloric" about it. Such base use make we of our perversity.

Sacré nom de Lavoisier! Oxygen a misnomer! Hydrogen chloride an acid! Asticot would say: *C'est abracadabrant!* Are we not told that when the *Quartier Latin* so calls a thing, there is no more to say? Is it not truly written and for evermore: "La Chimie est une Science Française, *Elle fut constituée par Lavoisier*," etc.? In designing the word Oxygen, Lavoisier rose to the greatest height of his unparalleled genius. Not only is the word a monument to his astounding insight into chemical phenomena, to his philosophic power; it is also proof of deep philological feeling and acumen, as well as of his sense of the beauty of words. Think of the astounding step he took, after his instant appreciation of Priestley's discovery, in translating the old nonconformist's ponderous reminder of the doubtful past of our science conveyed in the name *Dephlogisticated Air* into an all significant word of the aural and lingual perfection of *Oxygen*, paralleled only, to those who have an ear for nordic harmony, by *Sauerstoff*, which unfortunately we cannot translate into English, though *Sauerkraut* sounds just as well in our tongue as in German: stuff unfortunately has gone out of fashion in our language; at best we associate it with either nonsense or dreams.

Lavoisier did more—he atticised our Science for all time; and the scribes and literary Goths, uncultured in all but their own works, scoff at us as Greekless! The while they are unable to interpret a word so all-meaning as Oxygen or construe a single passage in our writings. Don't let us think of Lavoisier merely as a man who heated mercury in air and lost his head; think of him as the pioneer who not only sought to put system into the souls of chemists but also tipped their tongues with harmony.*

In my early days, the Berzelian sun was not yet set. Oxides were of two classes, acidic and basic; and these combined to form a third, the salts. Debus and Williamson spoke of the *oxide* formulated SO_3 as sulphuric *acid*; the compound formulated H_2SO_4 was hydric sulphate. Messel always spoke of this latter as *monohydrate*—a survival of the significant Berzelian nomenclature.

Some disturber of the peace then came along and gave unnecessary prominence to the least of atoms, Hydrogen. A fashion arose of teaching chemistry, instead of allowing students to learn it; so it was necessary to furnish with definitions the poor mummers who taught. For text-book purposes, an acid was defined as a compound containing hydrogen displacable by metal through the action, if not of the metal itself, of a base, a miserably thin description subject to many more exceptions than the oxygen rule of Lavoisier, if indeed there be any to this latter. There is none, if the acid formed in water by the addition of hydrogen chloride be in truth chlorhydric acid, $HCl.OH_2$, as I contended so far back as 1885.

When hydrogen is turned out from an acid, it is in no direct, open and honest way; the more stal-

---

*This is equally true of the name Lavoisier gave to the companion of oxygen in air. The passage in which he states his reasons for terming this *Azote* is of extraordinary interest.

> "Les propriétés chimiques de la partie non respirable de l'air de l'atmosphère n'étant pas encore très-bien connues, nous nous somme contentés de déduire le nom *de sa base* de la propriété qu'a ce gaz de priver de la vie les animaux qui le respirent, nous l'avons donc nommé *Azote*, de l'*a* privatif des Grecs et de ζωή, vie; ainsi la partie non respirable de l'air sera le gaz azotique.
>
> Nous ne nous sommes pas dissimulé que ce nom présentait quelque chose d'extraordinaire; mais c'est le sort de tous les noms nouveaux; ce n'est que par l'usage qu'on se familiarise avec eux. Nous en avons d'ailleurs cherché longtemps un meilleur, sans qu'il nous ait été possible de le rencontrer; nous avions été tentés d'abord de le nommer gaz alcaligène, parce qu'il est prouvé, par les expériences de M. Berthollet, que ce gaz entre dans le composition de l'alcali volatil ou ammoniaque; mais, d'un autre côté, nous n'avions pas encore la preuve qu'il soit un des principes constitutifs des autres alcalis; il est d'ailleurs prouvé qu'il entre également dans la combinaison de l'acide nitrique; on aurait donc été tout aussi fondé à le nommer principe nitrigène. Enfin, nous avons dû rejeter un nom qui comportait une idée systématique."

It is unfortunate that we did not follow the French in preferring *Azote* to nitrogen—the name is so perfect and significant—as applied to the inert gas in air: the contrast would have been complete had the active constituent been termed *Zote*. In some way this latter word seems to lack force without the privative *a*. Still, it would not be difficult to accustom our ears to Zote and Azote; we should then be able to draw the distinction that is so desirable between the two chief materials of air and their constituent stuffs symbolised by O and N, which represent ideals: Lavoisier clearly intended the names Oxygen and Nitrogen to apply to these ideals; he as definitely draws a distinction between azotic gas and azote, in the above passage, as he does between oxygen gas and oxygen in giving his reason for the adoption of this name.

> "Nous avons donné à la base de la portion respirable de l'air le nom d'oxygéne, en le dérivant de deux mots Grecs, ὀξὺς acide, γείνομαι j'engendre, parce, qu'en effet une des propriétés les plus générales de cette base est de former des acides en se combinant avec la plupart des substances."

The distinction is again made clear in the following passage:—

> "De la Décomposition du Gas Oxygène par les Métaux." Lorsque les substances métalliques sont échauffées à un certain degré de température, l'oxygène a plus d'affinité avec elles, qu'avec le calorique: en conséquence toutes les substances métalliques, si l'on en excepte l'or, l'argent et le platine, ont la propriété de décomposer le gas oxygéne, *de s'emparer de sa base* et d'en dégager le calorique."

Lavoisier's clearness of vision in seeking for a name other than azote, significant of the chemical character of the element, is very remarkable. Had he known of the amines, he would surely have proposed *Aminogen* and we should then have been in possession of two of the most perfect names possible.

The quickness of the Darwinian uptake of ideas is well shown by Erasmus Darwin's early use of Lavoisier's term in Canto IV of his poem "Economy of Vegetation."

Sylphs! from each sun-bright leaf, that twinkling shakes
O'er Earth's green lap or shoots amid her lakes,
Your playful bands with simpering lips invite
And wed the enamour'd Oxygene to Light.

wart metal is brought in *sub rosa* at the stage door and is effective owing to the superior attraction it offers to the *oxygenated* radicle of the acid: in symbols—

$$\text{Neg.}\left|\begin{array}{l}\text{H}\ldots\text{HSO}_4\\ \text{H}\ldots\text{HSO}_4\end{array}\right|\ \text{Zn}=\text{Neg.}\ \left|\ \text{H}_2\ \right|\ \begin{array}{l|l}\ldots & \text{HSO}_4\\ \ldots & \text{HSO}_4\end{array}\!\!>\text{Zn}$$

We are agreed that in chemistry we must rely upon formal definitions: no single definition based upon behaviour is of universal application. No acid so-called functions as an acid *per se*. The compounds *named* acids are all inert—for the simple reason that they cannot conduct electricity, all chemical change being electrolytic in character. This could be asserted fearlessly in Faraday's time; how much more then to-day, now that we worship the electron and regard it as concerned in and guilty of every chemical crime.

The acid takes form only when water is brought to the rescue of the dielectric: as we know, when a man's married, then trouble begins; what happens when a dielectric marries water has long been a subject of debate. Perhaps debate is a wrong term to use. Religions are not established upon a basis of debate: they are accepted as faiths by adoring, unreasoning, credulous believers, in response to dogmatic assertions. In the early eighties, a young prophet arose who appears to have had some training in mathematics and physics but to have aquired no feeling for chemistry; he preached a gospel in which the acids were described as degenerating into the most abandoned of libertines, as becoming drunk with freedom, when cast into solution.

From this time on, the wandering hydrogen atom became in itself the personification of acidity—it s true it was featured as in the leading strings of an adoring opposite positive charge but the bond was admittedly of the weakest and the loose partnership was subject to constant change. The youthful propagandist was properly told by his master that he did not know enough to deal with so serious a subject and that he deserved to be smacked and put back into the nursery; had he been put into a *camisole de force* the world would have been saved much pother and many printers' bills. Unfortunately, as prophets too often are, he was taken at his own valuation and seriously; it was not his ault but a consequence of our lack of logic, of the urvival of our primitive habit of yielding obedience o priests and sorcerers.

As Mr. Arnold Bennett somewhere says, we need o have "an ironic realisation of the humanity of human nature." Science is a new habit which does not fit our human constitution; our mental machinery is a congeries of mechanisms which are only imperfectly correlated; heredity makes us dogmatists and prime worshippers of the Idols of he Theatre. My objection has always been not to he speculation itself but to the maladroit zeal with which it was spread, the unscientific way in which t was rammed down our throats and all discussion burked by people like Ostwald, who obviously did not know what they were talking about and disregarded the findings of chemists in general. Many of the contentions were not only irrational but the ignorance displayed—particularly in the discussion on indicators—has often been astounding; the work put forward was biassed and superficial. Unfortunately, the physicists have not helped us; they have often smiled at our ionic rhapsodies but I have seen no evidence that they have regarded them seriously.

The great chemical blunder made by Arrhenius and his worshippers was in regarding water as hydrone and in representing hydrone as behaving altogether differently from the allied hydride, hydrogen chloride—by their assertion that when the two compounds were mixed, whilst the molecules of the one underwent practically no change, those of the other fell almost entirely to pieces. No reasonable explanation of the suicide was ever offered. Even that great genius van't Hoff, a giant among the pigmies, was carried away by the seeming agreement of fiction with fact. Evil communications corrupt good manners; had he kept other and higher company he would not so easily have been led astray but his vanity was tickled by the way in which his osmotic dreams were apparently made true by "ionic" coincidences. Had he but witnessed a scrum on a football field and considered its applications in chemistry his vision would have been clearer. Unfortunately, he paid no attention to water and yet he loved beer. The Arch-Ionian prophet, perforce of his Scandinavian heredity, was necessarily a Hydrophobe and put no measure of aqueous humour into his Koran. Never yet has justice been done to water, least of all in the U.S.A. Mathematician and physicist, rather than chemist, van't Hoff lacked just that element of feeling, the artist's practical sympathy with his subject and devotion to his studio; we must never forget that the laboratory worker is an artist and that, as a rule, practice comes first; so-called theory is usually but brought to the aid of practice in justification of its acts. This is true of agriculture throughout time and of industry to-day. The fancied explanations that have been given need not be taken too seriously; tentative and provisional for the most part, they but help us on our way and we must often be content to retrace our steps, recognising that the alley up which we are led is a blind one; the exercise, however, serves to keep us fit and is a preparation for the next excursion. Everest is not climbed in a year; many avalanches may wreck us, and

> 'Tis not antiquity nor author
> That makes Truth truth, altho' Time's daughter.

One real service the ionic school has rendered in systematising the application of Faraday's beautiful word *ion* to radicles which do not stand upon the order of their going but go once the chance be given. We now speak of salts generally as composed of positive and negative *ions* and the definition is full of meaning. By implication, it conveys the information that the compound consists of easily mobile radicles. On the other hand, compounds such as chlorethane and chlorobenzene, which do not behave as salts, are sufficiently described as composed of positive and negative *radicles*—the term radicle having a wider but less definite meaning. The distinction is not absolute but sufficient to justify a line being drawn. Why the positive hydrocarbon radicle should exercise so superior an attraction and keep the negative radicle at home and in order we cannot say. The electron worship of the day is too static and simple a faith to satisfy our longing to explain such a mystery.

The second service of the Arrhenists has been in emphasising the difference in the strength of acids and bases, always well recognised but not numerically expressed prior to the advent of the ionic speculation. Unfortunately the service is marred by the way in which the conception has been wrapped up in the term *hydrogen-ion-concentration*, a stilted phrase which is not only caviare to the general public but most misleading. Nothing more was necessary than to distinguish between *acidity* or if you will *apparent acidity*, as meaning quantity of acid; and *effective acidity*, as meaning the proportion of the acid present in the immediately active state. A layman can read such terms, even put some meaning into them and without his ear being offended; hydrogen-ion-concentration is pure gibberish, a chord that cannot be struck upon "the lyre of language clear." It is just a shibboleth which too often covers a pretence of learning; unfortunately, its forbidding presence is to be met with everywhere and it is being shouted loudly in the galleries of the new Babel which more than threatens to overwhelm science and deprive it of all public support. Even the brewing world only recently was entertained with talk on *Hydrogen Ions in Beer*. Fancy Brother Bung's joy at such a topic being under discussion—the query of the Bar Parlour: "What new poison are they putting into our swipes? Is this why beer is now such poor stuff? [*] Hang hydrogen ions, give us a little more body and spirit in our drink." It would comfort them to know that there are no hydrogen ions in alcohol: it occurs to me to ask—Is that perhaps the reason why Glasgow is so fond of petrolised water?

Necessarily I am reminded here of Samuel Butler's story of the conversation he overheard in an inn, summed up in the remark of the speaker to the barman—"Imagination will do any bloody thing almost." Yes, unfortunately, it will, even in the ranks of science—except make us wise.

One unforgivable result of enforcing the doctrine is, that acidity is regarded not as the function of an acid but of just one little bit of the molecule and that split off and away from it! I have sufficient belief in sulphuric acid to feel satisfied that it has a real sense of its own importance and that it acts accordingly—that its positive and negative radicles are equally concerned, directly or indirectly, in all its actions—always bearing in mind that all chemical interactions are electrolytic manifestations and polar phenomena, never unilateral.

Electrolytic conductivity

The position to-day is but little, if in any way, different from that of 1851, when Williamson's most remarkable communication *On Etherification* was made to the Chemical Society—remarkable because of the far-reaching character of his inferences and because of his youth and inexperience. By a stroke of genius he laid bare, probably for all time, the conditions in a solution—by drawing attention to the constant interchange of radicles which it was to be supposed must always be going on, to account for the state of equilibrium at once established whenever two or more salts are brought together. Williamson appears to have contemplated only an interchange of the radicles, never their free existence in solution. Kekulé afterwards suggested that the interchange was preceded by the association of the interacting molecules, a view I advocated in later years when interpreting the formation of substitution derivatives of benzene.

Clausius, in 1857, to explain the behaviour of electrolytes, first suggested that occasional violent molecular encounters in a solution now and then led to the disruption of the molecules. Arrhenius extended the speculation, by assuming that chemical activity was proportional to the degree of disruption and that specially active solutes, such as the strong acids, were all but entirely dissociated. He thus opened up a path for the mathematical treatment of the subject—by directly connecting chemical activity with electrical conductivity in a more definite way than had Clausius, who was merely concerned with electrical behaviour. He thereby did considerable service; but he and his literary body-slave, Ostwald, followed Clausius in regarding the action of the solvent as merely that of a screen; only later did they hedge in face of our protests. By attributing the "dissociation" to the high specific inductive capacity of the solvent they were but paraphrasing our contention that the change was due to an interaction of solvent and solute, brought about by the residual affinities of the associated molecules; but at all times it was useless to argue the point with them on chemical grounds: they would not understand us: a banner with a new device had been found and its possessors hurried on to plant it everywhere—as revolutionaries mostly do, without counting the cost of the doctrine they profess. The one point I am anxious to make is, that whilst we must have imagination, progress being dependent upon its exercise, we must give it always the controlled and guarded use implied in Tyndall's well-known and immortal phrase. An unscientific use may give us music, indeed genius must often operate in disregard to the rules of science; but science is founded upon imagination controlled and tried.

Probably we can assert as indisputable and all will agree, that in aqueous solutions the ions H and OH are ever on guard at the gates of entry and exit, armed and ready for immediate action on receipt of an electric call. The analogy of a corporal's guard is by no means one that is far fetched; in this the units are connected by the invisible link of discipline and are the counterpart of an electrolytic system. An interchange of sentries is not effected at random but by a regulated polar process. This, at present, is perhaps as far as we either can or may see. The whole subject is in need of further experimental study from an H. B. Baker point of view. We have not only to learn to use clear and just language but to labour to be clean. In the light of Baker's recent results, I am now inclined to take up a position more absolute than that I adopted 36 years ago, in March, 1886; to doubt if there be such a thing as a simple electrolyte—a substance which is an electrolyte *per se* in the pure state. Maybe some day a Baker will show that metallic halides—silver chloride, sodium chloride—are not electrolytic conductors and that metals are the only primary conductors of electricity; we have yet to learn where entire prohibition of impurity will carry us. I foresee a physics very different from the present—no longer a physics of freedom but one of slavery to unrestrained residual affinity.

We need to study afresh the passage of matter through its several states. It is already recognised, on the basis of Aitken's observations, that the condensation of hydrone to water involves the presence of "nuclei": the nucleus may act as a catalyst but what of the determinant—is one required? What would be the behaviour of exceptionally purified gases generally in exceptionally cleansed vessels? Might not the Andrew's "critical temperature" be greatly modified? Monatomic molecules of materials such as hydrogen, oxygen, nitrogen, may well persist under "clean" conditions. Rayleigh's observations on nitrogen and R. W. Wood's more recent studies of hydrogen already lend support to the view.

Thus far my dream—I trust I have made clear my vision of the process of change.

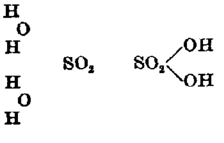
Structure and Basicity of Sulphuric Acid

In my days of early innocence, in 1871, I wrote—"Occupied with an investigation into the constitution of sulphuric acid"—as the opening sentence of the first of my Studies on Sulphonation. The subject still occupies a cell in my mind. It is strange that, excepting perhaps soda and not even that before the advent of the Solvay-Mond process, the compound manufactured on a more colossal scale than any other should to-day be a sealed book to us: it contains but seven atoms, which cannot well be otherwise than simply arranged. Perhaps X-rays will soon melt the seal which chemists have so long left intact. It is the old story—familiarity breeds contempt; and simplicity is the most diffi cult of attributes to interpret. The major riddles of chemistry are carbonic and nitric oxides, CO and NO; *and* sulphuric acid.

---

[*] Beer, too, would seem to be a terribly toxic substance from the point of view of "Colloid Chemistry," to judge from a recent essay presented to brewers on the influence of the "dispersity" of the colloid on flavour. We must abolish such moonshine and speak English.

It is commonly ranked as a *bibasic acid*—what precisely does this mean? What valid evidence have we of its structure? Practically nothing of consequence. Graphic formulæ such as Horace Brown and I constructed on paper, out of our heads, 55 years ago, still prevail over fact. Williamson and Odling, having their minds filled with types, derived the acid symmetrically from the double molecule of hydrone,



$$\begin{matrix} H \\ O \\ H \\ \\ H \\ O \\ H \end{matrix} \quad SO_2 \quad SO_2\begin{matrix} \diagup OH \\ \diagdown OH \end{matrix}$$

Their souls were satisfied, because the acid could be produced from sulphuryl chloride, SO_2Cl_2, and water: this proves nothing more than that it can be so made. Sulphuryl chloride often acts as a mere chlorinating agent; years ago I argued that it was conceivable that in contact with water it gave up ilorine and that this acted as oxidising agent pon its co-partner sulphurous oxide. Sulphuric id or rather the chlorhydrol, SO_2ClH, gives not ilphuryl chloride but pyrosulphuryl chloride, $_2O_2Cl_5$, when subjected to the action of phosphorus entachloride. The behaviour of the supposed cond hydroxyl is peculiar: in fact, there is no roof that sulphuric acid has the symmetric strucire depicted in the formula

$$HO.SO_2.OH$$

n its behaviour, too, the acid is not properly aindful, that this is the reputation to which it has live up: the Batesonians would term it a faculative monogamete; the sulphates of the magnesian eries apparently are all hemi-sulphates of the type

$$HO.X.SO_4H$$

nly the dry elements, such as silver and the lkali metals, insist on keeping undisturbed comany with the acid radicle. Most significant of all, s Worley and I have contended and shown, the ulphonic acids generally have 90% of the hydrortic power of sulphuric acid—and they are formed, is supposed, by the mere displacement of one ydroxyl in sulphuric acid by a hydrocarbon radicle

$$HO.SO_2.OH \qquad R.SO_2.OH$$

n my early days, Kolbe and Würtz quarrelled over ictic acid—"The Mountain called the Squirrel ttle Prig." Kolbe said the acid was uniasic though dihydric; Würtz said it was biasic. Kolbe won the victory and it was settled or all time that the basicity of an organic acid roper is determined by the number of carboxyl roups it contains. I have thrown down my gage, n like manner, in defiance of all comers who seek o rate sulphuric acid as bibasic and I challenge a efinition of basicity. Inorganic chemists to-day re but fainéant fighters: policeman Arrhenius eeps them in order still. Surely someone will adenture his skill against my light weight: if not oon, I shall claim the stakes and insist that basicity s to be defined as the number of times the characeristic acid radicle is repeated in the molecule nd that sulphuric acid is but a mineralised lactic cid. The argument is equally applicable to other nineral acids (including the organic acid, carbonic cid) rated as polybasic.

It is in no wise certain even that sulphuric acid s a hydroxylic derivative: I believe it to be more probable that the original Berzelian conception, embodied in the formula

$$SO_3.OH_2$$

may come to be regarded as the more suitable expression of its structure and behaviour. Perhaps only carboxylic and sulphonic acids are properly represented as hydroxylic derivatives. We must always remember that our structural formulæ are mainly used as shorthand expressions of actual behaviour in terms of a conventional symbolism.

Very remarkable too is the electrolytic behaviour of sulphuric solutions—in no way in accord with the tenets of the ionic school. The stable term is pyrosulphuric acid; this is almost a non-conductor. In the passage from $H_2S_2O_7$ to H_2SO_4, conductivity increases to a maximum, then falls to a minimum which is not so low as the first; it then rises to a high maximum approximately at $H_2SO_4.4OH_2$, after which it gradually drops to zero when water is reached. No other compound is more subversive in its behaviour of the simple ionic faith; but its vicious example has been quietly kept in the background. Altogether the acid is one of the most wonderful of compounds.

My theme is in no wise exhausted; I have but touched the fringes of thionism. Not a little should be said of the manufacture of sulphuric acid, of the part played by the catalyst in the anhydride process and by the determinant in the chamber process. Particularly I should like to consider, using Erasmus Darwin's melodious words—

How nitrous gas from iron ingots driven
Drinks with red lips the purest breath of heaven

and acts as go-between to raise sluggish sulphurous acid to corrosive rank. The neglect of nitrous chemistry by the text books is phenomenal. Something also should be said of the peculiarities of thionic activity in general and of θειον itself but here to-day my drama must end, although the tale of heroes to be borne by the Valkyrie across the bridge into the thionic Valhalla is complete. I have but given you leit-motiven, the undercurrent of melody, perhaps I should say of discord, for which the complete score has yet to be written. The support to my arguments must be given, if not in an appendix, in footnotes, a course for which I have the precedent set by the master mind of inorganic chemistry, Mendeléeff, whose fruitful service to our science we can venerate more than ever now that our countryman Moseley has placed his great imaginative work upon a solid spectral foundation and the elements are taking shape as structural units. We have reason to hold the M's in fond memory in chemistry and a special corner in Heaven or Hades might well be railed off for them — Mendeléeff, Moseley, Mond, Müller, Meldola. To-day we add Messel to their number, as the most skilful user, in our time, of an element which shares its name with the Divinity—probably the element which first attracted the real attention of man, if not the foundation stone of chemical science.

During over fifty years past, as I have watched the progress of chemistry, the advance of the organic workers has been steady and a monumental industry has grown out of their labours: the building is there upon impregnable foundations, only a few towers and turrets and features of ornament remain to be added. The foundations are of surprising simplicity—those laid by Frankland and Kekulé, not forgetting Pasteur—but they were well and truly laid and have been duly and honestly built upon.

In other branches of chemistry, however great the cackle and whatever fuss may have been made, no corresponding progress can be recorded; the progress has been chiefly on the practical side. There has been little conscious, systematic effort tr develop a theory of chemical change; the unassailable foundation laid by Faraday has in no way been properly extended. The careless methods of Society have been made the methods of a pretentious science. The growth of fact has made us mere worshippers of facts—and, as I have already said, the teacher has taken the place of the learner and the teacher can but follow fashion. Whilst claiming to be members of a scientific fraternity, we are not sufficiently developing and using scientific method.

It is only necessary to glance at books like Mellor's comprehensive Treatise or Bayliss's great work on General Physiology to realise the bemuddled condition of our subject. Fortunately there is evidence of a return to an eclectic philosophy, to what Jacques Loeb naïvely calls "the classical chemistry as contrasted with Colloid Chemistry," exemplified by Loeb's own praiseworthy efforts to raise the character of the proteins from mere indeterminate lumps of jelly to a status of definite materials behaving in a simple and definite, orderly manner, if only put under comparable conditions: then all the rhodomontade of the glue-stuff school can be put aside and translated into a few common-sense, simple propositions.

Let us recognise that Chemistry is Chemistry, one and indivisible; let us put all pretence aside and abolish sects and sectarianism.

Il faut cultiver notre jardin

If I quote from *Candide*, following the example of that most delightful of Bohemians, whose name alone should recommend him to Catalysts, Berzélius Nibbidard Paragot, it is with emphasis upon our need *to cultivate*—first the Cabbage Patch, the vegetable section, which will give us all necessary advitants. If we be good gardeners the flowers will follow naturally and will be well placed; but let us always give care to the garden as a whole, that all be well ordered in it, planted in due season; never over-fertilised and so made to yield overgrown fruit of poor flavour and substance, as is too much of our modern produce; constantly tilled and weeded most carefully, this last especially: then will it yield crops in full measure and of good quality.

> "By our proficiency we know that we are in the way to heaven, as we know a tree is alive by its daily growth."

Prof. G. G. HENDERSON, in proposing a hearty vote of thanks to Professor Armstrong for his lecture, said that the meeting would be memorable for at least two things. One was that for the first time in the history of the Society a Canadian chemist occupied the presidential chair. Another was that they had witnessed a brilliant inauguration of the series of Messel Memorial Lectures. The Society had been indeed fortunate in its lecturer. The brilliant, exhilarating, and characteristic address to which they had just listened had set a standard for future Memorial Lectures which would ensure that they were worthy of the man whose memory they recalled. They owed Professor Armstrong a very great debt of gratitude, not merely for his lecture but also for the fact that he had provided the Society with a new President in the shape of his own son. More than this, he would like to associate himself with every word that Sir William Pope had said and to add what could not be denied, that not only every chemist in this country but every chemist in the civilised world, had profited largely by his work and example. He, therefore, asked them to accord Professor Armstrong the vote of thanks with acclamation.

The vote of thanks was accorded enthusiastically.

Professor ARMSTRONG briefly expressed his thanks.

Canadian Sections.

Meeting held at Ottawa on May 16, 1922.

MR. F. J. HAMBLY IN THE CHAIR.

ANALYTICAL PROBLEMS IN THE METALLURGY OF NICKEL.

BY FRANK E. LATHE.

The main object of this paper is to show how the requirements of both speed and accuracy have been fulfilled in the selection and development of the principal methods used in the laboratories of the nickel plants. Where several methods have been available reasons will be stated for the choice of a particular one. Details will be given only of those procedures which may not be generally known or widely applied.

At the outset I wish to disclaim any considerable share in the development of the methods now in use. To each of the many chemists who have worked in the laboratories of the nickel companies belongs some of the credit for such efficiency as has been attained.

Decomposition for the determination of copper and nickel.

The ore of the Sudbury district consists of pyrrhotite, chalcopyrite, pentlandite, and other sulphides in a gangue of norite and greenstone which is very resistant to the action of acids. Its decomposition for the determination of copper and nickel is usually effected by a short fusion with sodium or potassium bisulphate. Nitric and sulphuric acids may also be used satisfactorily, and if a naked flame be employed to expel the nitric acid this method is probably the more rapid of the two, but when used for air-cooled slags and roasted products a little hydrofluoric acid should be added to insure complete solution of the two metals.

Copper.

The commoner methods in use at copper plants are the electrolytic, iodide, cyanide, colorimetric, and permanganate methods. Of these the cyanide and colorimetric processes are excluded because the presence of nickel interferes. The permanganate method would not give a solution suitable for the determination of nickel, which is almost invariably required. The result is that only the electrolytic and iodide methods are used for copper in the nickel district, the separation of copper in the former being made by electrolysis in acid solution and in the latter by precipitation with hydrogen sulphide gas. Both methods, in the hands of experienced men, are quick and accurate. Each has its advocates. In general, it may be said that the electrolytic method is to be preferred for accurate results on high-grade samples. For those of low and medium grade it probably requires more time (unless gauze electrodes and rotating anodes are used) but less manipulation.

In the electrolytic method, on account of the amount of iron present in Sudbury ores and furnace products, it will usually be found best in accurate work to deposit in sulphuric acid solution, then dissolve and re-deposit in nitric acid. The metal first deposited can often be rapidly and completely dissolved by simply reversing the current in the nitric acid solution.

In the iodide method the precipitated copper sulphide is dissolved in bromine water and nitric acid, the solution evaporated almost to dryness to coagulate the sulphur and expel the bromine, then mixed with water and finished as usual. The greatest danger of loss is by spattering when the evaporation is nearly finished.

Nickel.

The best methods available are (1) electrolysis, (2) titration with cyanide, and (3) precipitation with dimethylglyoxime.

The electrolytic method is used principally on high-grade samples, such as refined nickel and converter matte. For low-grade samples it is not more accurate than precipitation by dimethylglyoxime, and it takes much longer. For electro-deposition the nickel should be present in sulphate solution, strongly ammoniacal, and containing little or no chloride or nitrate. Iron causes some trouble by adsorption of nickel when precipitated with ammonia. If filtered off the precipitate will always retain some nickel, so the best method is to precipitate in such a way as to reduce adsorption of nickel to a minimum, and then to leave the ferric hydroxide in the solution during electrolysis. The following procedure, worked out at Deloro, Ont., is satisfactory: Sufficient ammonia is added to produce a slight precipitate, and this is dissolved with a few drops of dilute sulphuric acid. After cooling, 25—50 c.c. of ammonia is added, and the solution stirred. When these precautions are observed accurate results may be obtained even in the presence of a considerable amount of iron.

In accurately determining the nickel content of high-grate material which is fairly uniform it is customary to take a sample of 1·0—2·0 g. and electrolyse. If the sample be "spotty," however, a larger portion must be used. The usual method is to dissolve 100 g., dilute to one litre, and measure out 10—25 c.c. of the solution with a pipette standardised against the flask used. This method is accurate only if the greatest precautions are taken, and the average chemist will secure far better results by modifying it as follows: The sample is dissolved in a flask of which the dry weight, with stopper, is known to the nearest 50 mg. The rate of solution should be regulated by the gradual addition of acid so that spattering may be avoided, and a small funnel should for the same reason be kept in the mouth of the flask. When solution is complete, it is cooled somewhat, diluted to about one litre, and mixed well in the stoppered flask. The outside of the flask is dried and it is then weighed to the nearest 50 mg. Into each of three previously weighed weighing-bottles about 25 c.c. of the solution is poured, the bottles are at once stoppered, and weighed accurately. The contents are transferred to beakers, evaporated with sulphuric acid to remove the nitric acid, and finished as usual. By thus weighing the solutions no close attention need be paid to measurements or temperatures, which introduce the more serious errors into the usual method. The only special requirement is a balance, sensitive to 50 mg., which will weigh a litre flask. The results are excellent.

Nickel deposited by electrolysis always contains the cobalt as well, and if the percentage of nickel alone is required the cobalt must be determined, as below, and deducted. It is customary to make only occasional determinations of cobalt, and as a rule to report the total of the two as nickel, because only a small percentage of cobalt is found in the Sudbury ore.

The standard rapid method for nickel is by titration with cyanide in alkaline solution, using a little silver iodide as internal indicator. Results are accurate in the hands of a careful and experienced operator. As text-books do not make sufficiently clear all the points to be observed, this method will be given in detail.

The following solutions are required:—Sodium citrate, about 140 g. per litre. Silver nitrate, 1·0 g. per litre. Potassium iodide, about 40 g. per litre. Potassium cyanide, 23 g. per litre for samples containing 0·1 g. of nickel or more, and 11·5 g. per litre for lower-grade samples, the latter reading directly in percentage on 0·5 g. To standardise the potassium cyanide it is usual to employ 0·5 g. of converter matte in which nickel has been determined by electrolysis. It is much quicker, however, and at least equally accurate, to use a nickel salt, such as the carbonate, free from copper and of known nickel content. The treatment of the standard should be the same as that followed in the determination—after separation of the copper—but excess of cyanide should be avoided, for, owing to the absence of iron, there is great danger of over-titration.

The solution to be used for the determination is either the electrolyte from plating of the copper or the filtrate from the copper sulphide. The latter will have been freed from hydrogen sulphide by boiling. In either case the solution will contain, besides nickel, whatever cobalt, iron, and aluminium passed into solution in the decomposition. The presence of any of the ordinary acids is permissible, and if the solution contains no sulphates or free sulphuric acid, a few c.c. of the latter should be added, as it greatly aids the subsequent titration. The iron must first be oxidised, and this is usually done by the addition of a few crystals of potassium chlorate, with subsequent boiling. Many chemists prefer to separate the iron and nickel if there be over 0·3 or 0·4 g. of the former in solution, on account of the greater ease of titration, though it is neither necessary nor more accurate. If desired a good separation may be effected by Rothe's ether method, as follows:—Iron and aluminium are precipitated with ammonia, filtered off, and washed once or twice. The filtrate is retained. The hydroxides are dissolved in a little hydrochloric acid, and the solution evaporated to a few c.c., cooled and washed, by means of dilute hydrochloric acid (sp. gr. 1·13) in a wash-bottle, into a small separating funnel. A volume of ether equal to that of the solution is added and the mixture shaken thoroughly while cooling under the tap, and then allowed to settle for a few minutes. The lower solution containing the nickel and cobalt is drawn off, a few c.c. of the dilute hydrochloric acid is added to the ether in the funnel, the mixture again shaken, cooled, allowed to settle, and the lower layer separated and combined with the other acid solution. The ether is expelled by warming and finally boiling the liquid, which is then combined with the ammoniacal filtrate for determination of the nickel.

Whether or not the ether separation has been made, the nickel solution requires the addition of sodium citrate or similar reagent to prevent the precipitation of iron and aluminium on the subsequent addition of ammonia, and to make the solution clear enough for titration. A minimum of 5 c.c. is recommended, and as much more than this as will make 1 c.c. for every 10 mg. of iron in solution. Thus 2 g. of slag with 40% of iron will require 80 c.c. if the ether separation has not been made. After the addition of a sufficient volume of sodium citrate solution, the liquid is made just alkaline with ammonia, and about 1 or 2 c.c. added in excess. If as much as 5 c.c. in excess be added the end-point will be indistinct and the result slightly low on account of the solvent action of ammonia on silver iodide. After cooling thoroughly, preferably below 10° C., 5 c.c. of the silver nitrate solution is added from a burette or pipette. If a precipitate of silver chloride be produced enough ammonia is added to dissolve it, then 5 c.c. of the potassium iodide solution, when silver iodide will be precipitated at once. This amount of potassium iodide is much more than the theoretical quantity necessary to combine with the silver nitrate, but is essential to a satisfactory titration. Many chemists add the potassium iodide before the silver nitrate, but if that procedure be followed an insufficiency of ammonia may be overlooked and the true end-point will occasionally be passed. The solution is now ready for titration, and if several determinations are to be done at once it is best to have a separate burette for each, to avoid a multiplicity of burette readings with consequent liability to error. It is usually necessary to make several additions of cyanide to each. If much nickel be present in the solution the change in colour will indicate when the end-point is being approached. Great caution must then be observed not to add an excess, especially if little or no iron be present. When the solution contains much iron it is safe to add several drops at a time until the solution is perfectly clear, the silver iodide having been dissolved by the excess of cyanide. On standing for a few moments, however, the turbidity will reappear, and it must be destroyed by the addition of more cyanide until the solution remains clear for 15 minutes. Not more than two additions will usually be necessary for converter matte or other samples low in iron. When finished, deduction must be made from the burette reading of a volume sufficient to titrate a blank to which 5 c.c. of silver nitrate has been added. The result, calculated to nickel, includes cobalt as well. If the end-point be passed, sufficient silver nitrate may be added to restore the turbidity, and the titration again finished, with a correspondingly large deduction, but this is not recommended for the most accurate work. In titrating solutions high in nickel the volume should be increased and the cyanide added rapidly till near the end to prevent the precipitation of nickel cyanide, $Ni(CN)_2$, which does not readily redissolve.

The determination of nickel by precipitation with dimethylglyoxime possesses the advantage that it gives the nickel only, without cobalt. It is both quick and accurate, and its greatest disadvantage lies in the fact that the reagent is very expensive. Its use is therefore limited chiefly to checking cyanide results on weekly or monthly samples of ores and slags. Iron is retained in solution or is separated as described under the cyanide method. The degree of alkalinity there recommended is also correct for the dimethylglyoxime precipitation. Five times as much reagent—in 1% alcoholic solution—should be added as the total of nickel and cobalt present. The precipitate is filtered on a Gooch filter, preferably using a small disc of strong filter paper instead of the usual asbestos mat. A small amount of copper in the solution does not interfere with the dimethylglyoxime precipitation of nickel, but if much be present it may give trouble by coming down as hydroxide.

Cobalt.

There is not, so far as I am aware, any method for the determination of cobalt which is both quick and accurate in the presence of nickel, copper, and iron. This determination is not a part of the daily routine at the nickel plants, but when required is accurately made as follows: Nickel and cobalt are separated from all other elements by electrolysis, as already described. The deposit is dissolved and the cobalt precipitated by either potassium nitrite or nitroso-β-naphthol, as described in the text-books. I prefer the latter method, as the cobalt precipitate is more readily washed free from nickel. In either case it is well to ignite the cobalt precipitate, dissolve in acids, and electrolyse the sulphate solution, testing the deposit for nickel with dimethylglyoxime.

When the ratio of nickel to cobalt is approximately 1:1 (this does not apply to the Sudbury ore) the above method may well be modified by dissolving the electrodeposited nickel and cobalt and precipitating the former with dimethylglyoxime, obtaining the cobalt by difference. This is much quicker, and, I believe, more accurate.

The error introduced by reporting cobalt as nickel in Sudbury products is seldom a large one, and generally decreases as the metallurgical treatment proceeds, due to the fact that cobalt is the more easily oxidised and slagged, in both the furnaces and converters. The converter slag produced during the latter part of the blow is relatively the highest in cobalt of any smelter product.

Silica.

This is one of the determinations most frequently made at the nickel smelters, but it is safe to say that very few results reported are really accurate. Accurate determinations are possible only by the free use of platinum dishes, repeated evaporations of filtrates to dryness, correction for impurities in the weighed silica, and various other precautions which are fairly well known but rarely exercised. Fortunately great accuracy is seldom necessary, and even quick results may be approximately correct through the balancing of dissolved silica against the impurities weighed.

Most silicious slags which have been properly granulated are readily decomposed by ordinary acids. Those produced at the nickel plants are fairly low in silica, however, and the metallurgists in charge require carbonate fusions for all routine work. It may be of interest to mention the methods adopted in two of the laboratories for securing quick results.

Plant No. 1.—0·5 g. of sample is fused over a flame with about 2 g. of mixed sodium and potassium carbonates in the "corner" of a large platinum evaporating dish. When well fused the mixture is cooled somewhat, a small excess only of hydrochloric acid over that necessary to decompose the melt is added, and the liquid evaporated to dryness in the same dish; after cooling, the residue is extracted with acid, the solution diluted, and the precipitate filtered, ignited, and weighed. Results are regularly reported in 1—1¼ hours.

Plant No. 2.—Here neither gas nor large platinum dishes are available, so the method is modified as follows: The sample is fused in a muffle for six minutes at a high temperature with mixed carbonates, using a 25 c.c. platinum crucible. After removal from the muffle, the crucible cover is placed in position on a small porcelain crucible, and as soon as the melt has cooled to a dull red heat it is poured into the lid. When properly done it does not adhere to the metal. Both crucible and cover, with the melt, are placed in a small casserole, which is covered with a watch glass, and a small stream of 1:1 hydrochloric acid is directed into the crucible through the lip from a wash-bottle. When the action decreases the watch-glass is removed and the crucible and cover are washed down with diluted hydrochloric acid. The solution and separated silica are transferred completely to an eight-inch porcelain crystallising dish, with flat bottom, keeping the total volume down to 25 c.c. if possible. The solution is evaporated to dryness on an asbestos ring on a hot plate, the time occupied being not more than 7—8 minutes. The residue is cooled, and about 15 c.c. of hydrochloric acid added, and then 25 c.c. of water. The solution is filtered at once by suction, and the paper containing silica is placed in a platinum or nickel crucible and set just inside the muffle door. The burning of the paper may be greatly hastened by directing into the crucible through a tube a very gentle stream of oxygen or air. When the paper is burned the crucible is moved to the hottest part of the muffle for a couple of minutes, then removed, cooled in ater, and the silica weighed. This method equires the almost constant attention of the hemist, but results have been reported regularly from 30 to 40 minutes, and with all the accuracy ecessary for plant control.

Iron.

The ordinary bichromate method is the one enerally employed. One interesting point is that the analysis of samples like converter matte, hich contains an appreciable amount of the metals the platinum group, stannous chloride does not ake the iron solution colourless. It becomes early so, then the addition of more stannous loride darkens it somewhat, and no amount in cess will clear it. The brownish coloration persts even after the addition of mercuric chloride.

Alumina.

The phosphate method is used exclusively, it ing found impossible completely to free an ammonia precipitate of ferric hydroxide and alumina from nickel and other salts, even by dissolving and reprecipitating several times. It is of course necessary to remove copper with hydrogen sulphide prior to the precipitation of aluminium phosphate.

Lime and magnesia.

The usual methods for these bases are employed. Neither one occurs in large amount in the Sudbury ore.

Sulphur.

The accurate determination of sulphur in many ores is a comparatively easy matter, but it is rendered difficult at the nickel smelters owing to the strong tendency of free sulphur to separate during the decomposition of the Sudbury pyrrhotite. After numerous experiments I have found the best method of decomposition to be by means of a saturated solution of potassium chlorate in nitric acid, using about 30 c.c. per 0·5 g. sample. Even then it is necessary to watch for separated sulphur; when this is found, as it occasionally will be, the determination must be begun anew.

The ordinary precipitation of barium sulphate in acid solution, in the presence of ferric salts, will almost invariably result in the inclusion of iron. This may give a low value for sulphur, due to iron replacing barium, or a high one, if iron salts other than the sulphate be retained. These difficulties may be avoided by making the filtrate from the "insoluble" alkaline with ammonia, following this with the necessary amount of barium chloride solution, heating for a few minutes, and then acidifying with hydrochloric acid, using only a small xcess.

Acidity.

This is required only at the refineries. Three different methods are used, depending upon the egree of acidity to be determined:

(1) Strongly acid solutions from the copper re-ning department, by titration with sodium ydroxide or carbonate, either in the cold, using methyl orange as indicator, or hot, when the indiator may be dispensed with and the first permanent ydroxide precipitate taken as the end-point. I refer the former.

(2) Feebly acid solutions from the electrolytic ickel department, containing sulphuric acid up to few grams per litre, and with copper and iron ractically absent, by the iodate method. As this not very well known the details are given:—olution required: Sodium thiosulphate, about 75 g. per litre; 1 c.c.=0·005 g. Cu. The acid quivalent, expressed as sulphuric acid, is 0·00385 g. he method is based on the following reaction:

$$KIO_3+5KI+3H_2SO_4=3H_2O+3K_2SO_4+6I.$$

he iodine thus set free is titrated with sodium thiolphate. To 10 c.c. of sample in a beaker a few crystals of potassium iodide and a little starch solution are added. If any colour appears the solution is titrated with sodium thiosulphate, the volume of which indicates the amount of copper present. A few milligrams of potassium iodate is then added, when the blue colour will reappear if any acid be present. The solution is at once titrated with thiosulphate until colourless. If ferric salts be present the colours will always reappear. The first clearing of the solution therefore represents the end of the reaction. In spite of the slight interference of iron this method is an excellent one, and it may be used for acidity as low as 10 mg. per litre.

(3) When the acid is much lower than 10 mg. per litre, and an accurate determination is required, the potentiometer method of measuring hydrogen-ion concentration should be used. As a detailed discussion of this method would require too much space a few points only need be mentioned. The most common impurity which interferes with the electrometric determination of acid in nickel solutions is copper. About the only satisfactory method of removing it without changing the acidity is to "cement" it out with sheet nickel. If present it will be easily detected by the steady lowering of successive voltage readings, though arsenic may cause the same trouble. The presence of hydrogen peroxide or similar strong oxidising agent in the solution will lower the readings and make them irregular, owing to action on the hydrogen electrode. Both temperature and barometric pressure have some effect on the readings, by changing the concentration of hydrogen on the electrode. For the most accurate work correction should always be made for them unless the conditions are standard. It is essential that the instrument be standardised frequently. For this purpose a solution of sodium or potassium hydrogen phthalate has been found satisfactory.

Precious metals.

No review of the analytical problems in the metallurgy of nickel would be complete without mention of the most difficult of them all—the determination of silver, gold, platinum, palladium, iridium, rhodium, ruthenium, and osmium in Sudbury ores and products. A discussion of these, however, would in itself be sufficient for a paper of considerable length. So far as I know, none of the large companies handling these metals has published details of their analytical methods. It is to be hoped, however, that this conservative policy will not be indefinitely maintained.

(Department of Coal Gas and Fuel Industries, The University, Leeds.)

INTRODUCTION.

Prior to 1914 the supply of ammonia compounds was dependent mainly on the industries using fuel in by-product recovery processes, but the development of the production of synthetic ammonia, with output and selling price largely independent of the circumstances of the fuel industries, has abolished the virtual monopoly of by-product processes. A new interest is given to methods of increasing the yield of ammonia per ton of coal handled, therefore, whether by increasing the proportion of the nitrogen of the coal liberated as ammonia, or by preserving the ammonia once formed from destruction in or after leaving the retort or oven.

The ammonia obtained in normal carbonisation practice represents 15—20% only of the nitrogen of the coal. A similar proportion is obtained as free nitrogen in the gas, and it is important in considering the development of by-product processes to know how much of this results from destruction of previously formed ammonia. It is, however, possible that a part of this free nitrogen is liberated as such from the coal, and is therefore an inevitable loss.

The first problem is being dealt with by A. C. Monkhouse and J. W. Cobb (Trans. Inst. Gas Eng., 1921; J., 1921, 760 A; 1922, 532 A). The experiments recorded in this paper were initiated to study the conditions of destruction of ammonia by oxidation as distinct from dissociation, because it has been recently suggested that the former is the more important. On account of dissociation, the ammonia in a hot crude gas (even if free from oxygen) from coal is in an unstable condition, and progressively reverting into its elements. A calculation based on the known equilibrium conditions at 800° C. shows that, given time, practically the whole of the ammonia present in crude coal gas could be decomposed at that temperature. This decomposition, however, proceeds slowly enough for a considerable proportion to survive. At a temperature at which the loss in this way may still be small—say 600° C.—oxidation of ammonia in air may occur at an appreciable rate. A knowledge of the conditions conducing to loss of ammonia in the retort, oven, or producer, by oxidation by indrawn air is clearly important, and in particular, information as to the part played by water vapour and materials used in the construction of the plant. While an extensive literature has been compiled dealing with the oxidation of ammonia for the production of nitric acid, this other aspect has received no great amount of study. Data respecting the production of nitric acid from ammonia where conditions are so unlike those found in gas production are of limited application. There is a particular obscurity as to the influence of moisture on the oxidation of ammonia. Although the contrary opinion has been stated, it is regarded as being unimportant in the catalytic formation of oxides of nitrogen (Partington, "The Alkali Industry," p. 229) and moisture is ignored in practice. On the other hand, there is in the carbonisation industries a widespread impression that water vapour exerts a definite preservative action on the ammonia in coal gas. This view is frequently held to account for the higher average yields of ammonia obtained in coke oven practice, where wet slacks with 10% or more of water are carbonised. An attempt has been made to give a quantitative evaluation of the effect of moisture, and Foxwell[*] (J., 1921, 193 T) states that 9% of moisture in the slack gives the conditions most favourable to high ammonia yields. Foxwell seems to have in mind several effects traceable to the water, the increase in ammonia formation, retardation in ammonia destruction due to dilution with attendant accelerated flow of the gases, or to some specific action of the water. Of the first influence—increased production of ammonia—there is no doubt, both as a result of experience in practice and the experiments of Monkhouse and Cobb (*loc. cit.*). Respecting the other two, there seems to be less certainty. Sommer (Stahl u. Eisen, 1919, **39**, 261, 294, 349; J., 1919, 350 A) has gone further, and drawn definite conclusions as to a distinct preservative influence exerted by water vapour. He also appears to regard oxidation as more important than dissociation in causing losses of ammonia. In his experiments, ammonia in admixture with air, dried or saturated with moisture at 20° C. (about 2·3% of moisture), was passed through a heated porcelain tube packed with broken firebrick. The mixture contained 1·5—2% of ammonia as in carbonisation practice. Even at 250° C. under this treatment, loss of ammonia by oxidation was detected. The presence of moisture did appear to exert a specific preservative action. At 450° C. the effect of moisture was apparently profound. In the dried mixture a loss of 12·89% of the ammonia was observed and one of only 2·01% when 2·3% of water vapour was present.

In order to account in some way for the results, he postulated the formation in moist gases of a hydrated ammonia molecule—say NH_4OH—possessed of increased stability as compared with ammonia at high temperatures. The theoretical interest and practical importance of such results reposing on so slender an experimental basis seem to justify a critical examination. Sommer appears to believe that these results are applicable to the carbonisation process, though quoting no experiments made in coal gas mixtures, but from our experience these observations cannot be transferred directly to the very different conditions found in a crude coal gas.

Thau has endeavoured to ascertain the relative importance of oxidation and dissociation of ammonia by experiments on a working coke oven (Brennstoff-Chem., 1920, **1**, 52, 66; J., 1921, 137 A). He compared the ammonia content of the gas when the oven was carefully sealed and when oxygen was admitted from a cylinder into the space above the charge, in which case the yield was much reduced. Owing to heat developed here by combustion of the gas with oxygen, the temperature was considerably raised, so that the comparison of dissociation and oxidation was not made under identical temperature conditions. The results, however, do bring out the deleterious action of indrawn air on the yield of by-products, if the oven temperature exceeds 600°. The conditions in an oven at work are so complex as to make it difficult to associate effect with cause. Nevertheless, Thau appears to regard oxidation as the main cause of ammonia loss in the oven.

The oxidation of ammonia, as is well known, is very sensitive to the influence of catalysts, both as regards speed of reaction and nature of products, which may be either free nitrogen or oxides of nitrogen.

The reactions may be written thus:—

(1) $4NH_3+3O_2=2N_2+6H_2O+237{,}600$ cals.
(2) $4NH_3+5O_2=4NO+6H_2O+215{,}600$ „

Reaction (1) would represent the reaction which might conceivably occur in carbonising practice, but by the use of suitable catalysts under the proper conditions, a yield of nitric oxide can be obtained almost quantitatively, according to (2), even on a large scale. Neither reaction is reversible under any known conditions. Ammonia appears to be completely unstable in presence of oxygen at all temperatures. This is in agreement with theoretical requirements. Rideal and Taylor

---

[*] Foxwell returns to this subject of ammonia losses in carbonisation in a recent paper (J., 1922, 114 T) but does not take oxidation within his purview.

"Catalysis in Theory and Practice," p. 91) calculate, by means of Nernst's heat theorem, the values f the equilibrium constants of the second reaction, f assumed to be reversible. The partial pressures f ammonia which must exist at the equilibrium o satisfy the Nernst equation are inconceivably small. The circumstances are similar as regards reaction (1). The decomposition of ammonia by xidation cannot then be regarded as limited by the attainment of any equilibrium or, in accordance with the law of mass action, by the operation f the reaction in the reverse sense. This is important in considering any theories to account for a retarding influence of water vapour.

For a given catalyst and set of conditions, there is an optimum temperature at which the yield of nitric oxide is a maximum. Above and below this temperature, the production of free nitrogen increases. At the lower temperatures this is ascribed to the sluggishness of the reaction, unchanged ammonia being left to react with nitric oxide formed thus:—

$$4NH_3+6NO=5N_2+6H_2O$$

This alone would suffice to account for the fact that nitrates and nitrites are never observed in gas liquors. Moreover, the time of contact in commercial oxidation of ammonia is very small—say one-hundredth of a second—whereas in carbonisation it is probably several seconds. This is also true of the experiments dealt with in this paper, and it is easy to understand why no large quantity of oxides of nitrogen has been observed in the presence of the most active contact substance employed.

The object of the experiments now recorded was to ascertain the conditions under which oxidation of ammonia would occur, comparable with those current in carbonisation and gasification practice. The effect of substances of varying catalytic power was examined and also what influence, if any, could be traced to the presence of water vapour.

A time of contact was chosen which was believed to be of the same order as that of the gases with the charge in vertical gas retort practice. In the calculation of this time of contact a number of arbitrary assumptions must be made, for the process by which the gas escapes is complex, and the exact mechanism uncertain (*cf.* Foxwell, *loc. cit.*, on this subject). For a given gas delivery in the following experiments the time of contact will depend on the temperature to which the gas is heated. In the calculation, a mean temperature of 600° C. was assumed, and the time of contact in the experiments adjusted to seven seconds, unless otherwise stated.

EXPERIMENTAL.

The apparatus (Fig. 1) consisted essentially of an arrangement for producing a constant stream of air, or other gas, and ammonia, and of suitable devices for sampling the mixture, before and after it had traversed the reaction tube.

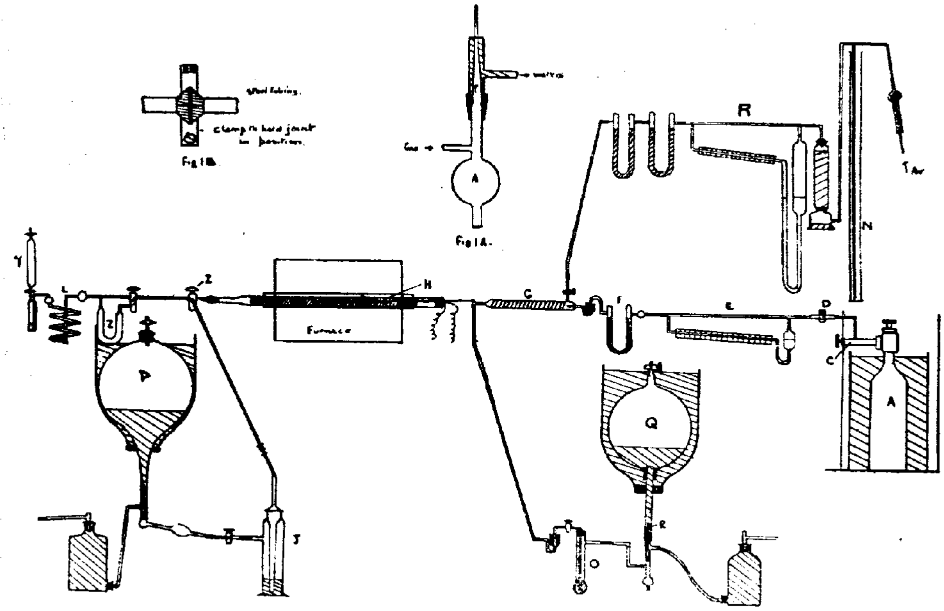

FIG. 1.

Method of producing the mixture of air and ammonia.

The ammonia was obtained from liquefied ammonia gas contained in the small steel cylinder, A, fitted with a coarse valve and a fine needle valve, C, for an accurate adjustment of the stream.

The steel capillary from C was connected to the gauge E by a special steel-faced joint, D, the construction of which will be understood from the enlarged section (Fig. 1 B). The ammonia gauge was a modification of an ordinary differential manometer, the one limb being nearly horizontal, and the other enlarged into a bulb. In this way a magnified reading could be obtained.

The ammonia, dried by the soda-lime tube, F, passed viâ a mercury-sealed joint into the mixing tube, G, consisting of a glass tube 20 cm. long and 2 cm. in diameter, loosely packed with glass wool. The air (or other gas) was drawn from a steel cylinder charged at 50 atmospheres pressure.

In order to maintain a constant rate of flow, the excess air was allowed to bubble continuously through the water seal, N. The air passed through a tower containing pumice and sulphuric acid and then via the gauge, R, for measuring the rate of flow to the final drying tubes containing calcium chloride and phosphorus pentoxide.

The air gauge was similar in construction to the one previously described, with the exception that the ammonia gauge was filled with paraffin oil, whereas for the air gauge concentrated sulphuric acid was used.

After leaving the mixing tube the gas mixture could be diverted through the absorption tube, O. The ammonia is here absorbed by $N/10$ sulphuric acid, the remaining gas passing forward to the gas holder, Q, of capacity about 700 c.c. The gas enters the holder through the capillary, R, whereby a pulsating flow is avoided. The narrow tube at the base of the holder (Fig 1 A) is calibrated so that the gas volume can be read off to within 0·2 c.c.

When the mixture was not being sampled as above, the gases passed directly through the reaction tube, H, then through a second absorption vessel, J, where any unoxidised ammonia was absorbed, the residue being collected in the gas holder, P. This was similar to the one previously described, though of capacity 1700 c.c.

Alternatively, the mixture could be passed through the Winkler worm, L, containing dilute caustic soda solution to absorb oxides of nitrogen, followed by a guard-tube containing a solution of diphenylamine in concentrated sulphuric acid, to indicate incomplete absorption. The gases then finally left the apparatus through the detachable sampling tube, Y.

When desired, the oxidation products could be by-passed through the soda-lime tube, Z, to determine the amount of water formed in the reaction.

In order to compare the oxidation with dry and moist gases under identical conditions, a three-way tap was later inserted after the air gauge (Fig. 2). The air (or other gas) could then be passed either through the drying system as above, or else through a Claisen flask, where the gas was saturated with moisture at a known temperature. To prevent condensation of moisture, the succeeding portions of the apparatus were maintained above this temperature by suitable heating devices.

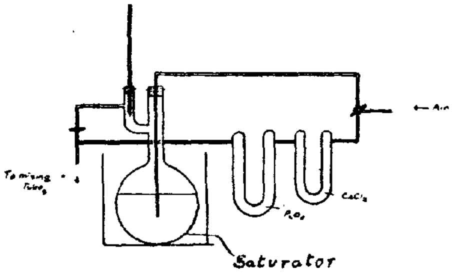

FIG. 2.

The reaction tube was made from hard glass tubing, and connected to the three-way cock, I, by a sleeve joint, the packing consisting of a mixture of finely powdered silica and water-glass. The other end of the reaction tube was closed by a rubber stopper, through which were inserted the tube conveying the gas mixture and also the thermocouple sheath. The junction of the thermocouple could thus be placed within the contact mass, enabling the temperature of the latter to be measured and kept constant within ±5° C. The reaction tube was heated in an electric furnace wound so that the zone occupied by the contact mass was uniformly heated.

The tube was normally packed over a length of 6 in. with the material on which experiments were to be made, the volume of the material being such that the time of contact of the gases in this zone was approximately the same with each type of material.

Uniformity of flow of the ammonia was maintained by keeping constant the temperature of the cylinder, A, and therefore the vapour pressure of contained ammonia. The cylinder was placed in a bath of water, and the whole surounded by a cardboard box, the intervening space being loosely packed with cotton wool. The back pressure thrown by the various absorption systems was so regulated that the rate of flow was unchanged when the gases were passed through any one of these systems.

Method of experiment.

The streams of air and ammonia having been regulated to give the desired percentage of ammonia, the mixture was passed through the apparatus for about three-quarters of an hour. The gases were then passed directly into the holder, Q; when this was full the stream was diverted through the reaction tube and again collected, on leaving, in the holder, P. When this was filled, the stream was diverted again into the smaller holder, Q. Thus the initial percentage of ammonia in the gases could be determined at the beginning and end of an experiment. The acid in the absorption tube, O, was titrated directly with standard alkali, but the ammonia in the second tube, J, was determined by distillation in the usual manner, since the presence of oxides of nitrogen in the oxidation products would vitiate the results of a direct titration.

The traces of oxides of nitrogen were estimated by matching the colour obtained with phenylenediamine hydrochloride against a standard nitrite solution.

Oxidation in contact with fused silica.

In order to obtain some idea of the range of temperature over which oxidation takes place when catalytic influences are minimised, the reaction tube was packed with fragments of fused silica taken as an example of a relatively inactive contact material.

In the initial experiments, these fragments filled the whole tube, but in all the succeeding work only the central uniformly heated zone as already stated was filled and the rest of the tube was occupied by cylindrical distance pieces of fused silica.

The time of contact of the gases was materially greater in the initial experiments, and hence a greater oxidation was found (Table I.). Below 500° C. small quantities of nitrous acid were detected in the absorption apparatus, but never nitric acid. Above this temperature the ammonia oxidised was all converted into free nitrogen. The absence of nitric acid is presumably due to the small velocity of the reaction $2NO+O_2=2NO_2$. Using the figures given by Lunge and Berl (Z. angew. Chem., 1907, **20**, 1716) we find, assuming that 3% of the ammonia is converted into nitric oxide, that the minimum time necessary for its further oxidation to nitrogen peroxide would be about 2 minutes at 20° C., whereas the time available in these experiments was not greater than 5 seconds.

A series of experiments was also carried out with nitrogen containing about 1—2% of oxygen, instead of the air, without altering the packing in the reaction tube. The results given in

FIG. 3.

Table II. and Fig. 3 show that the oxidation of ammonia is retarded by a decrease in the concentration of the oxygen, but the influence of this factor becomes less pronounced at higher temperatures. The absence of oxides of nitrogen from the reaction products is in agreement with theory. Their formation in the absence of an active catalyst is slow and decomposition follows by reaction with the excess of unchanged ammonia.

Destruction of ammonia in coal gas.

On substituting coal gas containing oxygen for air, the loss of ammonia was greatly reduced (Table III. and Fig. 3), and was much less also than the loss in the presence of nitrogen with a similar low concentration of oxygen. These results show that below 800° C. under the conditions obtaining, though the ammonia passes through the apparatus practically unchanged, the whole of the oxygen is removed, presumably by reaction with hydrogen or hydrocarbon constituents of the gas. If the whole of the ammonia lost had been removed by oxidation, it would have consumed only a fraction of the oxygen actually disappearing. Even at 600° C., a temperature at which the oxidation in air and (nitrogen + oxygen) was considerable, the whole of the oxygen was removed in the reaction tube, while the ammonia passed through unimpaired. This points to the conclusion that in a coal gas the oxidation of the hydrogen or hydrocarbons takes precedence over that of ammonia, and that if any of the latter is decomposed at all, it must be due rather to a dissociation phenomenon.

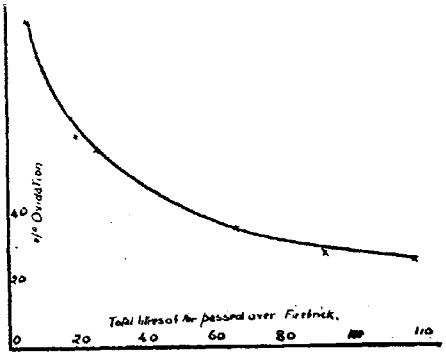

FIG. 4.

Loss in activity of firebrick.

Oxidation in contact with firebrick.

As contact material, the silica was replaced by fragments of unused fireclay brick, which is porous and contains iron or other oxides which display marked catalytic activity towards these reactions. Firebrick from the Leeds district containing 1·4% of ferric oxide was used.

Though the material at first displayed marked activity this was found, on repeating experiments at any one temperature, to fall off rapidly. The results in Table IV. (Fig. 4) clearly show this decrease in activity. Other samples of firebrick from the same source gave almost identical results. Further, the oxidation fell off at the same rate with mixtures of ammonia with either air or coal gas.

The passage of dry air alone had a similar effect which cannot, therefore, be attributed to any reactions involved in the actual oxidation of the ammonia. The cause of this decay of the catalyst remains unexplained. The results obtained when the firebrick had attained a stable condition are collected in Table V., and for the purposes of comparison have been plotted in Fig. 4, along with the figures obtained with fused silica.

Destruction of ammonia in coal gas mixtures.

The loss of ammonia in the presence of stabilised firebrick was similar to that observed in the presence of silica, and as before, the products were practically free from oxygen after contact. Contact material in its originally more active condition caused a considerably greater decomposition. An increase in the percentage of oxygen from 1% to 2% had no appreciable effect on the rate of decomposition of ammonia. Here again, at 600° C. the oxygen is taken up by some constituent of the coal gas while the ammonia remains intact, as in the experiments of Table III. There are, then, no grounds for ascribing any loss of ammonia in a coal gas under the conditions of these experiments to oxidation at all. If this is correct, then Sommer's conclusions are unsound, and experiments on mixtures of air and ammonia are irrelevant to the phenomenon in coal distillation.

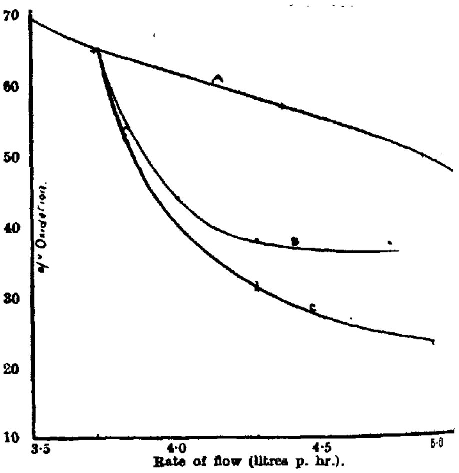
Influence of water vapour on the oxidation in air.

The experimental figures are given along with those for the dry gases in the various tables to which reference has already been made.

When mixtures of ammonia and air were heated in contact with silica (Table I.) the influence of moisture was negligible at the lower temperatures, and a reduction of 2·5% only was observed in the oxidation at 700° C. In coal gas (Table VI.) no appreciable difference was observed in the experiments made.

In the presence of the firebrick already mentioned, the oxidation in a mixture of ammonia and air was materially influenced by the presence of moisture, *e.g.*, 2·8% of water vapour caused a decrease in the percentage oxidation from 64% to 52·3% at 740° C. (see Table V., Fig. 3).

In view of these results, the experiments were extended to higher percentages of moisture (Table VII.), but the difficulty of preventing condensation limited the saturation temperature (65° C. corresponding to 25% H_2O). The greater stability of the ammonia observed in the presence of water vapour may be attributed, generally speaking, to two factors, viz., the increased rate of flow with consequent shortened time of contact, and some specific action—chemical or physical—of the water vapour.



Influence of moisture on oxidation of ammonia.

FIG. 5.

Curve A (Fig. 5) shows the influence on the degree of oxidation at 740° C. of the rate of flow alone in the dry mixture of ammonia and air. In curve C the percentage oxidation is plotted against rate of flow when the gas mixture contains water vapour in proportion depending on the temperature of saturation employed. The percentage of water vapour is also indicated. By subtracting curve A from curve C, we are left with curve B, which may be regarded as showing the specific effect due to the water vapour.

This "specific influence" of the water vapour increased with the water content at first, but when 12% was reached, the observed effect can be accounted for by the smaller time of contact due to increasing percentages of moisture.

These results, then, confirm qualitatively Sommer's experiments at lower temperatures, although no such powerful influence as recorded by him has been observed. Thus, at 450° C. his loss of ammonia by oxidation fell from 12% to 2% with the addition of 23% of water vapour.

TABLE VII.

Temp. °C.	Rate of flow, litres per hr.	% NH_3 entering.	% NH_3 leaving.	% NH_3 oxidised.	Sat. temp. °C.	% H_2O.	Rate of flow of air + water vapour per hr.

740	3·76	1·936	1·348	30·4	50	12·3	4·28
740	3·70	1·930	1·470	23·6	65	25·0	4·93

In mixtures of coal gas and ammonia up to 800° C. the moisture appeared to have no appreciable effect, but the total amount of ammonia decomposed is small, and at higher temperatures the results might differ.

From a general survey of these results, as regards mixtures of air and ammonia, we see that a marked preservative effect of moisture only occurred in the presence of substances displaying a considerable catalytic power. The activity of the catalyst is only partially impaired by the moisture, since the oxidation in presence of firebrick and 15% of moisture is considerably greater than with silica in the absence of moisture.

It is common knowledge that the presence of moisture is important in many reactions, but its effect is usually accelerative and the inhibiting action observed here, and by Sommer, is difficult to explain. As just shown, it is greater than can be accounted for by mere dilution, and consequent increase in rate of flow. Moreover, the effect is more intense with the first additions of moisture, which have a small effect on the rate of flow. Nor can it be ascribed to an accumulation of the reaction product on the basis of the law of mass action, for the reaction, as indicated at the outset, is in no appreciable degree reversible. The observation that the influence of moisture was not marked when the relatively inert fused silica was used as contact material, suggests that in some way the catalyst is involved. The most helpful conception has been obtained from Langmuir's theory of the unimolecular film at the catalyst surface. If we suppose that the oxidation occurs between ammonia and oxygen, possibly atomic, adhering to the contact mass, but not covering it entirely, we can see that the introduction of any other gas or vapour capable of sticking to the surface, and therefore restricting mutual access of oxygen and ammonia, will have a preservative effect towards the latter. Any gas or vapour prone to adhere to the catalyst would have the same effect which might be caused if the proportion present were only small.* The available catalyst area once tenanted by water molecules, the addition of further water vapour would apparently have no influence. There is a difficulty, however, as it would appear that the water vapour resulting from the oxidation of ammonia in dried gases should also have this "blanketing" effect.

It is also necessary to reconcile the apparent importance of water vapour here with its unimportance in the commercial oxidation of ammonia. This may, however, possibly account for the apparent paradox just mentioned. In the experiments chronicled here, in dry mixtures of air and ammonia the proportion of ammonia was low (1—2%), and as this was only partially oxidised, the proportion of water vapour in the product was also small, and added water vapour might make itself appreciably felt. In commercial oxidation 10—15% of ammonia is employed and completely oxidised, yielding a corresponding proportion of water vapour large enough to render unimportant the presence or absence of water vapour in the air employed.

Conclusions.

The destruction of ammonia at low partial pressures and in atmospheres of air, of nitrogen containing 1—2% of oxygen, and of coal gas containing oxygen, at temperatures up to 800° C. both in presence of fused silica and unused fireclay brick, has been examined.

The oxidation of ammonia in air and in contact with the fireclay brick under the conditions of the experiments is distinctly retarded by water vapour present even in small proportions.

In coal gas containing oxygen, the destruction of ammonia is much less marked at corresponding temperatures than with air, and this destruction, owing to the preferential union of the oxygen with the hydrogen etc. present in the coal gas, is due not to oxidation, but to a process of dissociation. In these experiments no marked influence of water vapour was observed.

It is doubtful whether direct oxidation of ammonia occurs to an appreciable extent during carbonisation even when oxygen is present. The known deleterious effect of air indrawn during carbonisation and gasification is then presumably due to the local overheating of the gas following upon the union of the oxygen with combustible constituents. The rise in temperature then facilitates dissociation. It remains to be proved that a preservative effect can be ascribed to the large volume of water vapour in coke oven gas, *i.e.*, as distinct from that due to dilution and shortened time of contact of the ammonia.

The experimental work on this subject is being amplified and will be the subject of a further communication.

DISCUSSION.

PROF. J. W. COBB said that he had seen this work in progress and appreciated the way in which experimental difficulties had been overcome. If air was drawn or forced into a gas-retort, coke-oven, or gas-producer (at the wrong point) it undoubtedly lowered the ammonia yield. Presumably from this work this loss was not due to direct oxidation of the ammonia, but resulted from local combustion of the gas and a dissociation of ammonia, intensified by rise of temperature and catalytic action along the solid surfaces of brick-work or coke.

MR. W. McD. MACKEY said that the introduction of steam or water vapour into the by-product coke oven had often been advocated, but the difficulty was that the steam would intervene between the walls of the oven and the mass of coal in course of coking and prevent the passage of heat from the flues to the coal.

MR. AUTY said that the effect of water vapour was rather similar to the effect of charcoal on phosgene. If the charcoal used and the mixture of phosgene and air were dry, hydrochloric acid was produced, but if the charcoal contained 5% of moisture, the phosgene was absorbed without the formation of hydrochloric acid.

MR. HODSMAN, replying to an inquiry as to the effect of carbonising in iron retorts on the yield of ammonia, said that the temperatures attained in such apparatus were much below those of current practice and in consequence no just comparison was possible. Referring to Mr. Mackey's remarks on the effect of water vapour, he did not wish to imply that water vapour was without benefit to the yield of ammonia. On the contrary, he believed that it did operate favourably, but thought caution desirable when accounting for this effect. The conditions in practice were complex, and even under the simplified conditions of laboratory experiment the expected result was often not attained. The reactions of ammonia were very sensitive to catalysts and to temperature under the conditions of practice.

Communications.

THE PREPARATION OF COD LIVER OIL AND THE EFFECT OF THE PROCESSES ON THE VITAMIN VALUE OF THE OILS.

BY J. C. DRUMMOND, D.SC., F.I.C., AND S. S. ZILVA, D.SC., PH.D., F.I.C.

From the Biochemical Laboratories, Institute of Physiology, University College, London, and the Biochemical Department, Lister Institute, London.

In the early summer of 1921 we spent several weeks in Norway visiting the chief centres of the cod liver oil industry, on behalf of the Medical Research Council, in order to study the cause of the variations in the medicinal value of this valuable oil. During the trip a considerable number of factories of one type and another were visited, and a large number of oil samples of known origin were collected and brought home for testing their vitamin content. We were accompanied throughout by Professors Hjort and Holst, of the University of Christiania, who were also interested in the problem under investigation and who gave us very great assistance in every way.

Cod fisheries.

The Norwegian cod fishing can be broadly divided into two seasons which are usually named the Lofoten or "Skrei" fishing, and the Finmarken fishing. The reason for this differentiation, which is a fairly sharp one, is apparent from a study of the valuable memoirs published by Hjort and other investigators on the life history of the cod (Vol. 20, Rapports, Conseil Permanent International pour l'Exploration de la Mer, Copenhagen, 1914). Their investigations covering a number of years have shown that the spawning grounds of the cod in Norwegian waters are on the coastal banks at depths of 10 to 40 fathoms, extending right up the coast as far north as Sörö in the western part of Finmarken, but in particular on the famous Romsdal and Lofoten banks. The mature cod termed "Skrei" visit these banks in enormous numbers at the spawning season from January to April and are fished there during the "Skrei" fishery. The ova develop over the banks, and by June the small fry are drifting with the current northwards along the Norwegian coast so that by August and September they are found in far northern waters. The "Skrei" fishing, which has its chief centre at the Lofoten Islands, therefore covers the whole time during which the fish are on the spawning grounds (January to April or May) and the fish caught are almost solely mature cod; the other gadoids from which liver oils are prepared elsewhere—the haddock, *G. aeglefinus*, and the coal fish or saithe, *G. virens*, etc.—have different spawning habits (see Meek, "Migrations of Fish," 1916, p. 212; also Howell, "Ocean Research and the Great Fisheries," Oxford, 1921). It is probably for this reason chiefly that the cod liver oil produced at the Lofoten Islands has acquired a high reputation, for the makers have been able to claim that it is prepared from cod livers only.

The later fishing, the Finmarken season, sometimes termed the "lodde" fishing (from "lodde" the local name for the caplin) lasts from May to as late as August and is quite different in character from the "Skrei" fishery. In the spring as the light becomes more intense there is a remarkable outburst of plant life in the sea (Moore, Chem. Soc. Trans., 1921, 149, 1555), which is followed by an equally remarkable increase in the minute animals, copepods, amphipods, larval decapods, and molluscs, which feed on the microscopic plants and which in their turn form the food supply of large numbers of small fish and other marine animals, salps, squids, and certain mollusca which are the food of the cod. On the northern shores of Norway the appearance of these vast swarms of living organisms, sometimes so massed as to give the water a cloudy or muddy aspect, usually occurs just before great shoals of a small fish called the capelan or caplin (*Mallotus villosus*) migrate in from the more notherly waters to spawn on the Finmark coast, after which they proceed in a general direction eastwards along the coasts of Finmarken and Murmansk as far as the White Sea, eventually turning northwards in the Barents Sea. Their appearance at the coast is a signal to the fishermen that the cod will soon appear, for they form an attraction for enormous numbers of larger fish, chiefly cod, haddock, coal-fish, and pollock, which pursue and devour them in great quantity. These shoals of cod and other fish are, however, not all of one origin, as Hjort has shown (1914, *loc. cit.*). To some large extent they are the immature cod of various ages and size which have followed the caplin from Arctic waters but these are joined by large numbers of spent "Skrei" which have spawned on the more southerly banks and which, since they feed little during spawning, have proceeded up the coast to intercept the caplin migration and "fatten up." The Finmarken fishing usually moves along the coast in an easterly direction as the caplin move along and the fish caught are chiefly mixed gadoids. One consequence of this is that mixed cod liver oils are frequently and indeed somewhat generally prepared along this littoral. The composition of these mixed oils is very variable but it would appear that those prepared in the early part of the season (June) in western Finmarken are mixed oils from cod, haddock, and coal-fish but with a strong preponderance of cod. Later in the season on the eastern grounds the proportion of haddock may become very high.

*Manufacture of cod liver oil.**

The general methods employed in the preparation of cod liver oil are well known (Möller, "Cod Liver Oil and Chemistry," London, 1895; Lewkowitsch, Vol. II., 5th edn., London, etc.).

Rotting process. There are few places in Norway where oil is still prepared to any appreciable extent from the fresh livers by the old rotting process, which was the general method of preparation prior to the introduction of the steaming methods in 1853 by Möller (Möller, "Cod Liver Oil and Chemistry"). Occasionally in the very small fishing hamlets where the supply of livers is not worth the introduction of modern methods this process may be seen in operation. The livers are thrown into large wooden vats as they are collected from time to time and allowed to rot for long periods, the oil rising to the surface as the liver tissue slowly disintegrates. In some cases the vats may remain for as long as 2—3 years before sufficient oil has been prepared or an opportunity to sell the oil arises. The oil yielded by this process is usually a clear golden-brown coloured product, the depth of colour being to a large extent dependent on the length of time the contents of the vat have been standing. It also tends to possess a rather objectionable odour owing to the presence of traces of products of putrefaction. As far as we could ascertain such oils are seldom if ever sold or refined for medicinal purposes, but are used for cattle oils, tanning, and the other uses of ordinary cod oils. We were especially interested to find survivals of this process because there appears to be a general impression prevalent in medical circles that the results of the therapeutic use of modern liver oils are less striking than those formerly obtained when the dark and "black" oils were used, for it must be remembered that cod liver oil achieved its reputation when no other than the products of the rotting process were available and that for some time the introduction of the white "steamed" oil was regarded with disfavour both by merchants and users.

---

* In the descriptions of the processes we have eliminated all details which may be regarded as confidential and have given only the broad outlines which are generally known.

It was impossible for us to ascertain the extent of destruction of the vitamin A during the preparation of a rotted oil, for the only samples we were able to obtain were many months old and represented a miscellaneous collection of livers throughout that period. The samples we tested for vitamin-A value showed that they were valuable sources of that factor, although there could be little doubt that long standing of the oil with a considerable surface exposed to air and light must have reduced the amount of vitamin. The rotted oils will be discussed in dealing with oils produced from rotted "Graxe."

"Steaming" processes. The introduction of a steaming process about 1850 revolutionised the cod liver oil industry, and to-day there are few factories which do not employ one or other modifications of this method.

Broadly these may be classified into those methods in which the oils are melted out in steam-jacketed pans and those in which the liver tissue is broken up by direct steam. Generally speaking there are more of the former type of plant in the Lofoten Island area, and it is sometimes spoken of as the Lofoten process. The direct steaming is on the other hand more frequently employed along the Finmarken coast. The two processes are widely used, and almost every village has one or more "Tranfabrik."

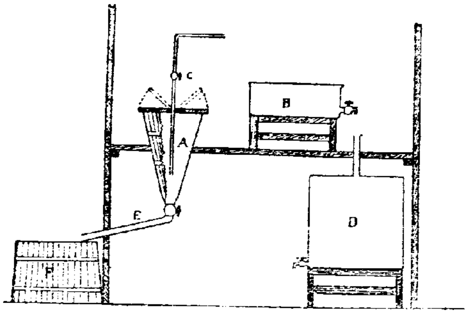
Steam-jacketed pan process or "Lofoten process." The fish, which are absolutely fresh and in fact usually alive when brought to shore, are gutted on the quay and the sound livers after stripping the gall bladders are placed in barrels. All discoloured or spotted livers are discarded. At the larger centres the guts and entrails are used for manufacture of fish guano, but where there is no facility for this they are thrown overboard. In the Lofoten Islands since the fish are then in spawn the roes are often collected and salted. The barrels of livers are taken to the factory and tipped into the jacketed vats, which are heated by low-pressure steam. When in the opinion of the operator the oil has separated satisfactorily the protein matter is removed by passing the liquid through a sieve ladle whilst the oil is kept warm and allowed to stand and separate. The product, which is a clear white oil, constitutes the first fraction and on cooling it tends to deposit crystals of "stearine." The residue is again heated and yields a second fraction of high-grade oil of slightly inferior taste, but this fraction is frequently mixed with the first. The hot residue is then usually allowed to drain through a number of cloth filtering bags hung up over a tinned gutter which collects the oil as it drops through. This oil, termed "posetran," is usually of a clear yellow colour and possesses a more pronounced taste owing probably to contact of the drops with air as they fall from the bags. This oil is sometimes mixed with the other two fractions, but more generally it is sold directly for cattle oil or industrial use. The residue from the filtering bags is termed "graxe" and is treated by one of three methods.

In some cases it is put back into the steam kettles and afterwards passed through a hand press which yields a dark yellow oil mainly used for technical purposes. The advantage of this method of treating the "graxe" is that it leaves a residue suitable for drying into a commercial liver meal for which there is now an increasing demand as a cattle food. The second method consists of heating the "graxe" over an open fire in pans with stirring, until all the water is driven off with the formation of a dark brown oil termed "brandttran."

More frequently, however, the graxe is thrown into vats outside the factory and allowed to rot for 2—3 months with the formation of a deep golden-brown oil which is skimmed from the top when enough has accumulated.

During the season a small factory will turn out 5000 litres daily.

The direct steam process. The general arrangement of this plant, which is usually of the simplest type, is shown in the accompanying figure. The handling of the fish is similar to that already described and the selected livers are thrown into the conical vat, A, until it is about three parts full. A simple lid hinged at its diameter and perforated to permit the steam pipe, C, to enter the vat, is then fastened down on the vat by means of clamps at the sides. Steam is then blown into the livers until they are in the opinion of the operator "cooked." The steam is turned off, the lid is opened, and the contents are allowed to stand, after which the deep layer of oil at the top is ladled off and poured through an unbleached linen filter to remove protein matter, into the tank, B. The protein remaining on the filter is thrown back into the vat. The crude oil in B is allowed to settle to allow the small amount of moisture and traces of protein to settle out, after which it is run into storage tanks, D. The liver pulp remaining behind in the vat is generally run off by means of the outlet, E, into rotting vats, F, outside the factory and there allowed to yield after some months the usual type of golden brown oil often termed "surtran." Sometimes in the better factories the pulp is subjected to pressure to yield the second grade of oil and the residue is dried for liver meal.



Other methods. In addition to the very many factories where these widely-employed methods are used there exist some in which the processes are highly elaborated and scientifically controlled and in which oils are carefully prepared under conditions (use of vacuum, atmosphere of carbon dioxide etc.) which protect against oxidation (*cf.* Harrison, Wild, and Robb, E.P. 25,683 of 1907; Heyerdahl, E.P. 137,514 of 1919).

Present trend of the manufacture of cod liver oil.

The production of high-grade marketable medicinal oils as free as far as possible from pigment and unpalatable constituents is the general aim of the manufacturers, but there is at present in certain cases a revival of the interest in the actual medicinal or therapeutic qualities of the oils.

The lack of knowledge as to what constituents of cod liver oil actually are responsible for its therapeutic value is reflected in the opinions of the manufacturers, of whom many accept what is perhaps the most general view, apart from modern vitamin theories, namely, that the high digestibility and absorbability of the cod liver oil together with the peculiar nature of the highly unsaturated fatty acid which it contains are the chief factors concerned. Accordingly it is found that one of the chief aims of the more progressive of these people is to protect their oil from oxidative changes, and their efforts in this direction may range from the simplest precautions up to the elaborate use of atmospheres of carbon dioxide and vacuum vessels referred to above. It is is also considered by the practical people that contact with air or oxidative change generally tends to impart an undesirable flavour and render the oil unpalatable.

Refining.

(1) *Crude oils.* As remarked above there is a somewhat general impression prevalent especially in medical circles that the dark brown cod liver oils are, or were at one time, more effective as therapeutic agents than the clear water-white oils, and one of the chief problems with which we were faced was to discover the actual truth on this matter. It is also a popular belief in many quarters that the "brown" oils represent the crude cod liver oil, the "real thing," and that the white oils offered for sale by the retailers are highly refined products obtained from the crude oils by processes analogous to those employed in the refining of a vegetable oil. Indeed it is not infrequent to hear it stated that the "white" oils have lost much of their medicinal value during the refining to which they have been subjected.

After personal examination of many factories and careful interrogation of many sources of information we came to the conclusion that very small and quite negligible quantities of crude "brown" oils are refined to produce medicinal oils. Several processes for this refining have at one time or another been put forward in patents, but as far as we are aware none has proved of any commercial value on a large scale. The removal of free acid by the usual method would scarcely be likely to reduce the vitamin value of the oil, but all bleaching processes for reducing pigmentation which are based on oxidative changes, ozone, chlorine, sunlight, and aeration would be harmful. Such processes were also condemned years ago by Möller (*op. cit.*) on the grounds that they spoilt the flavour and palatability of the oils.

(2) *Medicinal oils.* The medicinal oils prepared in Lofoten, Finmarken, and other zones are usually bought in bulk and brought south to the larger town such as Bergen for the final refining processes. This refining essentially consists of freezing to effect removal of stearine, and in some cases the removal of a certain amount of pigment by mixing with an adsorbent and passing through a filter-press. The refining is practically always done the same year that the oil has been prepared and oils with a tendency to a high acid value are seldom if ever touched by the better class refineries.

The crystallisation of "stearine" is usually carried out in tanks at low temperature (0° to −10° C.) and the oil is then passed through filter-presses, to yield the first-grade oil, which is run off into storage tanks from which are filled the metal-lined barrels in which it goes to market. The residue from the filter presses may or may not be expressed under pressure to yield a second-grade medicinal oil, which is usually handled separately. The stearine is sold largely for technical use and varies in its content of oil a great deal with the different factories.

The highest grades of oil find the best market in England, whereas the lower grades not only sell well in Germany and France but actually appear to be preferred there, especially in the former country where a marked yellow colour is favoured.

Influence of processes on vitamin value of liver oils.

The difficulty of investigating satisfactorily this problem was considerable because of the variations in the vitamin value of the liver oils which occur naturally. As we have shown (Biochem. J., 1922, **16**), the food of the cod is responsible for the presence of vitamin A in the liver oils, its ultimate origin being the unicellular marine plants, diatoms, etc. (Jameson, Drummond, and Coward, Biochem. J., 1922, **16**, in the press).

Some variations in the vitamin value of liver oils may be traced to differences in the food supply, but also we are considering the view that to some extent the variations are associated with definite physiological changes in the tissues of the fish at the different seasons. We hope before long to be able to publish more fully our views on this important question. In view of this difficulty we have only been able to study the effect of the processes with accuracy when it has been possible to obtain samples of the same preparation before and after they have been treated.

We have throughout employed the technique described by Zilva and Miura (Biochem. J., 1921, 15, 654) for the quantitative estimation of the vitamin A in oils. This method is capable of yielding results of considerable accuracy in the hands of skilled workers, and during the whole course of this work the results obtained independently in our two laboratories on the same sample of oils have shown remarkably close agreement.

(a) "*Rotted*" *oils.* It was of course impossible to estimate the extent of destruction of vitamin A which had occurred during the preparation of the samples of these oils which we investigated, for we had no means of judging what was the potency of the oil in the original fresh livers. The alternative was to compare the value of these "rotted" oils with average oils prepared by the "steaming" process in the same locality. The results are given below; the dosage is that which just gives marked growth in a test animal (rat) of approximately 100 grams weight.

Sample.	Origin.	Locality.	Growth dosage in mg.
K_1 raw oil	Rotting of "graxe" after steaming out 1st fraction.	Finmarken	5
H_2 surtran	Do. Do.	Do.	2–3
H_{11} Do.	Do. Do.	Do.	3
N_4 Do.	Rotting of "graxe."	Do.	3
L_1 rotted	Rotting of fresh livers.	Lofoten	20

These values are all well within the limits we have found for oils prepared in these localities by the steaming process, so that although the exposure to air and sunlight must to some extent destroy vitamin A in the rotted oils the amount of inactivation is not as serious as we had expected to find.

(b) "*Steamed*" *oils.* From a consideration of the steaming processes as we saw them in Norway we formed the opinion that very little destruction of vitamin A would take place in the extraction of the oils from the livers. This opinion was borne out by the results of our experimental tests, in that oils prepared with the greatest care in the laboratory in an atmosphere of carbon dioxide as well as those prepared commercially by similar methods were not appreciably superior to oils prepared at the same time and from similar livers by the "Lofoten," or steam-jacketed pan method.

Sample.	Origin.	Locality.	Growth dosage in mg.
L_4	Steam-prepared oil, May, 1921	Lofoten	20
L_5	Steam-prepared oil, 2nd fraction, May, 1921.	„	Approx. 20
L_6	Oil prepared in CO_2 in laboratory, May, 1921.	„	15–20
L_7	Commercial oil prepared in CO_2, 1921 season.	„	15
L_8	Do. Do.	„	15

At one station in the Finmarken area, there were two factories in close proximity one of which employed the steam-jacketed pans and the other direct steam. Arrangements were made, therefore, for batches of oil to be made at the same time from similar batches of fish (mainly cod, but also coal-fish and haddock) by the two processes. The results of the tests on these oils was as follows:

Sample.	Origin.	Locality.	Growth dosage in mg.
K_1	Direct steam, June, 1921, unfiltered.	Finmarken	5
K_2	Ditto, filtered.	„	5
K_{10}	Jacketed-pan, June, 1921, unfiltered.	„	3–4
K_{11}	Ditto, filtered.	„	3–4

These figures appear to indicate that the steam-jacketed pan may be slightly the better method for preserving the vitamin, although it is questionable whether the differences are outside the range of experimental error.

(c) "*Posetran.*" As described above, the second fraction of the oils prepared by the Lofoten process is termed "posetran." The preparation of this fraction, although it involves slow passage of the oil drop by drop from the bags, does not appear to cause appreciable loss of vitamin. Several samples of posetran had approximately the same growth-promoting power as that of the first fractions.

Sample.	Origin.	Locality.	Growth dosage in mg.
K_{20}	Lofoten process	Kjelsvik (Finmarken)	3–4
K_{21}	Posetran of K_{20}	„	2–3
K_{22}	Haddock oil, Lofoten process	„	10
K_{24}	Posetran of K_{21}	„	10

(d) *Refined oils.* The influence of freezing out the "stearine" on the vitamin value would appear to be almost negligible from our studies of the growth-promoting potency of oils before and after being subjected to that process. This is more or less what would be expected from the nature of the process. The following experiments refer to a typical Lofoten oil refined at Bergen:

Sample.	Origin.	Growth dosage in mg.
B 1	Before any treatment	15–20
B 2	After freezing..	15–20
B 3	Refined, non-freezing	15–20

(e) "*Stearine.*" Different refiners of cod liver oil remove the "stearine" to different extents, or rather some press the "stearine" until a comparatively hard product is produced whilst others send it on to the market in a semi-liquid form. We have tested several samples of cod liver oil "stearine" and find that it may be a valuable source of vitamin A. A daily dose of 0·1 g. will usually give better growth than an equal amount of an average sample of dairy butter, so that the present practice of using the stearine for technical uses would appear to be wasteful. From a scientific standpoint it is difficult to understand why the removal of the "stearine" is insisted on by many authorities. Professor E. Mellanby has informed us that some two years ago he observed the high value of cod liver oil "stearine" in the prevention and cure of experimental rickets in dogs. This result has not been published but is confirmed by our results.

Conclusion.

From our exhaustive investigations of the effect of the modern processes of the preparation of cod liver oil on its vitamin value we have formed the opinion that the "steaming" methods yield oils of as high, if not actually higher potency than were yielded by the old and almost extinct "rotting" process.

Further, the modern methods of refining, if we exclude, as we justly may, the almost negligible amount of bleaching of dark oils which occurs, scarcely affect the vitamin value at all.

In the light of these observations it is obvious either that the popular belief that the "dark" oils are more valuable as medicinal products than the modern "white" oils is erroneous or that such belief arose at a time when some actual difference existed. To this we will return in a later paper.

There is no doubt that fairly wide variations in the vitamin content of liver oils do occur, and we believe that these variations are a reflection of changes in the diet or the physiological state of the fish at different seasons. Our information is as yet insufficient for us to advance our views on this matter, but we hope before long to present evidence which will throw considerable light on these changes.

The trend of modern methods of liver oil preparation is all in the direction of the exclusion of oxidative changes, chiefly on the grounds of improving flavour and palatability. Fortunately, these aims are just those which will tend to improve the vitamin value of the oil, although even now very little loss appears to take place, as far as the methods of testing at our disposal can detect. The introduction of any methods for bleaching or refining liver oils intended for medicinal use which involve oxidative changes are strongly to be deprecated. On the other hand, from a purely scientific standpoint there appear to be no adequate reasons why cod liver oils should not be mixed with oils from other fish livers. Indeed, we have found the oil from the coal fish (*Gadus virens*) to be usually markedly richer in vitamin A than the average samples of cod liver oil (Zilva and Drummond, Lancet, 1921, 2, 753; also Lancet, 1922). Further, from the same standpoint it would appear unnecessary to remove the "stearine" as is now done in the better quality oils. If, however, there are technical or other considerations which make the removal advisable, it seems a pity that so valuable a source of the vitamin should be used for technical and non-dietetic use.

In conclusion we wish to express our deep appreciation of the great hospitality and kindness extended to us throughout our visit to the Norwegian fishing grounds. In particular we would like to thank Prof. J. Hjort, F.R.S., and Prof. Axel Holst for valuable information concerning the life history of the cod, and Mr. Fredricksen and Mr. T. Lexow, of Melbö, Vesteraalen, Consul Robertson of Hammerfest, and Mr. Bruhn of Kjelvik, Magerö, for the untiring assistance they so readily gave us in studying the technical side of the problem.

We also desire to thank the Medical Research Council for a financial grant which enabled this visit to be made and covered the cost of the later experimental work.

THE DETERMINATION OF SMALL QUANTITIES OF SILICA IN THORIUM NITRATE.

BY H. V. HODGSON.

It has long been known that if the ash content (consisting of silica and silicate of iron) of the fabric used for the manufacture of incandescence gas mantles exceeds about 0·02%, the finished mantles are unduly brittle. It does not, however, appear to be generally known that a still lower percentage of silica in the thorium nitrate produces a similar effect, which is particularly noticeable and undesirable in those mantles where considerable flexibility is required.

The absence of any mention of this in the literature on gas mantle manufacture and the rare earths, and the fact that on both theoretical and practical grounds silica should not be present—especially in a soluble form—are doubtless the reasons why silica is not included in the list of possible impurities in technical thorium nitrate, and why, therefore, no method appears to have been devised for its detection and determination. It is rather remarkable that heating the nitrate to 150° C. does not render the silica insoluble, but conversion to the chloride—a somewhat tedious process—does so, and at a considerably lower temperature.

The brittleness of the mantles made from some thorium nitrate, which the author tested recently, was found to be due to the presence in the latter of silica, and the following method was devised and successfully used for its determination.

Fifty grams of thorium nitrate is dissolved in 150 c.c. of distilled water, and precipitated by the addition of 30 g. of pure oxalic acid dissolved in about 150 c.c. of hot distilled water. The precipitated thorium oxalate is well shaken or stirred and allowed to stand for several hours, preferably overnight. It is then filtered off and well washed with hot distilled water. The filtrate is evaporated to dryness, the excess of oxalic acid sublimed, and the residue heated nearly to dull redness. When cool, 4 or 5·c.c. of pure hydrochloric acid is added and about the same amount of distilled water, and the whole boiled till all that is soluble has dissolved. It is then diluted with hot distilled water, filtered, and washed. The filter paper and contents are ignited and weighed in a platinum crucible. The residue should be white or only faintly tinged with a trace of iron from the filter paper. It is treated with about 2 c.c. of pure hydrofluoric acid solution and a drop or two of sulphuric acid, evaporated to dryness, ignited, and the crucible again weighed, the loss representing silica.

To test the accuracy of the method, 50 g. of thorium nitrate free from silica was dissolved in distilled water, and to the solution was added 10 mg. of silica as a dilute solution of sodium silicate, so that no precipitation occurred. The whole was well stirred, evaporated to dryness on a water-bath, and when cool, the nitrate was dissolved and the silica determined by the foregoing method. The whole of it was recovered. The test was repeated, but with the difference that the nitrate was finally heated between 150° and 155° C. for 20 minutes. Again the whole of the silica was recovered.

In order to determine whether any silica was obtained from the oxalic acid or the vessels used, 30 g. of the acid was dissolved in distilled water, a few c.c. of pure nitric acid added, the whole evaporated to dryness, and the oxalic acid sublimed. The very slight residue left was then treated as above. This test was made several times, but the largest amount of silica obtained did not exceed 1 mg.

NITRIC ACID ABSORPTION TOWERS.

BY J. A. HALL, A. JAQUES, AND M. S. LESLIE.

The construction of towers for the absorption and conversion into nitric acid of useful concentration, of nitrous fumes from nitric acid stills, or from plant for the denitration of waste acids obtained n the manufacture of explosives, has been generally viewed in the past as primarily an engineering problem, and little regard has been paid to chemical factors such as the nature, concentration, and speed of the gases entering the towers. Although repeated trial may sometimes have produced designs highly efficient in the case of one particular set of conditions, these offered very little guide as to the changes to be introduced when the conditions differed to any considerable extent.

It was suggested by one of us that by a careful study of the rate of reaction of the gases in any given set of absorbing towers, and of the influence upon it of the velocity and composition of the gases and the rate of flow and concentration of the absorbing liquid, it might be possible to formulate a mathematical scheme by which the best conditions for the efficient treatment of any nitrous fumes whatsoever might be calculated. This was accomplished as the result of experimental work carried out in 1916 at H.M. Factory, Litherland, a formula being arrived at which reproduces the experimental results over a wide range of conditions. Certain assumptions were made in order to arrive at the formula, but it is not claimed that the experimental work proves the truth of these. The formula is merely put forward as an empirical guide for the sign of absorption towers.

Since the work was carried out a paper on the ubject by J. R. Partington and L. H. Parker (J., 919, 75 T) has appeared. These authors have alculated absorption coefficients for different conentrations of nitric acid in the absorbing liquid nd of nitrogen peroxide in the gas on the assumpion that, in general, sufficient empty spaces are rovided for oxidation. This treatment, whilst no oubt satisfactory for the average case of fumes rom a nitric acid plant, does not give any idea of he best distribution of packed and unpacked space nd of the optimum ratio between them—matters which become important in the case of very dilute cases or gases containing a low proportion of oxygen. As our work covers these points it was hought worth while to record it.

It was assumed that the whole reaction in the towers might be divided, for the purpose of the nvestigation, into two processes, one an absorption process the net result of which, whatever its mechanism, may be expressed by the equation

$$3NO_2+H_2O=2HNO_3+NO$$

(see Burdick and Freed, J. Amer. Chem. Soc., 1921, 43, 518), and the other an oxidation process whereby more nitrogen peroxide is produced ready for further absorption, namely,

$$2NO+O_2=2NO_2.$$

Absorption takes place in the towers themselves, in which is placed packing, such as pieces of quartz or pumice, earthenware rings, or anything else by which the water or nitric acid trickling over may be made to expose a large surface to the current of gas. Only oxidation can occur in the connecting pipes between the towers or in those parts of the towers left unpacked.

The plan followed was to establish an equation for each of the two processes in terms of quantities of reacting materials, velocity of gas, speed of flow of water, space traversed, and so on, and then from these two to develop a third which should express the relationship between the volumes of the absorption and oxidation spaces required for the most efficient absorption.

Absorption equation.—It is perhaps necessary to say something further in justification of the equation

$$3NO_2+H_2O=2HNO_3+NO.$$

It is probable that nitrous acid is one of the first products of the reaction

$$2NO_2+H_2O=HNO_3+HNO_2.$$

Some work carried out by Rây, Dey, and Ghosh (J. Chem. Soc., 1917, 111, 413, seems to indicate that the decomposition of nitrous acid according to the equation

$$3HNO_2=HNO_3+H_2O+2NO$$

is rather slow. On the other hand, Knox and Reid (J., 1919, 105 T) have shown that the rate of decomposition varies very greatly with conditions, and that agitation and exposure of a large surface of solution to air as in the case of absorbing towers, or even to an inert gas, greatly increases the rate of decomposition. The conclusion that the decomposition in the towers is very rapid is borne out by the fact that, under normal conditions, when the concentration of nitric acid issuing from the several towers may be anything up to 65%, the concentration of nitrous acid never exceeds 0·4—0·5%. The rate of absorption may therefore be measured by the rate of production of nitric acid.

It was assumed that, within the range of the experiments to be described, absorption depended on the partial pressure of the gas reckoned as NO_2 molecules. No account was taken of association to N_2O_4 molecules. This seemed to be justified both by later experimental results and also by the following consideration. Suppose that, instead of $2nNO_2$ we have nN_2O_4, then the rate at which molecules are absorbed by water in the first case will be twice the rate in the second, but in the second case each molecule contains twice as much nitrogen peroxide as in the first, so that the net result will be the same.

It was necessary to determine experimentally how the rate of reaction depended upon the flow of liquid. For this and later experiments a set of eight towers connected in series with the fume main from nitric acid stills was employed. Each tower consisted of four plain sections of earthenware pipe two feet six inches in diameter and about two feet six inches long, and sections at the top and bottom having junctions for the connecting pipes nine inches in diameter. A perforated tray was placed at the base of each section, and each plain section was packed two-thirds full of three-inch pumice. The gas was sucked from the nitric acid plant through a stoneware fan before being introduced into the towers, and a second fan was placed in series after the fourth tower, the towers being numbered from 1 to 8 in the direction of flow of the gas. Water was introduced at the top of number 8 tower, the absorption being carried out on the countercurrent principle, and the outflow from each tower was led into a movable tipping box with two outlets through which it could be delivered to either of two Pohle elevators. One of these raised the acid to the top of the same tower, and the other to the top of the following tower.

It may reasonably be supposed that the gases from nitric acid stills produced by the decomposition of sodium nitrate or of nitric acid consist almost entirely of nitrogen peroxide together with sufficient oxygen to reoxidise it to nitric acid. Air is drawn in through leakages in the pipework, and in our experiments the fumes formed 20—30% of the gases passing into the towers.

In the preliminary experiments to ascertain the effect of variation in the rate of flow of absorbing liquid no liquid was passed through towers 1—4, so that these acted as a condensing space for nitric acid vapour. Very little acid condensed in No. 1 tower, and none in the succeeding ones. A separate flow of water was arranged through each of the towers 5, 6, 7, and 8, and the gases were passed through these successively. A special constant-head apparatus was arranged so as to ensure a constant flow of water into each tower. The strength of the issuing acid was determined in each case by measuring its specific gravity.

From the speed of flow of water and the strength of the acid, the quantity of actual nitric acid formed per minute was calculated. This became successively smaller as the gas passed along the towers, the flow of water being approximately the same in all the four towers. The effect of altering the speed of flow was studied in succeeding experiments.

If a be the partial pressure of nitrogen peroxide in the gas, and f the average flow of water in litres per square foot of cross-section per minute, we assume that the speed of production of nitric acid per tower may be expressed by the equation—

$$-da/dt = k\,a^x f^y$$

The value of x was assumed to be 1. Integrating between 0 and t we have

$$\log_e a_0 - \log_e a_t = k f^y t$$

where a_0 and a_t are the partial pressures of nitrogen peroxide in the gases entering and leaving the towers respectively. For a constant rate of flow of gas t is constant. Thus the value of y can be calculated from two pairs of values of a_0, a_t, and f. The values of y were calculated for the first tower only, in order to eliminate the error due to neglect of the effect of oxidation of nitric oxide. It will be proved later that this is negligible under these conditions.

The nitric acid output for the remaining towers was determined in order to ascertain the total amount of gas absorbed, and also to afford a basis for the necessary extrapolation by means of which the value of z, the quantity of gas escaping, was estimated. This extrapolation was carried out by plotting strength of issuing acid against the number of the tower. The quantity z was added to the total quantity of gas absorbed in order to obtain a_0; a_0, a_t, and z were all expressed in kilograms of nitric acid formed per minute. The results are contained in Table I, and indicate that, within the limits of the experiments, the rate of absorption of nitrogen peroxide is very nearly proportional to the square root of the rate of inflow of water.

From 1 and 2, y=0·47.
From 2 and 3, y=0·54.
In subsequent calculations y was taken as 0·5.

The towers were next put into actual use, and for the purpose of the following experiments the liquid was caused to pass through each tower in succession, that is, from No. 8 to No. 1, without circulation. When the system had reached a steady state the strength of the acid issuing from each tower was determined by measuring its density. In most experiments the steady state was maintained for three hours. The quantity of nitrous acid in the liquid was very small when the sp. gr. was less than 1·4.

Considerable quantities of chlorine or nitrosyl chloride were evolved. The question of the distribution of chlorine in the towers will be discussed later. In the absorbing liquid it appeared to be present mainly as hydrochloric acid, in variable quantity. A typical example of its distribution is given in Table V. The chlorine was not all present as hydrochloric acid, and on account of this fact and the variability of the chlorine content during each experiment, it was considered that a certain error in the strengths of the acid issuing from the last three towers must be accepted. This affects the distribution of output from the towers, but not the total output. As an approximation, the sp. gr. of the liquid was corrected in each case by subtracting from it an amount equal to $d-1$, where d represents the sp. gr. of an average equivalent aqueous solution of hydrochloric acid. Control experiments showed that, so far as the hydrochloric acid content was concerned, this method of calculation is satisfactory, the following results being obtained:—

Percentage.		Sp. gr. of mixture.	Sp. gr. of hydrochloric acid of this concentration.	Calculated sp. gr. of nitric acid.	Calculated concentration of nitric acid.
HNO_3.	HCl.				
38·8	3·67	1·261	1·018	1·243	38·8
34·7	6·58	1·248	1·032	1·216	34·8
25·4	6·24	1·187	1·031	1·156	25·8
21·3	10·68	1·183	1·053	1·130	21·7
17·2	6·87	1·139	1·033	1·103	17·5

The velocity of the gas current was measured by means of Pitôt tubes.

The results of some of these experiments on the output of nitric acid are contained in Table II.

The rate of reaction of the nitrogen peroxide with the absorbing liquid is probably determined in practice by the rate at which the gas can reach the surface of the liquid, and may therefore be expected to depend simply upon the partial pressure of nitrogen peroxide in the gas. It may, therefore, be expressed provisionally by the equation

$$dy/dt = k_1\left(\frac{m}{v} - y\right)\sqrt{f}\cdot k_t \quad \ldots\ldots\ldots\ldots\ldots(1)$$

where m is the mass of nitrogen peroxide expressed in kg. of equivalent nitric acid contained in volume v cub. ft.; y is the diminution in concentration of nitrogen peroxide during time t minutes, k_1 is the speed constant for absorption for the particular absorbing material contained in the tower; f is the

rate of flow of the liquid expressed in litres per square foot per minute; and k_f is a constant depending upon the units in which the flow is expressed.

By integrating equation (1) between 0 and t we get as the total change in concentration of nitrogen peroxide during a time t minutes—

$$y=\frac{m}{v}\left(1-e^{-k_1 t/f^{\frac{1}{2}} k_f}\right) \dots\dots\dots\dots (2)$$

Since the gas is flowing through the tower at a definite velocity of, say, V cub. ft. per minute, time may be expressed in terms of volume of absorbing space and velocity of gas through the towers. Let σ_y be the total packed space through which the reaction takes place, then the free space will be $k_c\,.\,\sigma_y$ where k_c is a constant depending upon the structure of the packing and $t=k_c\,\sigma_y/V$.

Thus equation (2) becomes

$$y=\frac{m}{v}\left(1-e^{-k_1 k_f/f^{\frac{1}{2}} k_c \sigma_y/V}\right) \dots\dots\dots\dots\dots (3)$$

The product $k_1\,k_f\,k_c=K_1$ which is the absorption coefficient for a liquid of definite concentration flowing at the rate of 1 litre per square foot per minute through a definite kind of packing.

Instead of expressing nitrogen peroxide in terms of concentration, we may consider the absolute quantities passing through the space σ_y in a definite time T, and put $Y=VTy$ and $P=VTm/v$. That is, P is the total amount of nitrogen peroxide entering a given space σ during time T minutes, and Y is the total amount of nitrogen peroxide reacting with the liquid in the space σ_y during the time T. Two-thirds of this is transformed into nitric acid and one-third into nitric oxide. In each case the quantity of gas is expressed in terms of equivalent kilograms of nitric acid. Equation (3) therefore becomes:—

$$Y=P\left(1-e^{-K_1\sigma_y/V.f^{\frac{1}{2}}}\right) \dots\dots\dots\dots\dots\dots (4)$$

The values of Y, P, σ_y, V, and f may be obtained from Tables I and II, and from these the values of the absorption coefficient K_1 determined for different concentrations of nitric acid and for water. The values of K_1 are derived from the amount of absorption taking place in the first tower only, and the oxidation in it is ignored. Table III shows the values of K_1 obtained in this way for acids of various concentrations.

Experiment ..	2	1	3	4*	2	5*	1	3

* Not shown in Table II.

There are considerable irregularities in the results, no doubt due to the impossibility of maintaining absolutely constant conditions, such as temperature, and due also, as will be shown later, to the presence of chlorine in the gases. With the help of these values, however, and the fact that, as Foerster and Koch (Z. angew. Chem., 1908, 21, 2161) have pointed out, the rate of absorption of nitrogen peroxide by nitric acid becomes very small when the concentration of the acid rises above 65%, and apparently ceases altogether at 69%, a curve showing the general order of magnitude of K_1 for any concentration of acid may be drawn (see Fig. 1).

Oxidation equation.—The equation $2NO+O_2=2NO_2$ represents a termolecular reaction. That the oxidation approximates very closely to such a reaction for concentrations of nitric oxide from 0 to 20% by volume has been shown by Lunge and Berl (Z. angew. Chem., 1906, 19, 807; 1907, 20, 2074). Their results were confirmed by Bodenstein (angew. Chem., 1909, 22, 1153). The rate of oxidation may therefore be expressed in the form

$$\frac{dx}{dt}=K_2\left(\frac{m}{v}-x\right)^2\left(\frac{m'}{v}-x\right) \dots\dots (5)$$

where K_2 is the oxidation constant; v the volum in cubic feet containing a mass m of nitric oxid

K_1 for flow of 1 litre per sq. ft. per min.

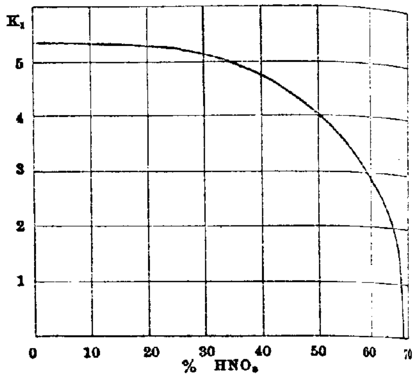

Fig. 1.

and a mass m' of oxygen *both expressed as kg.* *equivalent nitric acid*; and x the change in equivalent concentration of nitric oxide and of oxyge after time t.

Integrating between 0 and t we obtain

$$K_2=\frac{1}{t}\frac{1}{\left(\frac{m}{v}-\frac{m'}{v}\right)^2}\left\{\log_e\frac{\frac{m'}{v}\left(\frac{m}{v}-x\right)}{\frac{m}{v}\left(\frac{m'}{v}-x\right)}-\frac{\left(\frac{m}{v}-\frac{m'}{v}\right)}{\left(\frac{m}{v}-x\right)\frac{m}{v}}\right.$$

By converting Lunge and Berl's values in equivalent kg. of nitric acid the value of I in the required units was found. Their experimen were carried out at constant pressure, and th introduces complications in the change in co centration during the reaction, owing to shrinka of the system as the oxygen disappears. To obvia this difficulty the calculation was always ma between pairs of successive values, and the volu of the system in each case was taken as its volu at the beginning of the reaction interval. T values of K_2 calculated by this method from Lun and Berl's experimental results are shown Table IV.

TABLE IV

Reaction mixture: 125 c.c. NO, 500 c.c. air. Temp. 20° C.

Time in min.	Percentage of original NO.		K_2
	Converted.	Unconverted.	
0	0	100	128,000
$\frac{1·76}{60}$	52·49	47·51	114,150
$\frac{2·64}{60}$	61·33	38·67	
$\frac{3·96}{60}$	69·05	30·95	123,400
$\frac{7·92}{60}$	80·56	19·44	76,260
$\frac{13·78}{60}$	85·28	14·72	96,000
$\frac{29·92}{60}$	91·77	8·23	

The experimental data contained in this table ere also plotted, the values of dx/dt obtained raphically, and the value of K_3 calculated from his and the concentrations. In the case of the rst pair (t=0 to t=1·76÷60 minutes), the value ound was 112,700, agreeing substantially with the bove. The value of K_3 in round figures was taken s 100,000.

In many practical cases the concentration of the xygen is such that its changes are negligible comared with changes of nitric oxide concentration xtending through a considerable range, a fact hich admits of an important simplification in the quation, for, writing the differential equation

$$\frac{dx}{dt} = K_3\left(\frac{m}{v} - x\right)^2 [O_2] \;\ldots\ldots\ldots\ldots\ldots\ldots \quad (7)$$

here $[O_2]$ is the average oxygen concentration uring the time t, and integrating between 0 and t e obtain

$$\frac{x}{\frac{m}{v} - x} = \frac{m}{v} K_3 [O_2]\, t \;\ldots\ldots\ldots\ldots\ldots\ldots \quad (8)$$

f σ_x is the empty oxidation space and V the elocity of gas

$$t = \frac{\sigma_x}{V}$$

$$\therefore \frac{x}{\frac{m}{v} - x} = \frac{m}{v} K_3 [O_2] \; \frac{\sigma_x}{V} \ldots\ldots \quad (9)$$

Converting concentrations into absolute quantities, s in the absorption equation, we may put X= Tx and Q=VT$m/v$, where X is the total quantity xidised in the space σ_x and Q the total quantity ntering the space σ_x during the time T.

$$\therefore \frac{X/VT}{(Q-X)/VT} = \frac{Q}{VT} K_2[O_2] \; \frac{\sigma_x}{V}$$

Hence

$$\frac{X}{Q-X} = \frac{Q}{V^2T} K_2[O_2]\, \sigma_x$$

$$i.e., \qquad X = \frac{Q^2K_3\,[O_2]\,\sigma_x}{V^2T + QK_3[O_2]\sigma_x} \ldots\ldots \quad (10)$$

The product $K_3[O_2]$ may be regarded as a single onstant which will, of course, have a different alue for different average oxygen concentrations.

It has been found by several investigators that he velocity of oxidation of nitric oxide has a small egative temperature coefficient (Bodenstein, *loc. cit.*, also Z. Elektrochem., 1918, 24, 183, and Z. ngew Chem., 1918, 31, 145; Briner and Fridoeri, Helv. Chim. Acta, 1918, 1, 181; J. Chem. Soc., 918, 114, ii., 302; Wourtzel, Comptes rend., 920, 170, 229). Since, therefore, both the rate of xidation of nitric oxide and, probably, the rate of bsorption of nitrogen peroxide (Foerster and Koch, *loc. cit.*) are increased by lowering of temperature, it is evident that the gases should be cooled as much as possible before entering the towers. This is advisable also on another ground, namely, the liability to evaporation of the nitric acid solution by the passage of a strong current of air through it.

Relationship between oxidation space σ_x and bsorption space σ_y.—As the gas passes through a ertain portion of absorption space σ_y, it will become poorer in nitrogen peroxide and richer in nitric oxide, that is, at a certain point it will become more economical in space to stop absorption and allow oxidation alone to take place. To determine the exact ideal relationship between σ_x and σ_y would probably be rather difficult, but we cannot be far from the optimum condition if we regard xidation as equivalent in value to absorption and hoose such values as will make the ratio of oxidation and absorption with respect to space equal, that is,

$$\frac{dX}{d\sigma_x} = \frac{dY}{d\sigma_y}$$

It is evident that any considerable departure from this state of affairs would result in waste of space through devoting it to a slow process.

Differentiating equations (4) and (10) we get

$$\frac{dY}{d\sigma_y} = P\frac{K_1 ft}{V}\, e^{-K_1\sigma_y ft/V} \qquad \ldots\ldots(11)$$

$$\text{and} \quad \frac{dX}{d\sigma_x} = \frac{Q^2K_3\,[O_2]\,V^2T}{(V^2T+QK_3[O_2]\,\sigma_x)^2} \qquad \ldots\ldots\ldots(12)$$

$$i.e., \; \frac{PK_1 ft}{V} e^{-K_1\sigma_y ft/V} = \frac{Q^2K_3\,[O_2]\,V^2T}{(V^2T + QK_3[O_2]\sigma_x)^2} \quad (13)$$

From equation (13), for given values of P, f, V, T, and σ_y, we obtain two values for σ_x, one of which is always negative and has no meaning. The other may be either positive or negative. A negative value indicates that the absorption space is insufficient to enable the mixture to reach a point at which it is worth while to begin to oxidise. If the value is positive it gives the measure of the oxidation space to be added to the absorption space σ_y in order to produce the optimum condition. The value of σ_y is chosen arbitrarily and should not greatly exceed the value at which $\sigma_x = 0$. The smaller the total value of σ the more strictly does equation (13) represent the required condition and the smaller the total tower space necessary. Constructional requirements, however, may force the adoption of certain oxidation spaces, *e.g.*, the connecting pipes, but with the help of the above equation, knowing the nature and concentration of the gas under consideration, the plant can be adapted very closely to the form necessary for maximum efficiency.

Calculation showed that the towers employed in the above experiments would have been more efficient if all except the seventh had been packed full of pumice. The absorption space in tower 7 should be 40 cub. ft. instead of 49 cub. ft. In all other cases the pipes allow more oxidation space than is theoretically necessary. This would give an efficiency of 96% as against 92·5%.

Discussion of results in Table II.—The quantities of nitric acid produced in each tower in experiments 1—6 are shown graphically in Fig. 2. The ringed numbers on the curves indicate the corresponding experiments. The results are calculated to a time of three hours in each case.

In experiments 1, 2, and 3 the inflow of water was of the order of about 0·2 litre per sq. ft. per minute, and the velocity of the gas was 120 cub. ft. per minute. In experiment 4* the flow of water was somewhat greater, namely, about 0·3 litre per sq. ft. per minute, and the rate of flow of gas was made lower, resulting in an enormous absorption in tower 1. In experiment 5* the stream of gas was kept slow and the flow of liquid was also decreased to about 0·13 litre per sq. ft. per minute. In this case acid of sp. gr. approximately 1·44 containing nitrous acid issued from towers 1 and 2. The curve is drawn for towers 3—8 only. All the curves obtained up to this point show a distinct minimum at tower 4. It was thought that this might be caused through the output of tower 5 being raised in consequence of the large oxidation space occurring in the fan and connecting pipes at this point. In order to test this the fan was eliminated and towers 4 and 5 joined by a pipe of only slightly greater volume than those joining the other towers.

Experiments 6 and 7* were made under these circumstances, the velocity being about 90 cub. ft. per minute and the rate of inflow of water being somewhat greater than 0·2 litre per sq. ft. per minute. The acid running out of the first tower was a little weaker than formerly, namely, 58%, with the result that a very large absorption is obtained in the first two towers. The results of experiment 7 are very similar to those of experiment 6, and are therefore not plotted in the figure. In each case the results show a minimum in production at tower 4. The presence of the minimum is therefore not due to the fan space.

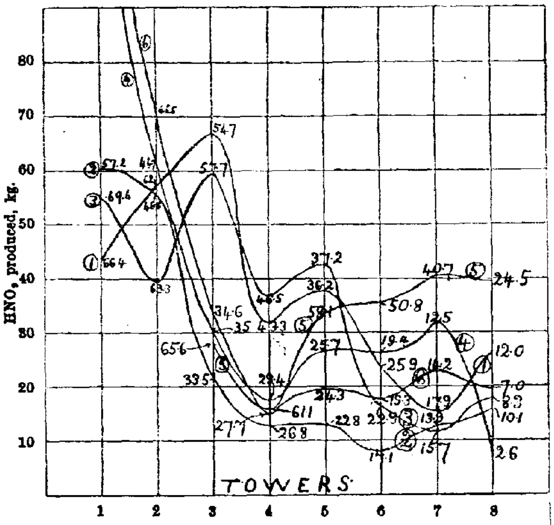

Fig. 2.

Production of nitric acid in each tower.
Time: 3 hours.
No. 5 not corrected for HCl.
The small figures refer to strength of issuing acid.

It is not improbable that small differences in the packing of the towers may affect the output considerably. For instance, if one of the trays in the sections were tilted slightly the stream of water, especially if small, would tend to run down one side of the tower and thus diminish the capacity for absorption. An experiment was made to test this. One section of a tower, filled with pumice, was arranged so that the water could be seen issuing from the bottom. It was found that on introducing even a considerable stream of water at one side the bulk of it flowed out at the bottom near that side and the stream did not spread beyond the middle of the section. This demonstrates also the necessity for efficient distribution of the liquid at the top of the tower over the whole cross-section.

The behaviour of the succeeding towers which show certain regularities in the recurrence of maximum and minimum outputs may possibly be similarly explained. Fluctuations will also be caused by variations in temperature in the towers, resulting in changes in speed of flow of gas and velocity of reaction, and by variation in the chlorine content of the gases.

It is evident that the speed of the inflowing gas causes important differences in the distribution of the output. In curves 4 and 6 in Fig. 2, in which the speed is very low, there is a very large initial output. It may therefore be concluded that a decrease in the velocity of the gas increases the efficiency of the towers, as is also shown by equation (4). The efficiency is, however, governed by other considerations than the velocity of the gas. For a given total quantity of nitrous gas, reduction in the speed of flow of gas involves a reduction in the concentration of the oxygen, so that although the absorption will be large at the beginning owing to large concentration of nitrogen peroxide, if the reduction in speed is carried too far the reaction will be difficult to complete because of the slowness of oxidation of the nitric oxide produced. In many cases, however, this velocity is determined by the source of the gas and cannot be diminished. For instance, a certain minimum velocity is necessary for the removal of fumes from nitric acid stills.

Fig. 3 gives an interesting comparison between the actual experimental efficiency of the towers and the theoretical efficiency, calculated for average conditions of concentration and velocity of gas and flow of liquid, from equations 4 and 10. Curves 1, 2, and 3 show the experimental rates of production reproduced from Fig. 2. Curve 4 represents the theoretical rate of production per tower. It will be seen that the calculated curve follows the same general course as the experimental one as closely as could be expected, although, as the conditions are supposedly ideal, the irregularities are smoothed out. Since the efficiency of the towers under the conditions of the experiments was over 90%, it follows that the formulæ arrived at represent the working of the process over a range of concentration of nitrous gases of approximately 10:1. Curve 5 shows the theoretical results to be obtained if the towers had been packed in the way indicated above as the best.

In obtaining the figures for curve 4 the amounts of oxidation taking place in the unpacked parts of the first tower were calculated. These were found to be negligibly small even near the end of the tower, thus justifying the neglect of oxidation in these spaces when determining the absorption coefficients and the influence of rate of flow of liquid.

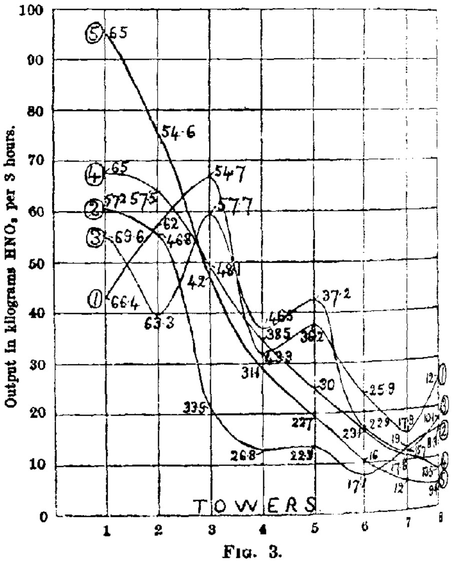

Fig. 3.

Procedure for the design of a set of towers for nitric acid stills.

As already stated, the velocity of flow of gas will probably be fixed within narrow limits by circumances. From this velocity, and the total equiva-nt nitric acid content of the gas, the value of P uring a certain time T may be calculated. The ow of liquid may be arbitrarily fixed, the strength f acid which it is desired to obtain determined pon, an approximate average strength of acid owing through the first absorption space thus ssigned, and the value of K_1 for that strength aken from the curve. A value of σ_y may then be hosen, the choice being guided by the fact that, if he gas is comparatively rich in nitrogen peroxide will probably require a fairly large absorption pace before it is worth while to begin to oxidise. rom equation 4 in which P, K_1, σ_y, V, and f have ow definite values, Y may be calculated. The mount of nitrogen peroxide will then have been iminished to $P-Y$, whereas the amount of nitric xide will have been increased by $Y/3$ to Q. In he case of the first tower for fumes from nitric cid stills $Y/3=Q$. $K_3[O_2]$ may be determined rom the known value of the oxygen concentration $K_3=100{,}000$ and $[O_2]$ must be calculated in kilo-rams of equivalent nitric acid per cub. ft. For 0% oxygen at about 20° C., $K_3[O_2]$ is practically 000). As indicated previously, equation (13) will hen give the value of σ_x which should follow y. If this should prove of suitable dimensions the alue of X may be calculated from equation (10) nd thus the composition of the gas at the end of he oxidation space determined. If σ_x should be egative or too large a new value for σ_y is chosen nd the calculation repeated. An approximate alue for the strength of the acid in the next bsorption space is now chosen and the process ontinued until the absorption has been carried to he desired limit. It will be seen from the fact hat the velocity of oxidation falls off as the square f the concentration of nitric oxide, and the velocity f absorption directly as the concentration of itrogen peroxide, that, other things being equal, he more dilute the gases the bigger the ratio of xidation space to absorption space required. The ollowing illustrates this. A set of towers was alculated for a case in which all the gas was riginally present as nitric oxide, and had a con-entration of 0·72 equivalent kg. of nitric acid per 100 cub. ft. The space required to absorb 82% was 795 cub. ft., divided into 410 of absorption space nd 385 of oxidation space. To absorb 91% an dditional 345 cub. ft. of absorption space and 406 f oxidation space were required.

---

*Not reproduced in Table II.

This example also demonstrates the greatly ncreased difficulty of absorption with dilution. It s practically impossible to reduce the concentration f the gases to much below 0·1 kg. of equivalent itric acid per 100 cub. ft. by water alone under rdinary atmospheric pressure. An alkali tower r increased pressure would be necessary for further absorption.

Equation (4) shows that increasing the flow of liquid increases the absorption. Increased flow without introduction of extra water may be obtained by more rapid circulation in each tower separately. There are obviously limits beyond which it would not be advisable to increase the flow, but the rate of absorption continues to increase with increase in the rate of flow up to at least 2·5 litres per sq. ft. per minute.

Absorption of nitrous fumes from other sources. Introduction of oxygen.

In the case of nitrous gases from denitration plants, the gases escaping from nitrating pots, or the oxides of nitrogen produced in the ammonia or nitrogen oxidation processes, the percentage of oxygen is often very low, the gases at the same time containing a large proportion of nitric oxide, resulting in slow oxidation and hence slow absorption. Absorption plants erected in some factories without due recognition of this fact proved deplorably inefficient. Indiscriminate addition of air, however, may prove equally fatal through too great a dilution of the gases.

Air must in any case decrease the rate of absorption because of increased dilution. If the initial concentration of oxygen is very low addition of air will speed up the oxidation at first in spite of dilution. As, however, the velocity varies as the square of the concentration of nitric oxide and only as the first power of the concentration of oxygen, a point will be reached at which the effect of dilution will overbalance the effect of increased concentration of oxygen, and the rate of oxidation also will be slowed down by further addition of air.

Equation (12) affords a guide as to the most favourable point for the introduction of air and as to the amount required to secure the best conditions. The average value of $dX/d\sigma_x$ through unit space at any point in the towers may be calculated from the equation (12) by putting $\sigma_x=1$. Then the changes in $K_3[O_2]$ and V due to a small addition of air may be determined and $dX/d\sigma_x$ calculated for the new conditions, and so on for increasing additions of air. If the values for $dX/d\sigma_x$ are then plotted on a curve against percentage additions of air it will be possible to see whether addition of air at that particular point causes increase or decrease of rate of oxidation, and if increase, at what percentage addition the maximum rate is reached. It is probably better to choose a value a little before the maximum, after the main bulk of the increase has taken place, because of the diminution in rate of absorption to which reference has already been made. Fig. 4 gives curves showing the variation of $dX/d\sigma_x$ with addition of air for different initial values of Q, V, and $K_3[O_2]$.

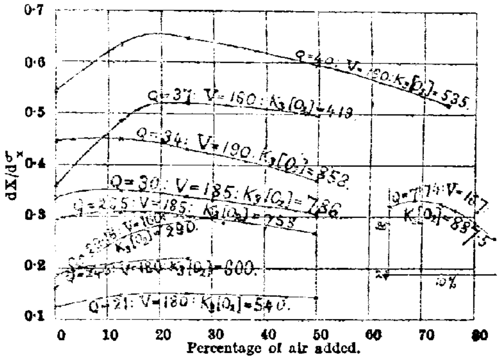

Fig. 4.

Effect of addition of air on rate of oxidation under different initial conditions.

For the absorption of very dilute fumes, such as those produced in the oxidation of nitrogen, it is conceivable that towers under pressure might be used. Suppose the pressure were increased to 10 atmospheres the amount of absorption space required would be of the order of 1/10th of that required under atmospheric pressure, and the oxidation space 1/100th.

In the nitration of phenol to picric acid by the old pot process about 22% of the nitric acid disappears entirely, even when efficient absorption plant for the escaping fumes is available. This points to the formation of unabsorbable nitrogen products, for example, nitrogen itself or nitrous oxide. These have been identified in large quantities in the fumes from the nitration by Dr. F. O. Rice. For the portion which is absorbable it is necessary to have large tower accommodation because of the variable rate of evolution. The latter applies to fumes evolved in all nitrating processes.

Further practical points in the construction and working of nitric acid absorption towers.

It has sometimes been found that the perforations of the plates supporting the packing have been few and small, causing great resistance to the flow of gas and thus necessitating greatly increased power for driving the suction apparatus. The total area of the perforations should at least be equal to the cross-section of the fume mains leading from the source of the gas and connecting the towers with one another, and these should be as large as convenient. For the same reason also, the towers should be wide, but only so wide as still to allow an even distribution of liquid over the whole cross-section.

Large towers may be built of acid-proof bricks and cement instead of earthenware pipes, but, in designing such towers, the number in series should never be less than four, and it is advisable to have six or more if the counter-current principle is to be worked successfully for any but weak acid. In order to obtain acid of the usual strength, that is, 55—60%, it is necessary to have acid of various strengths in the system simultaneously. The rate of circulation of liquid required to keep the packing effectively wet is much greater than the rate of forward travel corresponding to the maximum possible output of the system. This makes it impossible to provide, in one or two towers, the variations in strength necessary to produce the required degree of absorption. Several units, circulating independently acids of different concentrations, are necessary.

Packing should be of such a nature that it is not easily worn into channels which would direct the liquid by one or two streams only, and thus prevent the exposure of a large wet surface. It should give a large superficial area, and at the same time a large volume of free space, so as to offer as little resistance as possible to the passage of gas. Earthenware rings, hollow ball packing, and propellor packing may be recommended.

The concentration of the issuing acid should not be allowed to exceed 60%. Reference to Fig. 1 will show that above this concentration absorption will be too small to make it advisable to attempt it, and practice bears this out.

The percentage of nitrous acid in the issuing acid affords a rough test of the adequacy of the air supply. If it exceeds 0·3% more air should be introduced, either by increasing the suction of the plant or by blowing air into the fume main and carefully regulating until optimum recovery is obtained.

The efficiency of the towers may be judged by the absence of colour in the exit gases, unless the gas current is maintained by means of a steam jet at the end of the towers, when the oxidation of the brown fumes completes itself in the presence of the steam, giving a cloud of colourless nitric acid.

Effect of the presence of chlorine on the absorption of nitrous fumes.

With a view of studying the influence of the presence of chlorine on the production of nitric acid in the towers, investigations were carried out on the chlorine content of the gases entering and issuing from the towers, and of the nitric acid produced. Experiments were also made to determine the resulting products when air, both alone and charged with nitrous fumes, was passed through mixtures of nitric and hydrochloric acids of varying concentration. The results, and the general conclusions to be drawn from them, may be briefly indicated.

All the chlorine (free and combined) produced in the stills, from the chloride present as impurity in the nitrate, is carried to the absorption towers. Most of the chlorine appears to be evolved whilst the still is taking in acid, and probably also just after it has been lit up. Consequently, the gases passing into the absorption towers vary very much in chlorine content, and we may have the paradoxical result, at certain periods, that much more chlorine is present in the exit than in the entrance gases. It was found that for brief periods the chlorine content of the fumes might rise to 30—40% of the total gases capable of reacting with caustic soda, but for average conditions it was not more than about 5%, and might be less.

If the gases leaving the towers are left in contact with water until all the nitrogen compounds have been absorbed, a trace of free chlorine almost always remains, but its amount is usually very small compared with the amount of hydrochloric acid in the resulting liquid.

The acids from all the towers contained a certain amount of chlorine in some form, but it was only in nitric acid of concentration less than about 42% that appreciable quantities were found. Above that concentration not more than about 0·5%, reckoned as hydrochloric acid, was in general present. A typical example of the distribution of chlorine and nitrous acid through the towers is given in Table V.

TABLE V.

Tower No.	% HNO_3.	% HNO_2.	% HCl.
1	68·7	0·31	0·05
2	60·5	0·22	0·08
3	52·5	0·36	0·25
4	42·3	0·45	0·47
5	37·4	0·31	1·75
6	25·5	0·20	6·0
7	16·2	0·15	8·7
8	9·6	0·33	6·6

If chlorine is mixed with the brown fumes produced by the decomposition of a nitrite by an acid the brown colour persists even if the gases are damp, provided that no liquid water is present. On the addition of the latter, however, the brown colour disappears and the oxidation of the oxides of nitrogen to nitric acid appears to take place through the agency of the chlorine rather than of the oxygen of the air, even when the concentration of the latter exceeds that of the former by as much as five times. This conclusion agrees with that reached by Webb (J., 1921, 162 T).

If a small percentage of pure hydrochloric acid is added to pure nitric acid of a concentration even as low as 30%, a yellow colour is produced, presumably owing to the formation of nitrosyl chloride. If air is passed through such a mixture both chlorine and nitrogen compounds are found in the resulting gases, and on treating these with water some free chlorine is left. This was the case even with a mixture of 29·85% nitric acid and 6·8% hydrochloric acid. The total given off is in much greater equivalent quantity than the nitric acid. If air charged with nitrous fumes is now passed through the liquid, much more chlorine is carried over, but none of it is in the free state, and it is usually in much smaller equivalent quantity than the nitric acid.

These results suggest the following conclusions as to the behaviour of chlorine compounds in the towers.

In the still hydrochloric and nitric acids react practically completely to produce nitrosyl chloride and chlorine, so that the gases reaching the towers consist of a mixture of nitrosyl chloride, chlorine, nd nitrogen peroxide. The two latter do not re-ct in the gaseous state, but as soon as absorption egins and nitric oxide is produced the chlorine robably combines with it, producing more nitrosyl hloride instead of nitrogen peroxide (Boubnoff nd Guye, J. Chim. Phys., 1911, **9**, 290). The effect f this in the presence of the stronger acid will be o reduce the effective concentration of nitrogen eroxide and so diminish to some extent the amount f absorption. This will result in a greater fall in he production of nitric acid than theory indicates, nnoticeable in the first tower, but more marked s the concentration of nitric oxide increases. The ffect, of course, will be limited by the proportion f free chlorine in the fumes, and as we have seen hat this is very variable, the production of nitric cid will also vary with it.

When the gases reach the acid containing a con-iderable quantity of hydrochloric acid and still airly rich in nitric acid, say about 40%, a further actor in the diminution of production of nitric acid vill appear. As the acid becomes richer in nitric cid it will tend to decompose the hydrochloric acid, iving nitrosyl chloride and chlorine, which will ass on with the nitrous fumes. The fresh chlorine hus produced will react with more nitric oxide, eaving the gas still poorer in nitrogen peroxide. Soon after this point, however, at 35—30% itric acid, the nitrosyl chloride, if of sufficient apour pressure, will begin to react with water to orm nitrous and hydrochloric acids, the former eing rapidly transformed into nitric acid and itric oxide. If, therefore, the concentration of ydrochloric acid is not already very high, and if he original gases were rich in chlorine, absorption nay now become greater than theoretical, hence the endency to a minimum in the middle of the towers.

On the other hand, if the entering gases contain ittle chlorine, and the weaker absorbing liquids re becoming fairly rich in nitric and hydrochloric cids, more decomposition of hydrochloric acid, and ence of nitric acid, may take place than absorp-ion of nitrosyl chloride, so that more chlorine will scape than enter. It is probably under these cir-umstances that the largest amount of free hlorine will escape from the towers.

It is evident from the whole of the foregoing that he chlorine present is certainly responsible in part or the irregularities in the absorption coefficients. At the same time, owing to the very large varia-ion in the chlorine content of the gases, and the probability that it may both help and hinder the bsorption under different conditions, it seems nlikely that the curve in Fig. 1 gives values very ar from the true ones. This conclusion is sup-ported by the fact that comparison of theoretical with practical efficiency of towers absorbing fumes rom a denitrating plant, containing no chlorine, how the two to be in very satisfactory agreement, oth for low and high efficiencies.

Summary.

Assuming that the production of nitric acid from he fumes escaping from nitric acid stills consists ssentially of two processes—one, absorption of itrogen peroxide by water or weak acid, to form itric acid and nitric oxide, and the other, the xidation of nitric oxide to nitrogen peroxide—the xperimental data derived from an actual set of bsorption towers, together with the oxidation onstant determined by other investigators, have been utilised for the development of mathematical xpressions for the amounts of absorption and oxida-tion taking place under given conditions of velocity and concentration of gas, and of flow and con-centration of absorbing liquid.

From these expressions a third has been obtained by means of which the optimum ratio between bsorption and oxidation spaces might be fixed.

These mathematical expressions are intended as empirical rules, which are borne out by practical results, but are not put forward as evidence for the truth of the hypotheses as to the mechanism of the reactions used in developing them.

The method of employing these expressions for the design of absorption towers for nitrous gases from different sources has been indicated.

The effect upon absorption of the presence of chlorine in the gases from nitric acid stills has also been discussed.

In conclusion the authors wish to thank Mr. A. Moore and other members of the staff at H.M. Factory, Litherland, for their assistance in carrying out the experimental work.

THE VAPOUR PRESSURE OF ACETALDEHYDE.

BY ROBERT GILMOUR, B.SC., PH.D.

The following measurements of the vapour pressure of acetaldehyde at various temperatures were carried out some years ago, in connexion with other experimental work, and as there appears to be no mention of similar measurements in the literature, they are perhaps worth recording.

The acetaldehyde used was a synthetic product from acetylene and was available in quantity. The sample used for the measurements was the mid-fraction obtained from about a litre of acetaldehyde which was already of high purity. This fraction, amounting to about 70% of the whole, distilled within 0·03° C., and practically the whole of it came over at the constant temperature of 20·55° C. at a barometric pressure of 771 mm.

The distillation was carried out with a column about 1 in. diameter and 18 in. high, filled with glass beads and water-jacketed. This enabled the upper part of the column to be kept about 5° C. below the boiling point of the acetaldehyde. The outlet from the column was connected through a condenser cooled by ice water, with a receiver packed in ice, and the thermometer stem over the range used was entirely immersed in the vapour. The thermometer used was a "Jena Normal" which had been compared with a calibrated thermometer. For maintaining a steady pressure the excellent apparatus described by Wade and Merriman (Chem. Soc. Trans., 1911, **99**, 984) was used. The vapour pressure measurements were carried out with the apparatus described above, over the temperature range of 27° C. to 12° C.

Experimental readings. 1st Series.

Pressure in mm. .. 770, 731·1, 721·2, 709·1, 693·7, 672·4, 652·4, 628·8, 607·7, 581·0, 555·4.
Boiling point, °C. .. 20·43, 19·07, 18·70, 18·27, 17·70, 16·91, 16·14, 15·20, 14·32, 13·20, 12·08.

The pressure was then raised to atmospheric (770 mm.) and the boiling point again read. It was found to be the same as at the commencement, viz.:—20·43° C.

Experimental readings. 2nd Series.

Pressure in mm. .. 772, 794·8, 826·0, 858·8, 891·9, 922·2, 961·9, 1011·1.
Boiling point, °C. .. 20·51, 21·27, 22·30, 23·38, 24·40, 25·33, 26·51, 27·89.

For the temperatures below 12° C., Wade and Merriman's apparatus was used (Chem. Soc. Trans., 1912, **101**, 2438). This consists of a round-bottomed flask surrounded with cotton-wool, and provided with a very fine capillary, a connexion to vacuum, and a thermometer with the bulb immersed in the liquid.

Experimental readings. 3rd Series.

Pressure in mm. .. 557·8, 517·3, 504·9, 467·5, 425·2, 381·8, 336·8, 306·5, 275·5, 256·2, 227·7, 187·5, 156·8, 127·7, 100·0.

Boiling point, °C. .. 12·80, 10·60, 9·60, 8·40, 6·20, 3·67, 0·90, −1·23, −3·60, −5·50, −8·40, −12·15, −15·95, −19·65, −24·15.

The experimental values were plotted and the curve smoothed. From the smoothed curve the following values for pressure and boiling point were read, and from these figures dt/dp calculated.

Pressure in mm.	Boiling point, °C.	dt/dp	dp/dt		Pressure in mm.	Boiling point, °C.	dt/dp	dp/dt
1000	27·55	0·0278	35·9	..	550	11·71	0·0445	22·5
950	26·15	0·0290	34·5	..	500	9·41	0·0475	21·0
900	24·67	0·0307	32·6	..	450	6·94	0·0515	19·4
850	23·10	0·0321	31·1	..	400	4·23	0·0571	17·5
800	21·45	0·0339	29·5	..	350	1·10	0·0646	15·5
760	20·10	0·0355	28·2	..	300	− 2·50	0·0743	13·4
750	19·70	0·0357	28·0	..	250	− 6·40	0·0867	11·5
700	17·86	0·0377	26·5	..	200	−11·20	0·1027	9·7
650	15·92	0·0398	25·1	..	150	−17·00	0·1225	8·2
600	13·87	0·0420	23·8	..	100	−24·30	0·1670	6·0

The pressure-dt/dp curve was plotted and from it and the pressure-b.p. curve the following values were read and dp/dt calculated.

Vapour pressures of acetaldehyde.

Boiling points recorded at atmospheric pressure.

1. 20·55° at 771 mm. = 20·16° at 760 mm.
2. 20·43° at 770 mm. = 20·08° at 760 mm.
3. 20·51° at 772 mm. = 20·08° at 760 mm.
4. 20·20° at 762 mm. = 20·13° at 760 mm.

Mean value of b.p. = 20·11° at 760 mm.

Note.—The temperatures recorded are corrected for error of thermometer down to −5° C., but not reduced to hydrogen scale. Temperatures below −5° C. may be somewhat erroneous, due to superheating or error of thermometer, since no elaborate precautions were taken. The pressures are as read, at a temperature of 16° C. throughout.

Density of acetaldehyde.

The densities were taken in a carefully calibrated U-shaped pyknometer of capacity about 36 c.c. with capillary bore tubes surmounted by reservoirs which were closed by rubber stoppers instead of ground-in glass stoppers. As a confirmatory test, a determination was made in a pyknometer with calibrated capillary tube, with a small bulb at the top which was sealed before removing from the ice bath; the true volume of the acetaldehyde being read off on the scale.

The usual corrections for buoyancy were made when calculating the results. Densities at 0°/0° C. (1) 0·8056, (2) 0·8060, (3) 0·8058 (sealed pyknometer); mean value at 0°/0° C.=0·8058. The density was also taken at 16° C.

D at 16°/4° C.=0·7839; at 16°/16° C.=0·7847. On account of the extreme volatility of acetaldehyde great difficulty was experienced in obtaining concordant results for the densities. In addition the ease with which the substance oxidises makes it difficult to be sure of the purity.

Latent heat of vaporisation of acetaldehyde.

The latent heat of vaporisation was calculated according to the method of Lewis and Weber (J. Ind. Eng. Chem., 1922, 14, 486), using the curve obtained by plotting boiling points of aldehyde against the temperatures at which water has the same vapour pressure. This curve was practically a straight line over the range +27° to −24° C.

The value obtained was:—L=132 calories per gram at 20° C., from which Trouton's constant ML/T=19·8.

Robinson in "The Elements of Fractional Distillation," gives L=134·6 calories per gram at the boiling point, which agrees fairly well with the calculated value L=132.

In conclusion, I desire to express my thanks to Messrs. W. Dunville and Co., Ltd., in whose laboratory the work was carried out, for permission to publish these figures.

Annual Meeting.

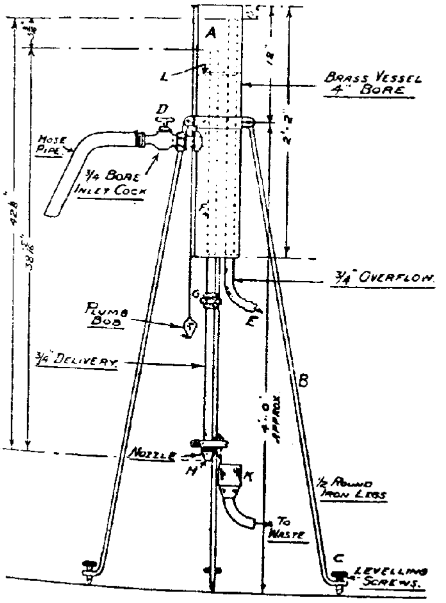
RAPID AND ACCURATE METHOD FOR THE CALIBRATION OF STORAGE TANKS.

BY J. W. M'DAVID, D.SC., F.I.C.

(Abridged.)

The volumes of storage vessels are usually deter-iined either by measuring the vessel and calcu-iting its volume mathematically, or by filling the essel with water and weighing the water as it is un out of the tank. The first method is accurate nly for rectangular tanks or cylindrical tanks tanding on end, while the second method, though ccurate, is somewhat laborious. Another method hich has been employed consists in filling a tank ith water, adding a known weight of a soluble alt, and then analysing a sample of the solution. his is an ingenious method for determining the otal volume of a vessel, provided there is adequate ieans of stirring the solution, but it becomes iborious if the volume per inch of depth is equired.

A fourth method which can be employed for the etermination of the volumes of tanks depends on he principle that water, flowing through a tube or rifice under a constant head, gives a constant rate f flow. This method, however, does not seem to ave been much used in practice, probably owing to he fact that the degree of accuracy of such a iethod was not known, and also, possibly, because he amount of time taken to fit up the apparatus equired, and to determine the rate of flow under given head, makes the method as laborious as the hers. It was thought, however, that it should be ossible to design, on this principle, a conveniently ortable and accurate apparatus which, after being librated once and for all, would be available for e rapid calibration of storage tanks of all shapes d sizes.



Such an apparatus was accordingly constructed, d, after a few minor alterations, was calibrated. A description of the instrument, and an account of the experiments carried out in order to determine the rate of flow of the water, are given below.

The apparatus, which was designed by Messrs. J. M. Weir, N. Taylor, and the author, is shown in the accompanying figure. A is a brass cylindrical vessel 4 inches in diameter, and about 2 ft. 1½ in. in length. The vessel is open at the top, and is held in a vertical position by means of three legs, B, each of which carries a levelling screw, C. A plumb-line is provided to ensure that the apparatus is set vertically. Water is supplied to the apparatus through the ¾-in. inlet cock, D, to which a hose-pipe can be attached. E is a brass overflow pipe ¾ in. in diameter, while F, a pipe of similar size, delivers water to the tank to be calibrated. In the first instrument this pipe was, for convenience, made in two parts connected together by means of a screw coupling, G, but in later instruments this coupling was omitted. The bottom of the delivery pipe is fitted with a screw thread, so as to take a nozzle, H. Five nozzles of diameters ¼, ⅜, ½, ⅝, and ¾ in. respectively were provided, so that the quantity of water delivered to the tank could be varied.

The funnel, K, works on a swivel, so that it can be placed underneath the nozzle in an instant, and so divert the water from the tank which is being calibrated. L is a plate perforated with holes ⅛ in. in diameter, and serves the double purpose of forming a support for the pipes, E and F, and at the same time reducing turbulence at the surface of the water. The complete apparatus only weighs 26 lb., and can therefore be easily carried about from place to place by one person.

The method of using the apparatus is as follows:—The instrument is set up in a vertical position over any convenient inlet hole in the cover of the vessel to be calibrated. The funnel, K, is placed under the nozzle, and sufficient water led into the apparatus through the cock, D, until there is just a slight trickle of water escaping through the overflow pipe, E. In the experiments carried out to calibrate the apparatus the quantity of water escaping through the overflow pipe was determined, and averaged 0·7 lb. to 1·5 lb. per minute. As soon as water is leaving the overflow pipe at the rate mentioned above, the head of water in the apparatus has reached a constant figure, and, so long as this level is maintained, the quantity of water delivered through the nozzle will be constant. When this condition has been obtained the funnel, K, is smartly drawn from below the nozzle, and the water is allowed to flow into the tank. At the same time a reliable stop-watch is started. If it is required to find merely the total volume of the tank, the time taken to fill it with water is noted, but if it is required to determine the volume per inch of depth, then the funnel, K, is placed beneath the nozzle after a definite interval of time, and the depth of water in the tank measured. By choosing suitable intervals of time the volume per inch of depth can be calculated.

The calibration of the instrument fitted with each of the five nozzles in turn was carried out in the following manner:—A large rectangular box was placed on a platform weighing machine and tared. The calibrator was set up so as to deliver water into the box while a short length of hose pipe was fitted to the overflow pipe, E, to carry the water passing from the overflow into a tared bucket. As soon as the box on the weighing machine had been tared, the funnel, K, was fixed beneath the nozzle in such a way that it prevented water from entering the box. The water was then turned on and regulated until the quantity passing out of the overflow was about 1 lb. per minute. The funnel was then drawn smartly away, the time being taken by means of a stop-watch, while at the same time the water running from the overflow was led into the bucket mentioned above. At the end of a definite time the funnel was replaced in position, and the bucket drawn from underneath the overflow pipe. The water both in the box and in the bucket was then separately weighed. The reason for weighing the latter was to ensure that a constant rate of overflow had been maintained. During the course of each test the temperature of the water was noted; in the case of cold water this did not vary by more than 0·2° C. in any one test, while in the case of the warmer water the maximum variation was not more than 1° C. The stop-watch employed was found to agree with several other watches to within 1 in 4000. The weighing machine was overhauled and tested before being used, and was found to be sensitive to the degree of 0·5 lb. in 700 lb. At least three tests were carried out at each temperature, and with each nozzle.

The results of the calibration experiments showed that the apparatus is capable of giving very accurate results. With the exception of those obtained with the ¼-in. nozzle, all the results in any one series agreed to within 0·3%. In the case of the ¼-in. nozzle the difference between the highest and lowest result in any one series was about 0·5%, and even this is satisfactory, since the measurement of the contents of a tank by dipping is not usually correct to ¼ in. in 50 ins. As the temperature of the water affects the quantity delivered, it is more convenient for purposes of calculation, in using the apparatus with water at any temperature between 5° and 20° C., to determine the quantity delivered in cubic feet instead of in lb. This has therefore been done, and the results are given in the subjoined table:—

Temperature of water, °C.	Volume of water delivered in cubic feet per minute.				
	¼" nozzle.	⅜" nozzle.	½" nozzle.	⅝" nozzle.	¾" nozzle.
4	.. 0·2720	.. 0·674	1·012	1·404	1·642
8	.. 0·2725	.. 0·675	1·015	1·412	1·651
12	.. 0·2731	.. 0·677	1·018	1·421	1·660
16	.. 0·2736	.. 0·678	1·021	1·430	1·668
20	.. 0·2743	.. 0·679	1·024	1·439	1·678

Stress has already been laid on the fact that, in order to obtain the best results, it is necessary that water should escape through the overflow pipe, E, at approximately constant rate, which during the calibration of the instrument was 0·7 to 1·5 lb. per minute. Any increase in the rate of overflow is accompanied by a slight increase of head; for example, when the overflow is 1 lb. per minute, the head is 3·19 ins. above the top of the delivery pipe, while when the overflow is 4 lb. per minute the head is 3·32 ins. above the same level. Thus, by increasing the overflow from 1 lb. to 4 lb. per minute the head is increased by ⅛ in. A few tests carried out showed that an increase of head of 0·1 in. increased the outflow by about 0·1%, so that the error caused by increasing the overflow from 1 to 4 lb. per minute is not very great. It is preferable to eliminate the source of error altogether.

When the rate of flow had been determined for each of the nozzles, the apparatus was used for the calibration of several tanks, in order to see whether concordant results could be obtained.

In the first test a plant-measuring vessel, designed to deliver a definite volume of acid to a cylindrical tank, was calibrated by running water into it from the calibrator until water just appeared in the sight-glass of the overflow pipe. In two consecutive tests, using the ¼-in. nozzle, the times taken to fill the measuring vessel were 50 min. 47·5 secs. and 50 min. 49 secs.—a difference of 0·05%.

The second test consisted in the calibration by two independent observers of a stoneware tank of about 200 gallons capacity, using the ⅜-inch nozzle. The difference between the two determinations for the same volume was 0·1 in 39 ins., or about 0·25%.

The third test carried out was the calibration of an egg-ended boiler, which had previously been twice calibrated by filling it with water and weighing the water which it delivered for each inch of depth. The water from the calibrator was delivered to the boiler during definite intervals of time. At the end of each interval the depth of water in the boiler was determined by means of the same measuring rod that had been used in calibrating the tank previously. In order to obtain the volume per inch, the volumes of water run during the various intervals of time were plotted graphically, on a very large scale, against the depths of water registered in the boiler. On connecting these points to furnish a smooth curve, it was found that whereas a few points lay outside the graph, out of these none was further from it than a distance representing 0·1 in. in the dip, whilst the very great majority were within half this distance. The volume per inch was then read off the graph, and these results compared with the figures obtained by actually weighing the water delivered from the boiler.

There was a considerable difference in the volumes of the boiler up to a depth of 10 ins. as found by direct weighing of the water and by the calibrator, probably due to the fact that an error of 0·1 in. in measuring the depth makes, during this part of the calibration, a considerable percentage error in the volume. At any rate, it does not appear to be due to errors either in the weighing of the water or in the calibrator, since at greater depths when an error of 0·1 in. in the depth has a comparatively small effect the agreement between the two sets of results is highly satisfactory.

The results showed that the apparatus is capable of giving results quite as accurate as, if not more accurate than, those that can be obtained by the direct weighing method.

From the results of the three tests described above, the calibrator appears to be capable of giving results correct to within 0·2%, provided that the depth measurements are read to that degree of accuracy. By using the largest nozzle a boiler of 600 cub. ft. capacity can be calibrated in a little over six hours, while the apparatus is also suitable for the accurate calibration of small vessels such as guncotton nitrating pans, one of which, by using the ½-in. nozzle, can be calibrated in less than ten minutes. Several of these instruments have been in use more or less continuously for the last two years, and have proved thoroughly satisfactory.

The author wishes to express his thanks to the management of Messrs. Nobel Industries, Limited, Ardeer Factory, Stevenston, Ayrshire, for granting permission to publish the information contained in this paper.

TAR DISTILLING.

BY W. A. WALMSLEY.

(Abridged.)

Up to about ten years ago town's gas was made almost exclusively in horizontal retorts at high temperature, and the resulting tar was thick and heavy. Horizontal-retort tar has been fairly thoroughly investigated by a number of workers, and its constituents proved to be of an aromatic character. On distillation, it yields approximately 60—70% of pitch of good merchantable quality, and 30—40% of oils containing aromatic hydrocarbons of the benzene, naphthalene, and anthracene series, phenols and phenol homologues, pyridines, etc.

With the introduction of the vertical retort, a radical change occurred in the tar. The specific gravity was lower, and the tar of a more oily nature. Glasgow vertical tar yields on distillation 40—44% of pitch and 56—60% of oils.

The tar vapours in horizontal retorts have to pass through the hot outer crust of the charge, and also to some extent along the hot walls of the etort. Breakdown occurs, and the resulting tar s benzenoid in character. In vertical retorts the earlier portions of tar vapours are provided with a cool means of escape from the retort through zones at a lower temperature than that at which they are formed. It is even possible that they have some solvent action on the coal in these lower temperature zones, and pick up, in passing, some of the primary constituents of the coal stuff itself. The tar resulting from such conditions is paraffinoid n nature, and is known as low-temperature tar. The later portions of tar vapours, however, are subjected to some extent to the conditions that appertain in horizontal retorts and give benzenoid tar.

Vertical-retort tar may therefore be looked upon as a mixture of high- and low-temperature tars. No thorough investigation has been made of vertical-retort tar. It contains less benzol than horizontal tar, practically no naphthalene, a large percentage of compounds extractable with caustic soda, containing very little real phenol. These compounds would appear to approximate to the phenolic substances extractable from wood tar creosote, which contains guaiacol and coerulignol.

Some recent experiments carried out by us appear to indicate the presence of even trihydric phenols in the higher boiling portions. They show great affinity for oxygen, absorbing it very readily in the same way as pyrogallol.

The following figures serve to show the difference in distillation range between the tar acids obtained from vertical and horizontal retort tars. The whole of the oils up to pitch were extracted with caustic soda, and the resulting tar acids dried and then distilled.

Horizontal-retort tar.

The crude dry tar acids obtained were equivalent to 9% by weight of crude tar, and had the following distillation range, using a Wurtz flask :—

Drop	186° C.
45·2% at	200° C.
69% ,,	210° C.
72·5% ,,	220° C.
81% ,,	230° C.
84·5% ,,	240° C.
88% ,,	250° C.

Vertical-retort tar.

The crude dry tar acids obtained were equivalent to 13·2% by weight of crude tar, and had the following distillation range, using a Wurtz flask :—

Drop	185° C
10% at	200° C
28% ,,	210° C
45% ,,	220° C
56% ,,	230° C
63% ,,	240° C
78% ,,	280° C
84% ,,	300° C
92% ,,	310° C.

Distilled above 260° C. ruby red in colour. Gave highly viscous fluid when cooled.

It was thought that tar acids obtained from vertical-retort tar might approximate to some considerable extent to the high-coefficient acids obtainable from blast-furnace creosote, and the comparison between the distillation ranges and physical properties was made, with the results given at the foot of this page.

The following, taken from monthly distillation and yield statements from two separate works, one distilling horizontal-retort tar, and the other distilling vertical-retort tar, illustrates the difference in specific gravity, percentage of volatile products, and percentage of pitch obtained during the primary or crude distillation of the tar.

	Vertical tar. Sp. gr. 1·091.		Horizontal tar. Sp. gr. 1·175.	
	Sp. gr.	% Yield.	Sp. gr.	% Yield.
Ammonia water	1·025	4·0	1·003	3·0
Crude naphtha	0·946	2·59	0·925	1·34
Light oil	—	—	1·007	6·02
Middle oil	0·996	30·91	1·025	6·18
Creosote	1·053	20·09	1·045	16·32
Pitch	—	41·47	—	66·56
	Total	99·06	Total	99·42

	Vertical tar.	Horizontal tar.
Viscosity (Redwood) at 100° F.	345 secs.	610 secs.
Free carbon	1·19%	11·5%
Calorific value	16,120 B.Th.U.	16,150 B.Th.U.
Pitch volatile matter	69·9%	53%
Fixed carbon	30%	47%
Free carbon	5%	25%
Ash	0·1%	0·1%

All crude tar contains a certain percentage of entangled ammonia water. The removal of this ammonia water, which comes over along with the crude naphtha fraction, is the most troublesome part of the distillation. The still must be fired very cautiously, until all ammonia water has been driven off, otherwise frothing takes place, and a considerable quantity of tar passes over to the condensers and receivers.

In a typical distillation carried out at the Provan works the total time of distillation was 28 hours, and the total distillate approximately 36—40%. The distillation of the crude naphtha and water, amounting to only 3%, took 22 hours, the remaining 33—37% coming over in 6 hours.

Even at 300° C. the distillate still contained 9% of oils boiling at 210° C.—probably the result of breakdown of more complex organic compounds, which occurs in all distillations.

Fuel used per ton of tar distilled at two of our works, using this type of still:—

Works 1.	For distillation only.	For steam throughout works and in steaming of tar stills.
	1·75 cwt.	1·18 cwt.
Fuel used	Dross and coke breeze.	Coke breeze.
Works 2.	1·625 cwt.	0·57 cwt.
Fuel used	Coke.	Coke breeze.

An experiment on the continuous distillation of vertical-retort tar was carried out in two Wilton dehydration coils, with a final steaming still. The tar in the first coil was maintained at 170° C. and at a pressure of about 30 lb. per sq. in. On releasing to atmospheric pressure, naphtha and water passed off as vapours to the condenser, and the residual tar was then pumped through the second

Note.—L after the specific gravity indicates that the fraction gives Liebermann reaction for phenols. N indicates that it does not.

coil, where the temperature and pressure were maintained at 360° C. and 24 lb. per sq. in., respectively. On reducing to atmospheric pressure, mixed carbolic and heavy oils passed away as vapours to the condenser, and the residual tar was steamed with superheated steam in the final superheating still. The experiments showed that tar could be distilled continuously with production of a good medium soft pitch of 120° F. twist-point, even without the final steaming-still.

In the ordinary method of distillation, the tar yielded approximately 57% of oils and 43% of pitch. Under the conditions of the experiment, the yields were 73% of oils and 27% of pitch.

Since the experiment, the top portion of the second coil has been dismantled, and six laps show a deposit of carbon. The first lap shows from ⅜ in. to ½ in. deposit. The next three show a ¼-in. deposit, and the next two ⅛ in. deposit of carbon.

The oil produced from the second coil during the experiment has been examined, and a comparison is given below between this oil and the oil obtained by distillation in the pot still.

	Oil obtained during experiment.	Mixed carbolic and heavy creosote oils obtained during ordinary distillation in pot stills.
Sp. gr. 15·5° C. ..	1·03	1·014
Fraction to 300° C. ..	0·991	0·987
Fraction to 300° C. washed free from tar acids and pyridine..	0·9568	0·9547
Paraffins (fraction to 300° C.)	15%	12%
Loss on washing with sulphuric acid (fraction to 300° C. washed free from tar acids and pyridine)	16%	12%
Tar acids	34%	34%
Sp. gr. crude dry tar acids	1·087	1·083
Character of tar acids	Apparently identical.	
Calorific value ..	17,100 B.Th.U.	17,400 B.Th.U.
Residue at 300° C. ..	Stiff, sticky, homogeneous mass. No evidence of low-boiling substances.	Mobile, oily mass containing crystals.

From these figures it would appear that there is very little difference between the fraction of either oil boiling up to 300° C.

On carrying the distillation of both oils to 360° C., the oil obtained in the experiment leaves a residue of soft pitch amounting to 24%, against 9% from the ordinary oil. Examined microscopically, the pitch produced during the experiment appeared to contain no more free carbon than that produced in the ordinary method of distillation by the pot still.

(NOTE: The full paper, which will appear in the Proceedings of the Chemical Engineering Group, also contains an illustrated account of the tar distilling and auxiliary plant at the Provan Chemical Works.)

MR. F. J. HAMBLY IN THE CHAIR.

THE OPERATION OF KOPPERS BY-PRODUCT COKE OVEN PLANT.

BY C. E. WALLIN.

In this paper the author will give a short description of the Koppers coke plant of the Dominion Iron and Steel Co., Ltd, at Sydney, Nova Scotia, and also touch briefly on some points in connexion with the by-product operation and give a comparison between results obtained from this plant and from the old oven plant of another design which was in operation from 1902 to 1921.

The importance and necessity at the present time of taking advantage of every possible mechanical improvement in quenching and handling coke, combined with short coking time and maximum recovery of by-products, led to the decision to modernise the coke plant; a contract for two batteries of 60 ovens each was placed early in 1917 and the whole plant was in operation in March, 1919, despite difficulties in the way of getting prompt delivery of material. A further battery of the triangular flue type has been constructed but is not yet in operation.

The coal carbonised is entirely from the Dominion Coal Co.'s mines at Glace Bay; the following is an average analysis:—Volatile matter, 33·50; fixed carbon, 57·50; ash, 9·00; sulphur, 2·50%. In order to eliminate a portion of the ash and sulphur the coal is crushed to ¾" and then washed in a British Baum Washer of 150 gross tons per hour capacity, the coal being delivered to the oven bin by a 36" belt conveyor without any further drainage than is obtained in the regular operation of the washer. In this condition the average moisture content is 11% and the average analysis calculated to a dry basis:—Volatile matter, 35·00; fixed carbon, 60·50; ash, 4·50; sulphur, 1·75%.

The ovens are of the standard Koppers regenerative type and of the following dimensions:—Length, 37′ 6″; width, pusher side, 15¾″; width, coke side, 18¼″; height from floor tile to top of coal, 8′ 7″. They have a capacity of approximately 11·3 net tons of dry coal; this capacity will vary somewhat with the percentage of moisture in the coal and also with the degree of fineness to which the coal is crushed.

Each oven has its own independent regenerator and is a separate unit. The gas for heating is supplied by means of a hollow gun brick running the entire length of the flues, and fitted with graduated clay nozzle bricks, each nozzle brick supplying gas to individual vertical flues, of which there are 16 on the pusher side and 14 on the coke side of the division wall. The nozzle bricks of the largest area are placed on the two outside flues to compensate for the heat lost through radiation at the doors and outside walls; the nozzle next to these is the smallest, and then the size increases again towards the centre of the oven to allow for loss in gas pressure and also loss in B.Th.U. per cub. ft. of gas burned owing to the increase in temperature of the gas.

The necessary air for combustion is drawn through the regenerators by stack draught, and is heated to about 1800° F., and from the regenerators passes into the vertical flues alongside the gas nozzles. The air supply to each regenerator is regulated by dampers, the damper for the oven farthest away from the stack having the widest opening, thus equalising draught conditions on each oven. Further adjustment for each vertical flue can be made by altering the size of the opening where the vertical flue joins the horizontal flue, by means of a sliding brick. The individual flues can be inspected by removal of a cast iron cap, and in this way it is possible to examine the state of the gas nozzles, change them if necessary, and generally keep a close check on the conditions under which combustion is taking place. This careful attention to the methods for regulating gas and air results in the even heating of the oven walls with the minimum amount of fuel gas.

The gas burns on individual sides of the division wall for periods of half an hour at a time, and the reversal of gas cocks and air and stack dampers is effected by a master control operated by a self-winding clock. This control sets in operation the lectric motors which close the gas cocks, reverse tack, and air dampers and open the gas cocks on he opposite side of the ovens.

The coal is charged into the ovens from a larry quipped with four hoppers, the coal from the oven in being weighed into each hopper, so as to obtain is even a charge as possible in the oven, and evelled by means of a levelling bar. The charging overs are then placed in position, luted on, and he ascension pipe connected to the collecting main y opening a butterfly valve.

A charge of 11·3 tons of coal can be carbonised n 18 hours with a flue temperature of 2500° F. The ovens are designed for a coking period of 16 hours, but with coal containing 11% of moisture t is not deemed advisable to raise the flue emperature sufficiently to accomplish this.

At the end of the coking period the oven is disconnected from the main, the doors removed, and he coke pushed out into a car of steel and cast iron onstruction, which is then taken by an electric ocomotive to the quenching station, where it is prayed with water for 30 to 35 seconds, and the oke, after draining for 5 minutes, is discharged n the coke wharf. From the wharf the coke is fed n to a belt conveyor, which delivers it on to a -inch grizzly screen, the furnace coke and breeze eing delivered direct into cars.

The gas generated during the coking period is arried by means of ascension pipes to the collecting main and thence by cross-over and suction mains o the header outside the primary coolers. The ross-over mains are fitted with a gas-governing levice, the function of which is to maintain a constant pressure on the ovens. It is operated by a loat which is controlled by the pressure in the ollecting main; this float actuates a lever making lectrical contact in the power circuit of a reversing notor, and this in turn opens or closes a butterfly valve on the main until the lever returns to a neutral position and cuts out the motor.

In order to keep all mains clear of pitch a flush of hot tar and gas liquor is circulated by a centrifugal pump and the solid matter filtered off by suitable screens and removed.

The gas passes through the primary tubular coolers in counter current to the cooling water, the exit temperature of the gas being determined by a Tagliabue temperature control operating a motor valve on the water inlet line. Here the greater part of the tar and ammonia liquor is condensed and flows to the hot drain tank to be used as a flush n the manner mentioned above.

The gas is drawn from the ovens by means of xhausters having a capacity of 700,000 cub. ft. per hour and driven by a steam engine fitted with piston valves. The cut-off of these valves is regulated by a Root's gas governor which maintains a onstant vacuum on the suction main and eliminates irregularities due to varying quantities of gas generated and also, to a less extent, to variation in team pressure. After leaving the coolers, the gas s led through a tar extractor which removes the ast traces of tar and then into a reheater, where ts temperature is raised to 60° C. by means of xhaust steam from the engines. The heated gas is hen passed into the saturator, which is a cylindrical cast-iron vessel lined with lead. Its passage is lown a vertical lead pipe inside the saturator, into horizontal cracker pipe also of lead. This cracker pipe is of inverted U-section, and is slotted with elliptical holes through which the gas bubbles into saturated solution of ammonium sulphate containing 7% of free sulphuric acid. The deposited ammonium sulphate is continually ejected by an air iphon on to the drain table, the mother liquor lowing back into the saturator. The addition of acid is controlled by the operator, who tests the acid content of the bath at intervals of half an hour.

The sulphate from the drain table is flushed into a centrifugal dryer, where it is washed with hot water and whizzed for 15 minutes and then discharged. It contains on an average 2% of moisture and 0·25% of free acid.

Dealing with the type of coal used on this plant, about 50% of the ammonia is separated as gas liquor at the primary coolers. The gas liquor, after separation from the tar, is fed into a 6-ft. still having free and fixed ammonia stills on separate foundations, the lime necessary to decompose the fixed ammonium salts being introduced into the bottom section of the free ammonia still; the steam for operation is obtained from the exhaust steam from the engines at 15 lb. pressure. The liquor feed is measured by a Venturi meter, and these stills have successfully treated 3000 gallons per hour with a loss of 0·02 g. per litre in the waste liquor. The ammonia liberated by the combined action of steam and lime is conducted by a covered pipe to the main gas line between the reheater and saturator. The saturator is at times liable to blockage from formation of "rock salt," but by increasing the acid content of the bath and raising the top temperature of the still to 103° C., that is to say, introducing an excess of steam, at the end of each shift, this difficulty is entirely overcome. The gas liquor contains 8·2 g. of total ammonia per litre, of which 65% is fixed, and of this nearly all is present as chloride. Although the coal used is obtained largely from submarine areas, it contains very little sodium chloride, leading to the assumption that the chlorine which is present as ammonium chloride in the liquor is organically combined in the coal.

After leaving the saturator the gas passes through an acid separator to remove traces of acid mother liquor and thence to the final cooler, a steel tower 60 feet high and 12 feet in diameter, containing wooden grids. The gas is here in direct contact with a descending spray of water, the consequent cooling being accompanied by partial deposition of naphthalene. No difficulty is experienced in cooling the gas if necessary to within 3° of the water temperature. After being cooled the gas passes through two towers 100 feet high and 15 feet in diameter, arranged in series, and is here washed with a petroleum oil of high boiling point which absorbs the benzol vapours from the gas. Under suitable conditions of gas and oil temperatures and oil flow, at least 92% of the total benzol is absorbed.

After leaving the benzol scrubbers the gas is passed into the holder, from which is supplied all the gas necessary for the coking operation, while the surplus is raised to a suitable pressure and used under boilers or in reheating furnaces. Of the total gas generated during carbonisation approximately 40% is used for heating the ovens, while 60% or about 6300 cub. ft. per ton of coal carbonised is available for other purposes.

This plant has had an experience which is probably unique, at any rate on this continent. It is constructed of silica brick, and although it has operated for three years and a half with coal containing 11% moisture, a factor which but a short time ago would have dismayed even the most courageous operator, as far as can be judged it has suffered no undue deterioration. In addition it has made coke in periods ranging from 17½ to 48 hours, with frequent changes in schedule owing to the changing business conditions in the past two years.

When washed coal is coked in silica ovens no undue harm appears to be done to the brickwork if the coal is in a sufficiently fine state to prevent the drainage of the water; this state of division will depend on the nature of the coal and the percentage of water present.

Changes in schedule, especially if frequent, are more difficult to combat, as alterations in flue temperatures will cause more or less serious leaks in a brick structure, and it is only by the closest co-operation between the battery and heater foremen and the oven patcher that these can be kept under control.

For successful operation of a coke plant both from the point of view of coke and by-product production it is necessary to keep a continual check on every part of the operation, and in order to accomplish this the plant is fitted with recording instruments giving a 24-hour record of all necessary particulars, such as pressure on ovens, gas temperatures at various parts of the plant, amount of gas consumed on ovens, and amount of surplus gas made. In addition daily analyses of coal and coke, gas, ammonia liquor, and loss of ammonia at stills and saturators are made by the laboratory department, and the coke is tested at the ovens daily by the shatter and hardness tests. It is only in this way that the operation can be maintained regular and errors in operation can be detected and rectified.

It is important that the oven should be filled to the proper level and that it should be as tight as possible, and in addition that the gas pressure in the oven should be kept as little above atmospheric pressure as is practicable. No ovens can be absolutely tight, and it can easily be understood that excessive pressure will cause loss of gas and other by-products into the flues, and thence into the atmosphere, or a suction will draw in waste products of combustion containing excess oxygen and burn up part of the gas in the oven. A pressure of 2½ mm. of water carried on the collecting main is usually sufficient to ensure correct conditions in the oven.

The most important factor in the nature of the coke and the yield of by-products is the temperature of carbonisation; this is determined by the speed of carbonisation and also the temperature carried at the top of the oven. This latter factor determines the yield and nature of the by-products, as if the temperature at the oven tops is excessive, the gas in contact with the coke and hot brickwork undergoes complicated chemical changes.

Generally speaking, with increase of temperature the coke is smaller and harder, more gas is generated per ton of coal, and more benzol and naphthalene are produced, while the tar and ammonia yields drop. The light oil made at high temperatures contains a smaller percentage of saturated and unsaturated paraffin hydrocarbons, the reason being that these are decomposed into benzene and its homologues, and this is evident in an increased yield of benzene and freedom from admixture of paraffins.

The yields of benzol and ammonium sulphate vary in opposite directions, higher temperatures being favourable to the former and reducing the latter.

A comparison of the ovens working with coking periods of 18 and 24—26 hours respectively, and also of the yields from the original ovens and the Koppers ovens will illustrate this:—

	Coking period 18 hours.	24-26 hours.
Flue temperature ..	2500° F.	2200° F.
Coke—		
Shatter test	52%	58%
Hardness test ..	83%	81%
Ammonium sulphate ..	28·3	30·3 lb. per ton of coal.
Tar	10·5	12·0 galls. per ton of coal.
Total gas	11,200	10,300 cub. ft. per ton of coal.
Benzol (pure)	1·8	1·6 galls. per ton of coal.

The presence of paraffin compounds in the benzol, although not detectable by a distillation test, is revealed by the difference in specific gravity. No figures for benzol, toluol, or solvent naphtha can be given, as these are recovered and purified together for use as motor fuel. But whereas a motor fuel made with a high oven temperature will have a specific gravity of 0·870, a product showing a similar distillation test, but the result of lower temperature carbonisation, will show a gravity of only 0·860, an unmistakable evidence of the presence of paraffin hydrocarbons.

A further interesting point may be noted in the quality of the tar produced. With a coking time of 19 hours the specific gravity is 1·158 and a plain distillation test gives:—3% at 190° C., 5% at 200° C., 22% at 250° C., and 35% at 300° C., while corresponding figures for tar made with a 25-hour coking period are:—Sp. gr. 1·132, 4% at 190° C., 8% at 200° C., 28% at 250° C., 42% at 300° C.

Comparison between the by-product yields from the operation of the old plant and the Koppers plant brings still further into prominence the differences due to temperature control and gas regulation.

In the case of the original plant the temperature control was of very indifferent nature, judged by modern standards. The fuel gas was introduced through one straight pipe at the side of the combustion flue and burnt as best it could, the result being that the charge was unevenly coked and the top of the oven generally as hot as the walls. There was no automatic control of gas pressure, and it was no uncommon occurrence to have excessive suction or pressure on the ovens. The yield of by-products was very much less than with the Koppers plant. The surplus gas would only average approximately 3000 cub. ft. per ton of coal against 6300 cub. ft. with the Koppers plant, and was of a very inferior quality, containing 25—30% of nitrogen. The tar yield was 7 gallons and the yield of ammonium sulphate 20 lb. per ton of coal as against an average of 11 gallons and, say 28·5 lb. respectively with the Koppers plant.

Again, the influence of indifferent gas pressure control and high heats at the top of the ovens show its effect in the widely different nature of the tar as the following table shows:—

	Original oven plant.	Koppers oven plant.
Sp. gr.	1·17	1·15
Naphthalene	80	20·7 lb. per ton of tar.
Pitch	13·2	13·2 cwt. per ton of tar.
containing	26%	18% of free carbon.
Creosote oil	14%	30%
containing	18%	29% of tar acids.
60's carbolic acid	2	1 gall. per ton of tar.

Montreal Section.

Meeting held on March 17, 1922.

A STUDY OF CONDITIONS CAUSING DISINTEGRATION OF CEMENT UNDER THE "ACCELERATED" TEST.

BY A. G. FLEMING.

(*Abstract.*)

The "boil" or "accelerated" steam test for cement, in use for many years, was first introduced by Michaelis in 1870. As first used, small balls of neat cement, of about 5 cm. diameter, were kept in moist air for 24 hours and then placed in cold water which was boiled for 6 hours. Despite various modifications, the essential details of the process have not greatly altered, as a study of the present-day American and Canadian specification shows. According to this specification the test should be carried out as follows:—

"A steam apparatus which can be maintained at a temperature between 98° and 100° C. is recommended. A pat from cement paste of normal consistency, about 3" diameter, ½" thick at the centre and tapering to a thin edge, shall be made on a clean glass plate about 4 inches square, and stored in moist air for 24 hours. In moulding the pat, the cement paste shall first be flattened on the glass and the pat made by drawing the trowel from the outer edge towards the centre. The pat shall then be placed in an atmosphere of steam at a temperature between 98° and 100° C., upon a suitable support, 1 inch above the boiling water, for 5 hours. Should the pat leave the plate, distortion may be best detected with a straight edge applied to the surface which was in contact with the plate."

The American specification further advises that: "In the present state of our knowledge it cannot be said that a cement which fails to pass the accelerated test will prove defective in the work: nor can a cement be considered entirely safe simply because it has passed these tests."

Despite various attempts to displace the "boil" test by others, it still finds much favour among American cement manufacturers as being a fair indication of weak points which need attention and a useful gauge of the essential qualities of a cement, although it is sometimes unnecessarily severe.

As alternative methods to the "boil" test the following are sometimes used:—

(1) *Autoclave test.*—Neat briquettes are made up in the usual way, and after 24 hours in a moist chamber are placed in an autoclave and covered with water. Steam is passed in until, in 45 minutes, a pressure of about 20 atmospheres is obtained. This pressure is maintained for 1¼ hours, after which the briquettes are cooled and broken in a standard testing machine. After a great deal of controversy in the United States and Canada, and considerable investigation, it was considered that this test was misleading and did not warrant the greater expense entailed, in comparison with the more rough-and-ready low-pressure "boil" test, which was held to be quite severe enough and fully as accurate in determining constancy of volume.

(2) *The Le Chatelier test*—as carried out in Great Britain.

(3) *The cold water test.*—Pats are stored in cold water for 28 days. This test loses much of its utility from the fact that many unsound cements improve under water. Usually, too, a much more rapid test is required.

(4) *Microscopical test.*—The determine free lime in cement a microscopical test is sometimes used. But since the microscope does not differentiate between the free lime (considered by some authorities as the cause of unsoundness) and the calcium hydroxide developed in the cement on storage and seasoning, it is not of much value.

A number of comparative tests were made in the author's laboratory with the primary object of noting the relative effect of the ordinary "boil" test on test pats stored under three different conditions, viz., in dry air, in moist air, and in water at 70° F. These tests were made on seven different cements (A, B, C, D, E, F, and G), obtained from three different mills, the chemical analyses of these cements being as follows:—

	Mill No. 1.		Mill. No. 2.			Mill No. 3.	
	Sample A.	Sample B.	Sample C.	Sample D.	Sample E.	Sample F.	Sample G.
	%	%	%	%	%	%	%
Silica ..	19·72	20·72	21·66	21·64	21·20	22·56	22·70
Alumina	5·90	5·98	7·05	7·25	7·18	5·90	5·66
Ferric oxide ..	2·86	2·62	3·05	3·25	3·22	2·00	2·12
Lime ..	65·05	63·74	61·67	61·59	61·53	63·05	63·13
Magnesia	3·28	3·14	2·14	2·16	2·10	2·75	2·78
Sulphur trioxide	1·69	1·72	1·90	1·86	2·08	1·72	1·51
Loss on ignition	1·06	1·10	1·80	1·48	1·88	1·04	1·09
Total ..	99·56	90·12	99·27	99·25	99·29	99·02	98·99
CaO ÷ (SiO_2+ Al_2O_3)	3·0	2·82	2·56	2·54	2·60	2·60	2·60

Mill 1. Cements A and B.—Neat pats of cement A completely disintegrated under the specification "boil" test, as also did neat pats stored under the three different conditions aforementioned when subjected to the accelerated test after various intervals up to 62 days. Mortar pats, made in the proportion of 1 cement:2 sand and 1 cement:3 sand, disintegrated up to the age of 1 month, after which there was a gradual improvement. After 2 months the 1:3 pats were sound, while the 1:2 pats, though greatly improved, still showed signs of checking and cracking when subjected to the test.

Test pieces made from cement B passed the test perfectly, at all ages and under every variation of storage. [N.B. Cement A was over-limed and contained at least 1½% excess of free lime—a probable cause of failure.]

Mill 2. Cements C, D, E.—Though these cements were practically identical in composition, C failed to pass the specification "boil" test, D was unsound at first but seasoned in storage and finally passed, while E was sound both at first and throughout all the tests. "Boil" tests were made on neat pats of these cements after storage in dry air, for periods ranging from 16 hours to 2 months. Cement C was unsound at every period; D, when tested after storing for 16 and 24 hours, showed some cracking and deformation, but was satisfactory after storing for 48 hours; E was sound at every period tested.

After storage in water, neat C cement failed at ages 1, 2, and 3 days. After a week pats were less unsound, but curled and cracked under the test. After three weeks, distortion was very slight; after four weeks pats were quite sound. The 1:2 mortar was sound after two weeks; the 1:3 mortar curled and cracked in the test after 48 hours, but was sound after 72 hours.

Neat pats from D (after seasoning), and E, as well as pats from 1:2 and 1:3 mortars, successfully passed the "boil" test after storage for 24 hours in moist air followed by storage in water.

Mill 3. Cements F, G.—Cement F passed the usual specification test, but the neat pats checked and warped in the test after being stored in moist or dry air. The effect of dry air was not so marked as that of moist air, as pats stored in dry air were sound after 4 days. Pats stored in water were sound at all periods tested. The mortar pats were sound at every period and under all conditions.

Cement G completely failed the normal specification test, as did neat pats stored under varying conditions up to 1 month. The mortar pats behaved better, and showed varying degrees of improvement until, after 2 weeks, they were sound under the test.

Conclusions reached from these experiments are:—

(1) The chemical composition of an average Portland cement gives little guidance as to its probable behaviour under the accelerated test. (*Cf.* cements F and G, which are almost identical in composition.)

(2) Unsound cement stored under water shows a marked improvement compared with that stored in air, either dry or moist—the natural storage for cement, at any rate during hardening, is under water.

(3) Mortars poor in unsound cement improve more rapidly than mortars rich in unsound cement. There is thus little danger of disintegration of a water-stored concrete made from poor cement such as C.

(4) Mortars in practice do not exhibit the weakness of their neat cement.

(5) Mortars and concretes are improved by water-storage; concrete should be kept moist, at any rate until completely set.

Unsoundness of cement.—According to Erdahl, unsoundness in the accelerated tests is due to the slower hydration of dicalcium silicate as compared with that of tricalcium silicate and calcium aluminates.

Klein and Phillips, on the other hand, maintain that it is due to hydration of free lime, which, unless very fine, may hydrate in a crystalline condition and exert disruptive forces by the growth of the crystals, thus causing disintegration in the test. Some cements, however, will pass the " boil " test, but not the autoclave test; others will pass both tests, but only after seasoning. In the first case, according to Klein, the free lime may be so coarse or so highly-burned as not to hydrate in the " boil " test, but only under the higher pressure and temperature of the autoclave. In the second, aeration with insufficient water to allow of solution and crystallisation may cause the free lime to hydrate in the amorphous condition. In the light of this, it would be natural to expect that the addition of free caustic lime to a cement previous to mixing with water would cause the cement to fail under the test. In the author's experiments, however, on the products of a number of cement mills, additions of up to 6% of quicklime—in some cases even as much as 10%—had no effect on the soundness under the 5 hours' " boil " test. The probable explanation of this is that lime added in this way is immediately exposed to the hydrating action of the mixing water, and slakes before the setting of the cement begins. The disruptive force of hydration of free lime is thus expended before the test-piece becomes hard and inelastic. The danger from free lime comes when this lime is locked up in small nodules of clinker, and hydration is delayed until the steam can penetrate the nodules, by which time the cement is of course set and disruption occurs. This was borne out by tests made on the fine flour (passing 200-mesh) of an unsound cement. Test-pieces made from the finely-ground product successfully passed the accelerated test.

Experiments with calcium chloride showed that additions of from 1 to 2% of this substance to the mixing water would correct unsoundness in the " boil " test when the cement pats had been stored in air before testing. When, however, the pats of unsound cement, with the calcium chloride already added, were stored under water after they had set, in most cases they failed to pass the test. The application of some theory of chemical action or physical cause other than the hydration of uncombined lime appears necessary in explanation of this.

The addition of alkali carbonates quickened the set, and in some experiments as little as ½% caused serious deterioration of the cement in the accelerated test.

These various experiments seem to point to the fact that the unsoundness of cement under accelerated tests is not entirely due to free lime. The combination of the alkali bases (from the silicates of the raw clay) with carbon dioxide from the air and sulphur from the sulphides of the clinker, and the subsequent oxidation to hydrated carbonates and sulphates may, in some cases, be responsible for the disruption of the test-pieces. The salutary effect of the addition of less than 2% of calcium chloride may thus be due to the prevention of the formation crystals of alkali carbonates and sulphates, which, by their quickening action on the set of the cement, would prevent complete hydration of free lime in the early plastic condition of the test-piece.

Prevention of unsoundness.—As the combination of lime with the silica and alumina of the clay takes place at a temperature below fusion point, there is relatively little movement possible between the particles of clinker during burning. Hence the finer the raw materials are ground before entering the kiln the less chance there is of excess of either constituent remaining uncombined. The ability of cement clinker to pass the accelerated tests thus depends greatly on the fineness of the mixture entering the kilns, and great improvements have been made, both in quality and economy, by better pulverising machinery. Thus, where formerly in the " dry " process the mixed clay and limestone were ground to such a fineness that 90% passed the 100-mesh sieve, most plants now reduce their raw mixtures to a minimum fineness of 95—96% through the 100-mesh sieve and 80—90% through the 200-mesh sieve.

When natural cement rock is used, it is not necessary to grind so finely, as the combination of lime and clay is already an intimate one. (In this connexion it may be of interest to note that the Montreal Island deposit approximates so closely to the perfect Portland cement proportions that the average stone on a 20-foot face seldom requires the addition of either clay or stone of higher lime content.)

In the " wet " process, using marl and clay, there is not much difficulty in obtaining finely-ground materials, but in the " dry " process the necessary intimate mixing can only be obtained by heating the raw materials. It has been demonstrated that, for most materials, if the mixture from the dryers has a temperature of 150° C., this is sufficient to ensure a fine enough grinding to give sound clinker. If only one of the raw materials is heated, or if only the surface moisture be removed from both, the resulting clinker will probably be unsound. If both materials are heated to 150° C., this will ensure the removal of all surface moisture and a sufficient portion of the chemically combined water of the clay to give a sound clinker, provided that the proportioning and the burning conditions are correct. There is nearly always enough clay in the limestone to make the drying of it as important as that of the clay itself.

In the author's opinion very few cases of unsound clinker are caused by a high lime content of the mixture in the kilns. This is based on the daily records of a number of plants over some years; a comparison of the analyses showed a greater proportion of sound cements among the products of higher lime content.

Communications.

THE THERMAL DECOMPOSITION OF PETROLEUM RESIDUES AT REDUCED PRESSURES.

BY J. REILLY, M.A., D.SC., AND E. W. BLAIR, D.I.C., B.SC.

(Preliminary note.)

The dry distillation, at various pressures, of petroleum residues of high boiling point and viscous crude petroleum oils has been extensively carried out owing to the commercial importance of the fuel oils and other products produced by cracking. Refined petroleum residues have also been investigated from a more general aspect by many workers during the past fifty years. There is still, however, doubt as to the constitution of these complex petroleum products and as to the nature and extent of the chemical change or decomposition which occurs when they are distilled, especially under mild conditions in which secondary reactions are reduced as much as possible. In view of the remarkable results recently obtained by A. Pictet in the rapid dry distillation under reduced pressure of certain natural products it seemed to be of interest to subject various petroleum residues to similar treatment, and to separate, and if possible, identify, the different fractions of the distillate.

The first material which the authors had occasion to investigate is that known as "mineral jelly" or "petrolatum"—a viscous, highly fluorescent residue obtained from crude American petroleum by distillation at low pressure with superheated steam. The "mineral jelly" used in the following experiments contained approximately 87% of carbon and 13% of hydrogen, and had sp. gr. 0·883 at 38°/38° C. and flash point (close test) 238° C. The dropping point was 47° C. and the time of flow of 50 c.c. (at 60° C.) from a Redwood standard viscometer was 330 secs. The unsaturation value was equivalent to 85 mg. of bromine per gram of petroleum product.

A large number of rapid distillations of this material have been carried out in both glass and copper vessels at pressures ranging from atmospheric to 1 mm. of mercury. Experiments of this type are still in progress as well as others on the influence of time of distillation and on the effects of the introduction of a current of steam or inert gas during the heating. The initial experiments were carried out on 250 g. of material in glass retorts and the later distillations on 500—1000 g. in copper retorts. The properties of the various fractions obtained show that more than simple distillation has occurred even at the lowest pressures. The purified fractions are being investigated as to their ultimate composition and chemical nature, molecular weight, specific gravity, viscosity, refractive index, coefficient of expansion and calorific value. The oils separated from the various fractions by distillation in a current of steam, as well as the gases produced in the original distillation, are also under examination.

To illustrate the pronounced effect of the pressure and temperature (which latter depends to some extent on the rate of distillation) on the character of the distillate, the following typical examples of a series of distillations are recorded (see Table I):—

TABLE I.

Expt. No.	Pressures (mm.).		Temp. in the vapour, approx. ° C.	Dis-tillate yield %	Bromine (mg.) absorbed per gram of distillate (approx.).	Oil (in c.c.) volatile in steam per 100 g. of distillate.
1	762	Copper retort.	285—385	93·0	275	37
2	510		280—365	95·0	280	33
3	200		275—320	96·0	255	21
4	68	Glass retort.	260—310	96·5	235	9
5	45			97·0	185	4
6	16		260—300	97·5	170	2·5
7	14			97·5	140	1
8	1		255—300	98·0	130	Nil.

There is a decrease in the "volatile oil content" and in the degree of unsaturation of the distillate taken as a whole, as the distillation pressure is reduced. These two properties of the distillate, however, do not vary in direct proportion with the change in pressure. Moreover, the distillate collected at any one pressure is not of constant composition during the whole of the distillation, since the separate fractions show a measurable difference in the degree of unsaturation. Table II. records this effect at three pressures.

TABLE II.

Distillation pressure, mm.	Fraction.	Percentage distilled.	Bromine (mg.) absorbed per gram of distillate (approx.).
758	1	40·0	290
	2	21·5	270
	3	32·0	230
23	1	43·0	125
	2	32·0	230
	3	22·0	220
1	1	41·5	75
	2	24·0	135
	3	33·0	145

Part of the unsaturation of the first fraction, especially in the distillation at atmospheric pressure, is probably caused by condensation of the vapours at the commencement of the distillation. This refluxing effect would tend to increase cracking effects.

At low pressures the first fraction sets to an almost white and non-fluorescent crystalline wax. As the distillation proceeds the colour of the semi-solid distillate changes through yellow and orange to greenish-brown. The last drops of the distillate in vacuum distillation experiments show an intense green-red fluorescence. The fractions from the distillation at atmospheric pressure, while still liquid, are all less fluorescent than the original mineral jelly. On setting they acquire a characteristic brownish-red colour markedly different from the colours of the fractions obtained at low pressure.

The unsaturated and saturated portions of the fractions can be partially separated by steam distillation or by rapid distillation at very low pressure under certain conditions. These portions are being further purified and differentiated by their varying solubilities in organic and inorganic solvents and by other means.

It is hoped to publish a detailed account of this work at a later date.

THE OXIDATION OF HYDROCARBONS, WITH SPECIAL REFERENCE TO THE PRODUCTION OF FORMALDEHYDE.

BY E. W. BLAIR, D.I.C., B.SC. (LOND.), A.I.C., AND T. SHERLOCK WHEELER, B.SC. (LOND.), A.R.C.SC.I., A.I.C.

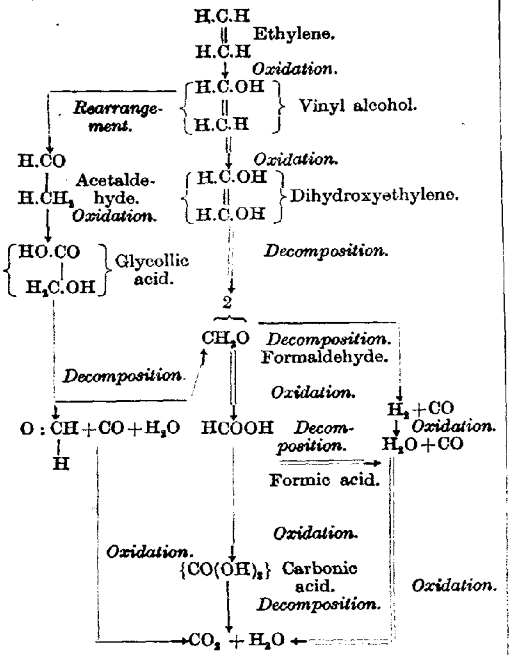
Part I. The Action of Oxygen on Ethylene.

At present formaldehyde is made from methyl alcohol by direct oxidation. This process has always had the disadvantage of being costly and even before the war many seemingly cheaper methods had been brought forward to replace it, but without success. With the object of investigating possible methods of manufacture, the authors have been engaged for some time past on a study of the oxidation of certain hydrocarbons. The following is an account of the first portion of the work, in which ethylene was the hydrocarbon employed. It was selected as the most suitable hydrocarbon with which to commence, after a study of the results obtained by Willstätter and Bommer (Annalen, 422, 36), and by Bone and his co-workers in their researches on the oxidation of hydrocarbons (Trans. Chem. Soc., 1902, 555; 1903, 1074; 1904, 693, 1637; Proc. Chem. Soc., 1905, 220).

According to the latter the interaction of ethylene and oxygen between 350° and 500° C. in contact with a surface occurs in the stages shown on p. 304 T (Trans. Chem. Soc., 1904, 1637).

From this and earlier work it seemed that only at temperatures above 500° C. does the action of oxygen on ethylene proceed with any great rapidity. Vinyl alcohol, considered to be the first oxidation product, is too unstable to be isolated, but the isomeric acetaldehyde has been obtained by Bone and Wheeler, who regard it as an intermediate only in very slow oxidations of ethylene.

Formaldehyde is the most prominent intermediate product because, comparatively speaking, it is the most stable. But although the general details of the course of the slow oxidation of ethylene had been worked out, precise information was, for the most part, lacking as to the effects of temperature, catalysts, etc. A quantitative investigation of the conditions of formation of formaldehyde from ethylene had been undertaken by Willstätter and Bommer (*loc. cit.*), who passed mixtures of ethylene, oxygen, and nitrogen through a tube at various temperatures and estimated the formaldehyde formed. They were led to the following conclusions:—



(Compounds that have not been isolated are enclosed in brackets. Double lines show the most usual course of the oxidation in their experiments.)

(1) That since ethylene, unless it be dilute, is unstable at temperatures above 350° C. it must not amount to more than 30% of the gas mixture, and the period of heating must be very short, *e.g.*, a second.

(2) That since formaldehyde, unless it be dilute, is unstable at temperatures above 310° C., it must not be formed in quantities greater than 2% by volume of the gas mixture, and, once formed, must be cooled as quickly as possible.

(3) All catalysts tried accelerated the oxidation of ethylene; but formaldehyde was never detected when they were used.

The present work amplifies these conclusions and in some respects modifies them; in principle the results are in complete agreement with the hydroxylation theory of hydrocarbon combustion first put forward by Bone and his co-workers. Evidence has been obtained that, even under very different external conditions, the stages by which the combustion of ethylene proceeds do not change; the formation of formaldehyde in contact with catalysts and in oxidations in which inflammation took place, has been proved (*cf.* Bone and Drugman, Trans. Chem. Soc., 1906, 660). Also acetaldehyde has been detected in oxidations under varying conditions, so it would appear that in our experiments the main course of the interaction of ethylene and oxygen is represented by the scheme on p. 310 T, which differs only in detail from that of Bone and Wheeler. The evidence for these views is set out below, together with some other deductions from our results; a full discussion is given at the end of the paper.

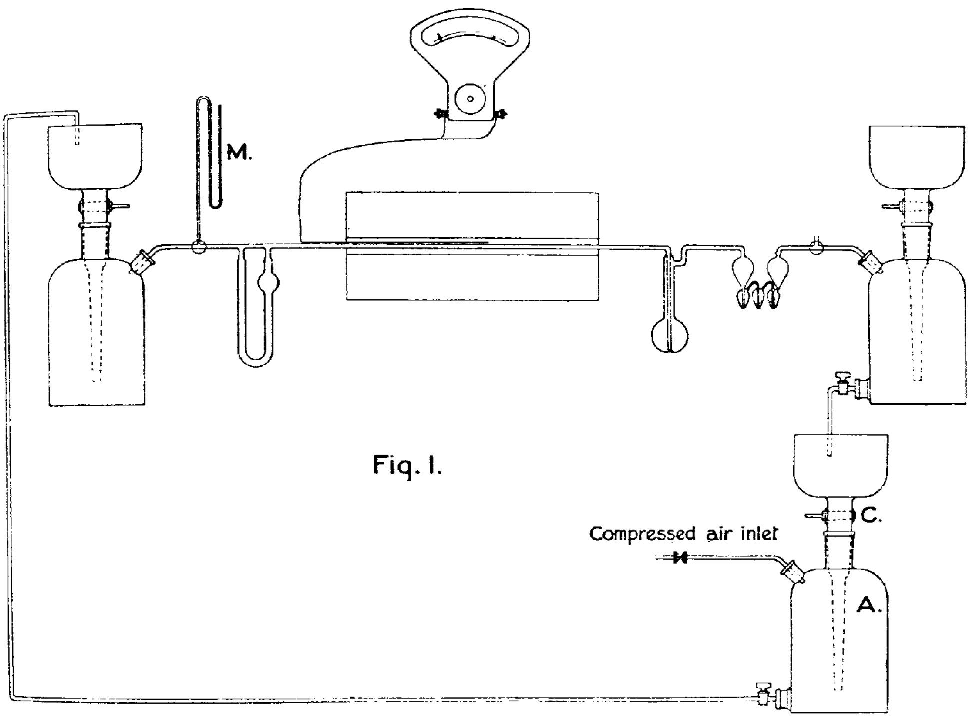
Preparation of gaseous mixtures.

The ethylene used was prepared by Newth's method (Trans. Chem. Soc., 1898, 915) and was well washed with caustic soda and with distilled water. We also made the gas by the action of zinc-copper couple on the dibromide in alcoholic solution and by the action of alcohol on sulphuric acid at 170° C., followed by a thorough purification, but found Newth's method the most satisfactory for the quantities we required. The gas was tested by explosion analysis and rejected unless the ratio contraction/absorption was between 0·99 and 1·01. Oxygen and nitrogen were obtained from cylinders and were washed with caustic soda and with water. The gaseous mixtures were stored over boiled-out 50% aqueous glycerin in which they were found to be insoluble; they were always rendered thoroughly homogeneous either by shaking or by allowing to stand overnight.

Apparatus for direct experiments.

Our first experiments (see Fig. 1) were carried out on the same lines as Willstätter's. The gas was passed from a graduated gasholder through a differential pressure gauge, in which the fall in presure of the gas in passing through a capillary tube was measured. By previous calibration this gave the rate of flow. The gas then entered a 3 or 4 mm. hard glass tube some 50 cm. long. This tube was heated at first in a gas furnace packed with asbestos, but in later experiments in an electric tube furnace, 40 cm. long, both ends of which were plugged with asbestos. The temperature was measured by means of a standardised indicator and thermo-couple; the junction of the latter was fastened to the centre of the hard glass tube. The gas, on leaving the tube, bubbled through a wash-bottle and a set of Liebig bulbs, both containing distilled water, and, freed from formaldehyde (this was proved experimentally), was collected in a graduated gas-holder fitted with a three-way tap.

An experiment was commenced by passing in the initial gas mixture to test for leaks. Three or four litres of gas was then passed through the apparatus and away by the three-way tap before the final receiver. Experiments showed that this was sufficient to remove all air. The furnace was brought to the requisite temperature, and the pressure, temperature, and volume of the initial gas mixture noted, allowance being made for the head of aqueous glycerin in the gas-holder. The pressure in the apparatus, as registered by the manometer, M, was also observed. The gas was then passed at a rate of the order of 1 litre in 10 minutes, and was thus heated for less than 2 seconds in its passage through the furnace. The rate was adjusted by controlling the flow of aqueous glycerin from the final gas-holder, which was used as an aspirator; the head of liquid in the initial holder was maintained by returning the liquid from A by closing tap C, and turning on compressed air. The pressure in the apparatus was kept as near to that of the atmosphere as possible during the experiment; at the end the manometer, M, was brought back to its initial reading before stopping the gas current. This ensured the same amount of gas being in the apparatus before and after an experiment. The pressure, temperature, and volume of the final gas were measured, and both gases were analysed in a Bone and Wheeler apparatus (Trans. Chem. Soc., 1904, 1640). All absorptions were repeated until no further contraction occurred. The residual gas, or an aliquot portion, was then mixed with a suitable quantity of pure oxygen, and electrolytic gas added before exploding to determine the ratio of contraction on explosion to absorption by potash and baryta water after explosion. This enabled the hydrogen and a figure for the thermal decomposition of the ethylene to saturated hydrocarbons to be obtained; these latter always had the approximate composition of methane. We never detected more than traces of acetylene in the products.



Fiq. I.

The volumes of the initial and final gases were reduced to N.T.P. and compared as a check, but these volumes could not be measured accurately enough to use both to deduce the quantities of ethylene etc. consumed in the experiment. This was done by using the initial volume only and calculating the final volume by comparing the analyses of the gases, and making use of the fact that the quantity of nitrogen did not change during the experiment. The absorbing water was made up to 250 c.c. and the formaldehyde estimated in an aliquot part, usually iodometrically (Z. anal. Chem., 36, 19), but when the presence of acetaldehyde was shown by a precipitate of iodoform, Ripper's bisulphite method (Monatsh., 21, 1079) and the potassium cyanide method were combined, the formaldehyde being estimated with potassium cyanide and the two aldehydes together with bisulphite; the amount of acetaldehyde could then be calculated. The iodometric method, though found best for dilute formaldehyde solutions, was not satisfactory when acetaldehyde was present; the bisulphite method was found to give more consistent results. All these methods were tested, with synthetic solutions of the strengths usually obtained. Also several experiments were made to prove that the amount of ethylene dissolving in the wash-waters was not sufficient to interfere with the iodometric estimation of formaldehyde.

After estimating the aldehydes and formic acid present, all other probable intermediate products —ethyl alcohol, glycol, glyoxal, ethylene oxide, and acetic acid—were tested for qualitatively in much the same manner as described by Bone and Stockings (Trans. Chem. Soc., 1904, 710), but all such tests gave negative results.

Experiments on catalysts.

Our first series of experiments was an extension of Willstätter's examination of the effect of catalysts on the reaction. Using a catalyst, the temperature was gradually reduced and the time of contact and the dilution of the gas increased until a barely perceptible reaction was obtained. If then formaldehyde is being formed and not being immediately decomposed some traces of it at least should be obtained. Formaldehyde was detected but even with a scarcely perceptible reaction hydrogen and carbon monoxide were the main products. Once the temperature is raised to any extent the catalyst causes the oxidation of carbon monoxide to carbon dioxide, and even more so of hydrogen to steam. The following examples taken from our experiments will make clear the type of action that occurs.

Experiment 9. *Catalyst: Platinum gauze. Temperature* 540° *C.*—Rate of gas-passage—I litre in 5 minutes. The gas was passed through a 4 mm. tube in the furnace described, a roll of platinum gauze 3 cm. long being placed in the tube 10 cm. from the exit of the furnace. The time of contact of gas with gauze was about 0·1 sec. No formaldehyde was obtained.

	Initial gas.	Final gas.
	%	%
CO_2	nil	8·3
O_2	17·6	0·6
C_2H_4	13·1	6·0
CO	nil	4·3
H_2	nil	3·0
Absorption	nil	0·5

No inflammation took place in this experiment, but the platinum was somewhat blackened and white fumes were formed. The gas mixture used suffered a contraction in volume of some 10% during the oxidation. The wash-water was faintly acid. The high CO_2 content is probably due to the oxidation of the CO first formed.

No formaldehyde was isolated by leading the gases in a capillary tube away from the gauze, so after a number of experiments a single thickness of gauze and a capillary tube were used.

Experiments 13, 14, 15. *Catalyst: Pt gauze.*—Rate of gas passage 1 litre in 5 minutes. 3 mm. tube. Gauze sealed across it 8 cm. from exit end of furnace. Capillary tube thence to exit. Time of contact less than 10^{-4} secs.

Experiment 13. 325° No action detected.
„ 14. 385° „ „

Experiment 15. 405°.

	Initial gas.	Final gas.
	%	%
CO_2	nil	nil
O_2	7·0	6·2
C_2H_4	25·5	24·7
CO	nil	1·3
H_2	nil	1·0
Absorption	nil	0·2

2 mmg. of formaldehyde was obtained per litre of gas. This result is of theoretical importance, as it shows that even with a catalyst formaldehyde is formed; it readily decomposes into hydrogen and carbon monoxide. Many experiments were made with varying mixtures of gases, but a satisfactory quantity of formaldehyde was never obtained using platinum gauze. It is probable, however, that with very high rates of gas passage and at a temperature of about 450° formaldehyde could be obtained in quantity with a catalyst, especially if a stabiliser were used (see later). Such experiments were not carried out, however, as we had not facilities for dealing with the high gas-speeds necessary. Among other catalysts platinised asbestos and ferric oxide were investigated. The action of the former is very vigorous. With these and with all catalysts tried, as the temperature rises, thermal decomposition of the ethylene can be observed; but this is not accelerated to such an extent as the oxidation. To sum up, the effect of a catalyst is to lower the temperature at which the various oxidation reactions take place and to bunch them together—so to speak—making them follow one another at very short intervals.

Extensions of Willstätter's experiments.

The next point that arose was whether in experiments without catalysts, as carried out by Willstätter, it might not be better to heat for a shorter time at a higher temperature. This was investigated in the same apparatus, using furnaces from 10 cm. to 35 cm. in length, and tubes of diameters from 1 to 5 mm. As the time of heating diminished at any given temperature the ratio of acetaldehyde to formaldehyde increased, but the total conversion was of course reduced; the percentage yield of aldehyde on ethylene improved, and if the time of heating at 540° was short enough, say, 1·5 secs., no carbon monoxide was formed, the only loss being due to thermal decomposition. With the same time of heating it is better to pass the gas through a narrow tube than through a wide one. This is probably due to turbulence giving more even heating with the former or perhaps to an increased surface effect.

Willstätter did not work with less than 20% of ethylene; on continuing his investigations in this direction by decreasing the ethylene and increasing the oxygen content, it was found that the percentage of formaldehyde on the ethylene converted rose. This also occurred as the temperature was reduced. Thus at 540°, using a mixture containing 17% of ethylene and 13% of oxygen, 4 mmg. of formaldehyde per litre in 70% yield, and a little acetaldehyde were obtained; no carbon monoxide was detected.

Experiment 45.—Four litres of gas was passed through a 3 mm. tube in the same apparatus in 60 minutes. Time of heating of gas, about 1 sec.

	Initial gas.	Final gas.
	%	%
CO_2	nil	nil
O_2	13·3	13·1
C_2H_4	17·7	17·5
CO	nil	nil
H_2	nil	nil

There is so little change in the volume in the gas before and after the experiment that the percentage of ethylene in the final mixture can be subtracted directly from the percentage in the initial mixture to obtain the quantity consumed.

Apparatus for circulation.

As the small quantities mentioned could not be determined very accurately, it was decided to circulate the gas mixture; in this way the course of the oxidation could be followed even when interaction was occurring slowly. Our experiments up to this point had convinced us that to make formaldehyde directly from ethylene in yields approaching the theoretical the gas mixtures must be circulated without a catalyst. For a successful circulation it is necessary that the conversion should be to formaldehyde, and very little else, even though the amount of formaldehyde is very small in consequence.

The circulation apparatus (Fig. 2) was as follows:—From the automatic Sprengel pump, A (*cf.* Bone and Wheeler, Trans. Chem. Soc., 1903, 1076), the gases passed to a bulb, B, of about 350 c.c. capacity. Fresh gas was admitted through the tube, *p*, and three-way tap, t^1, by means of a mercury valve, K, arranged to admit gas automatically as soon as the pressure fell below a predetermined amount. The gas then passed the three-way tap, t^2, whence samples could be withdrawn into the bulb, C, and thence delivered by three-way tap, t^3, and tube, *b*, into holders for analysis. The bulb, D, prevented any sudden sucking back of the water in the various wash-bottles during this operation. By means of the three-way taps, t^4 and t^5, the gas could be passed through either, or both, of two furnace tubes, and their corresponding sets of worms, *l*,*l*,*m*,*m*. E^1, E^2 were rate gauges, F^1, F^2 wash-bottles containing distilled water put in to act as flash-traps in the event of inflammation in the tubes. The second tube was used only when it was desired to compare the effect of tubes of different materials, construction, etc. *n* was a final worm common to both tubes. All the worms contained distilled water. The arrangement of tubes and thermo-couple in the electric furnace was as before. L, M, N, P, were four gas holders. L contained pure ethylene, M pure oxygen, N pure nitrogen, and P an almost equimolecular mixture of the first two, made up so that by adding it to the circulation gas, the latter remained nearly constant in composition. An experiment was started by exhausting the apparatus first with a water pump through t^6, and then with the Sprengel pump, using the three-way tap, *t*. When the apparatus was exhausted, as shown by the manometer and by the mercury clicking in the fall tube, exhaustion was stopped and the whole allowed to stand overnight to test for leaks. These being absent, nitrogen, ethylene, and oxygen were admitted in the requisite amounts, the quantities being controlled by means of the manometer, T. K and *p* were always swept out to the air with the gas to be treated, by means of three-way tap, t^7. The actual quantities of gases admitted were read from the graduated holders, and reduced to N.T.P. The gases were circulated for 6 hours thoroughly to mix them, saturate them with water vapour and enable all adjustments to be made before a sample was drawn off for analysis. The furnace was then heated to the required temperature, and the mercury in K adjusted so that gas was on the point of being admitted, by adding or withdrawing mercury by the bulb R. The gases were at times circulated for days, being analysed three times in 24 hours. The rate was kept constant by controlling the air-lift on the automatic pump as described by Bone and Wheeler (Trans. Chem. Soc., 1903, 1079). At Z was fitted a small glass reaching half-way across the top of the fall-tube. It was found that it broke even rapid streams of mercury, thus enabling high rates of gas circulation to be maintained.

By adjusting the taps connecting L, M, N, P with the tube, X, it was possible to admit gas from one of the holders continuously. Usually it was P that was connected. If the mixture in P was not keeping the composition constant its constitution was altered, by adding more ethylene or oxygen from L or M, or through Y, an open tube dipping under mercury, whence also samples of the gases in the holders could be taken. If the constitution of the circulating gas required altering some of it could be pumped off through *t* and fresh gas added, T being used to check quantities.

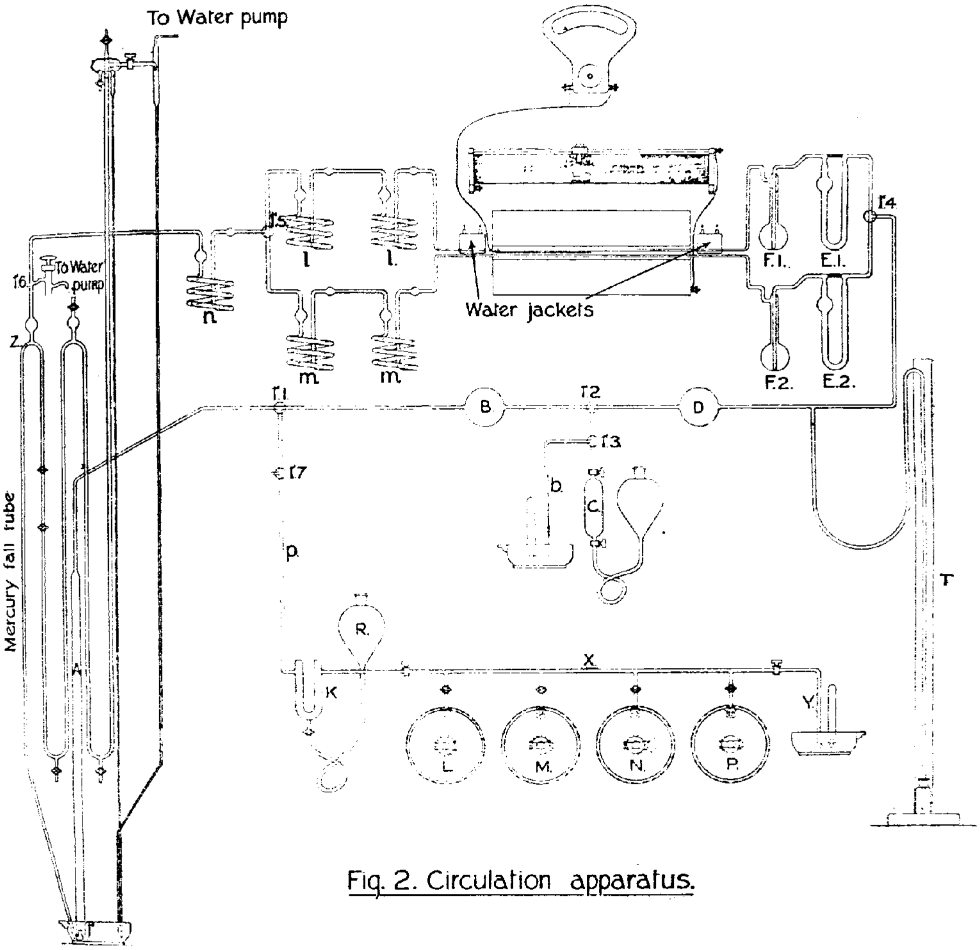


Fig. 2. Circulation apparatus.

Results of circulation experiments.

In our first experiments the circulation period was only 12 hours and no additional gas was admitted. Pressure readings were taken at intervals to control the experiments just as described by Bone and Wheeler (*loc. cit.*); the pressure curves obtained were of the type described by them. Dilute gases at temperatures of about 560° were used, as our previous experiments had convinced us that this was the optimum temperature. The following is a typical experiment.

Experiment 67. 0·720 litre of gas at N.T.P. was circulated at 560° for 12 hours at an initial corrected pressure of 748 mm. The corrected pressure fell 76 mm. during the experiment. The rate of circulation was approximately 1 litre in 30 mins.

A 4 mm. tube in a 30 cm. furnace was used, so the time of contact was about 4 secs.

	Initial gas. %	Final gas. %
CO_2	nil	0·3
O_2	9·6	3·5
C_2H_4	15·1	10·8
CO	nil	2·6
N_2 (saturated hydrocarbons included)	75·3	82·8

The yield of formaldehyde was 75 mmg. per litre (50%) and the amount of ethylene consumed 53 c.c. per litre.

Comparing the volumes of the gases before and after the experiment it can be calculated that 63 c.c. of oxygen and 53 c.c. of ethylene were consumed. There were obtained in the products per litre of gas:—

3 c.c. CO_2 = 2 c.c. C_2H_4 and 5 c.c. O_2 (allowing for
26 c.c. CO = 13 c.c. „ „ 26 c.c. O_2 „ H_2O)
75 mmg. CH_2O = 28 c.c. „ „ 28 c.c. O_2 „

43 c.c. of C_2H_4 and 59 c.c. of O_2 are thus directly accounted for. The remainder of the oxygen was consumed in the formation of intermediate products etc. The ethylene is not all accounted for, the difference in this case being due to thermal decomposition. Thus, for 100 c.c. of C_2H_4 used, 4 c.c. oxidised to CO_2, 25 c.c. oxidised to CO, 53 c.c. oxidised to CH_2O, and 18 c.c was thermally decomposed.

This is a good conversion, for as the oxygen-content decreased there was a greater possibility of thermal decomposition of the ethylene than if the oxygen-content was being maintained. The slow rate of circulation also helped this decomposition and also the oxidation of formaldehyde to formic acid and the further decomposition of the latter to steam and carbon monoxide. As no hydrogen was obtained, direct decomposition to hydrogen and carbon monoxide does not seem to occur to any extent under the conditions of the experiment.

Several circulation experiments of the above type were carried out. The automatic valve to admit fresh gas was then used, and experiments were performed with its aid, and many of the statements made in the earlier part of this paper as to the influence of surface, time of heating, dilution, etc. were confirmed. Also by circulating a mixture and raising the temperature a few degrees at intervals of 3 hours it was possible, by observations of the fall in pressure, to confirm our results as to the temperature at which an appreciable reaction occurs in a heating period of about a second. Of special interest is an experiment in which, using a short time of heating (0·6 sec.), in addition to 100 mm. of formaldehyde, 5 mmg. of formic acid was obtained per litre per day. With such a time of heating the gas does not reach the temperature of the couple, for even with a mixture within the explosive limits, inflammation does not occur below 610°. In all experiments in which much formic acid was isolated the percentage of oxygen was high (20%), C_2H_4 being usually about 13%. On the other hand, by decreasing the oxygen-content to about 10%, C_2H_4 remaining at 13%, at 540° as much as 5 mmg. of acetaldehyde per litre of circulating gas was obtained in a day. Bone and Wheeler, and Willstätter also detected these compounds.

Investigations were then carried out with this apparatus to determine whether it might not be better to use explosive mixtures at temperatures below the ignition temperature, 546° C. It has been shown that the greater the dilution of the ethylene the better the conversion, but mixtures containing less than 14% ethylene are inflammable, so it remained to see if such dilute mixtures could be used below 546°. The action, however, was too slow and the percentage of acetaldehyde in the formaldehyde produced was high, viz., up to 10%.

It is noteworthy that a large excess of oxygen inhibits the oxidation, much more than a large excess of ethylene (see also Trans. Chem. Soc., 1904, 703, 1643). Thus, starting with a gas containing 10% of oxygen and 20% of ethylene, and gradually increasing the oxygen content, keeping nitrogen at 70%, the rate of reaction increases until the mixture contains equal volumes of the gases but falls off rapidly when the oxygen is further increased.

By the aid of the second tube shown in the diagram the effects of tubes of steel etc. were compared by passing one half of the gas through the metallic tube and the other half through the glass tube. Slight oxidation of the metallic tubes occurs; the metal, and also the oxides formed, act as catalysts and cause the decomposition of the formaldehyde (see Expts. IV. and V., Table I.). Only 15 mmg. of formaldehyde per litre of ethylene was obtained in 48 hours at 600° with the steel tube, but the formation of even this small quantity confirms our results with platinum gauze. The yield was 1·5% on the ethylene consumed. Both CO and CO_2 were formed. Under similar conditions with a glass tube (O_2, 16%; C_2H_4, 19%) formaldehyde was obtained at 8 mmg. per litre per hour in 70% yield. There was only a small quantity of acetaldehyde in the product.

Experiment 69. (See Experiment III. Table I.). 0·625 litre (N.T.P.) of a mixture of ethylene, oxygen, and nitrogen was circulated at 575° for 39 hours. The rate of circulation was about 1 litre in 15 mins., the time of heating in the tube being about 1 sec. Fresh gas (C_2H_4 48·3%; O_2 51·3%) was admitted automatically and a 25 c.c. sample was taken after 15 hours, the pressure being kept constant throughout.

	Initial gas.	Sample.	Final gas.
CO_2 ..	Nil	Nil	0·2%
O_2 ..	15·8% = 99 c.c.	15·4% = 4 c.c.	14·2% = 89 c.c.
C_2H_4 ..	19·4% = 121 c.c.	19·1% = 5 c.c.	17·0% = 106 c.c.
CO ..	Nil	1·1%	3·5% = 22 c.c.
N_2 ..	64·8% = 405 c.c.	64·4% = 16 c.c.	65·1% = 404 c.c.

192 mmg. of formaldehyde and some acetaldehyde were obtained. 0·163 litre of gas containing 77 c.c. C_2H_4, 82 c.c. O_2, 1 c.c. N_2 was fed in during the experiment. Allowing for the quantities in the sample, there disappeared during the reaction 87 c.c. of C_2H_4 and 88 c.c. O_2, and there was found 17 c.c. of residual gas. The contraction due to reaction = 160 c.c. Making use of the following equations

$$C_2H_4 + O_2 = 2CH_2O$$

$$C_2H_4 + 2O_2 = 2H_2O + 2CO,$$ we have

192 mmg. CH_2O = 70 c.c. C_2H_4, 70 c.c. O_2, 140 c.c. contraction.
22 c.c. CO = 11 c.c. C_2H_4, 22 c.c. O_2, 11 c.c. contraction.

Total appearing in products =
81 c.c. C_2H_4, 92 c.c. O_2, 151 c.c. contraction.
Total consumed =
87 c.c. C_2H_4, 88 c.c. O_2, 165 c.c. contraction.

The oxygen is in fair agreement; the other differences are due to thermal decomposition which cannot well be allowed for, and to the difficulty of measuring accurately the volumes of the gases used. The experiment may be summarised as follows:—

Expt.	Temp.	C_2H_4.	O_2.	mmg. CH_2O formed per litre.	c.c. C_2H_4 consumed per litre.	% C_2H_4 → CH_2O
69	575°	19·4%	15·8%	300	160	70

The composition of the gas must be carefully controlled so that the ethylene does not fall below 14%. If a mixture of 50% C_2H_4 and 50% O_2 be added through the automatic valve the composition of the reacting gases will alter only slowly as the oxygen is usually consumed a little faster than the ethylene. The method of calculating the results of these experiments will be clear from what has been given above, so it is unnecessary to give further details of gas analysis etc.

The following is a summary of some of our circulation experiments:—

TABLE I.

Temp. of expt.	Diam. of tube.	% of ethylene in mixture before and after experiment.	% of oygxen in mixture before and after experiment.	Total time of experiment in mins.	Rate of passage of gas in c.c. per min.	Time of heating of gas in each passage through tube in secs.	No. of mmg. of formaldehyde produced in passage of 1 litre through tube.	% of C_2H_4 consumed, converted to formaldehyde.
°C.	mm.							
I. 560°	4	15·1% → 10·8%	9·6% → 3·5%	720	30	4	3	50%
II. 575°	3	13·4% → 10·5%	14·9% → 13·0%	840	50	2·4	2·3	70%
III. 575°	2	19·4% → 17·0%	15·8% → 14·2%	2340	67	1·0	2	75%
*IV. 600°	3	14·9% → 17·5%	11·6% → 0·0%	1080	31	2	0·3	1·5%
*V. 550°	4	12·8% → 9·8%	17·9% → 3·9%	2970	31	4	0·7	25%

* These experiments were made with a steel tube; the remainder with glass tubes.

Formaldehyde stabilisers.

(*a*) *Steam.*—The use of steam as a formaldehyde stabiliser was investigated; it was hoped by means of some such stabiliser to be able to isolate a quantity of formaldehyde from an oxidation giving little in the ordinary way. This would confirm the view that under all conditions formaldehyde is formed though only momentarily. In several experiments steam was added to the gases up to 50% of the total volume, by passing the ethylene-oxygen-nitrogen mixtures through water at the temperature (83°) at which its vapour pressure is slightly more than half an atmosphere. The steam in these experiments was condensed and the formaldehyde absorbed by passing the gases through two water-worms. The steam did stabilise the formaldehyde to some extent. From an explosive mixture ($O_2=50\%$; $C_2H_4=25\%$), using a 40 cm. furnace, 15 mmg. of CH_2O was obtained at 600° in 55% yield. No inflammation took place, but in another experiment at 610° inflammation took place and the yield was materially reduced (14 mmg. in 8% yield). The steam had also a protective action on the formic acid. Our experiments showed that, although no formaldehyde may be obtained, yet it is undoubtedly formed even under conditions which lead to inflammation of the gas mixture. It may be added that steam does not stabilise formaldehyde in the presence of catalysts; hydrolysis then seems to occur. $CH_2O+H_2O=CO_2+2H_2$. (See J. Amer. Chem. Soc., 1921, 1670.)

(*b*) *Ammonia.*—The use of ammonia to stabilise formaldehyde as hexamethylenetetramine was then tried (E.P. 156,136). It was introduced into the gases either directly or by bubbling through 0·880 ammonia solution (Trans. Chem. Soc., 1903, 1169), the hexamethylenetetramine being distilled with dilute sulphuric acid to recover formaldehyde. The following typical experiment may be quoted.

Experiment 74.—A mixture containing 42·1% ethylene and 43·2% oxygen was passed through a bulb of about 500 c.c. capacity, and ammonia was led into the bulb at the same rate. The mixed gases were then passed through a 4 mm. tube in the usual furnace, through three washers to remove ammonia and hexamethylenetetramine, and into a gas holder.

Rate of passage of the ethylene-oxygen-nitrogen mixture=1 litre in 20 minutes.

1·33 litres (at N.T.P.) of the mixture was passed through the tube in 15 minutes. The time of heating was 3 secs.

Expt.	Temp.	C_2H_4.	O_2.	c.c. C_2H_4 consumed per litre.	Yield CH_2O per litre.
74	590°	42·1%	43·2%	49 c.c.	60 mg., 50%

The stabilising effect of the ammonia is here clearly seen. A 50% yield at such a temperature and with such a mixture is interesting considering that almost 50 c.c. of ethylene had entered into the reaction. Also, with the aid of ammonia, we isolated some formaldehyde in contact with catalysts, but much thermal decomposition occurred. At lower temperatures better results were obtained, due to less decomposition of both the ethylene and hexamethylenetetramine. The latter decomposes if heated much above 100°; in a vacuum it is stable and also at high temperatures when formed in a gas current as above and swept out of the hot tube immediately. Since the best results were obtained at lower temperatures it would seem best to use ammonia in conjunction with a catalyst which would lower the oxidation temperature but would not thermally decompose ethylene. No such catalyst was found, but the subject was not pursued for the presence of formaldehyde had been proved, and on economic grounds the ammonia method seemed to offer no advantage over the direct oxidation process, more especially as a portion of gas is oxidised to nitrogen. It may be noted that excess of ammonia increases the stabilising action, but even when using only a little it still exerts to some extent its stabilising effect. It also hinders the decomposition of formic acid, which was always detected, sometimes in quantity, in the distillate in most of the experiments in which ammonia was used.

It was not impossible that in the presence of ammonia, hydrogen and carbon monoxide might yield formaldehyde owing to the latter being removed by the ammonia as fast as formed. To test this a mixture of 3 vols. of hydrogen, 3 vols. of carbon monoxide, and 6 vols. of ammonia was circulated for 5 days beginning at 500° and gradually rising in 2 days to 700°. Up to 640° no reaction was noted; at this temperature crystals appeared on the exit end of the furnace tube and a fall in pressure took place. The matter was not further investigated as the temperature at which this reaction took place was too high to affect our ethylene experiments. The crystals looked not unlike urea.

Discussion of results.

(*a*) *Course of the oxidation.*—Our experiments with ammonia and steam indicate that formaldehyde is always formed in inflammations and even in contact with catalysts. It then breaks down if the temperature is high, say above 600°, or if its concentration rises above 2% of the mixture. Otherwise the formaldehyde is oxidised, if enough oxygen is present and the time of heating is sufficient, to formic acid, which decomposes very readily into carbon monoxide and steam; the carbon monoxide then oxidises much more slowly to carbon dioxide. With dilute ethylene the action is slow and from such mixtures, with a short time of heating, the formation of appreciable quantities of acetaldehyde or of formic acid according to the proportion of oxygen present has been proved. A short period of heating is necessary for the detection of acetaldehyde because it is an early intermediate product and for that of formic acid because of its instability. A slight excess of oxygen helps the formation of the latter, a deficit or a large excess assists that of the former. The inhibitory action of an excess of oxygen has been noted. (*Cf.* Bone and Andrew, Trans. Chem. Soc., 1906, 1232.)

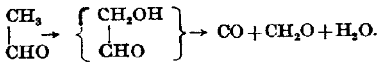
The effect of catalysts, concentrated gases, high temperatures or increased period of heating is to make the reactions follow one another very rapidly and to proceed further to completion. It is interesting to observe how with catalysts, as the temperature increases, the percentage of carbon dioxide, even with little oxygen, approaches that of carbon monoxide, owing mostly to an increase in the rate of oxidation of the intermediate products. One point may here be emphasised. Bone and Wheeler (Trans. Chem. Soc., 1902, 537) proved that under the conditions of their bulb experiments the following reactions do not take place:—

$$\begin{aligned}&1.\quad CO + H_2O = CO_2 + H_2\\&2.\quad 2CO + O_2 = 2CO_2\\&3.\quad 2H_2 + O_2 = 2H_2O\end{aligned}$$

so that in their experiments carbon dioxide and water were only formed as a result of nascent action and through direct decomposition of the hydrocarbon oxidation products. But in our experiments, though 1. and 2. were comparatively slow except with catalysts, yet 3. was not; so that a small direct decomposition of formaldehyde is not easy to distinguish from decomposition *via* formation of formic acid. The quantities of formaldehyde persisting make the latter more probable.

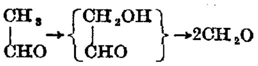
Acetaldehyde was obtained so frequently that we believe that under the conditions of our experiments acetaldehyde rather than dihydroxyethylene was the intermedeiate product of oxidation. It would seem that in oxidations where the gases are interacting slowly there is time for most of the vinyl alcohol first formed to isomerise to acetaldehyde before further oxidation occurs. In inflammations, however, and in oxidations accelerated by surfaces or by catalysts, the main course of the oxidation may be *via* dihydroxyethylene as indicated by Bone and Wheeler (Trans. Chem. Soc., 1904, 1637).

With regard to the oxidation of the acetaldehyde formed in our experiments, Bone and Stockings (*loc. cit.*) found that under the conditions of their experiments acetaldehyde was oxidised thus:—



$$\begin{matrix}CH_3\\|\\CHO\end{matrix} \rightarrow \left\{\begin{matrix}CH_2OH\\|\\CHO\end{matrix}\right\} \rightarrow CO + CH_2O + H_2O.$$

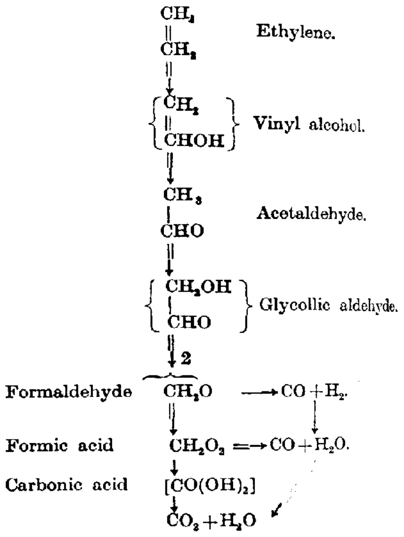
At first sight it would appear from this that it was impossible that acetaldehyde could be in the main course of the oxidation of ethylene where yields of over 50% of formaldehyde are obtained. But the scheme



$$\begin{matrix}CH_3\\|\\CHO\end{matrix} \rightarrow \left\{\begin{matrix}CH_2OH\\|\\CHO\end{matrix}\right\} \rightarrow 2CH_2O$$

is quite possible on the hydroxylation theory, and it is probable that under the conditions of our experiments acetaldehyde did oxidise in this way. This follows from the consideration that as the temperature of oxidation fell the ratio of acetaldehyde to formaldehyde increased, and yet the carbon monoxide formed decreased until at 550° none was to be detected, although acetaldehyde was present, and some must have oxidised (*cf.* Willstätter and Bommer, Annalen, **422**, 45; also our experiment 45, p. 306 T).

The following scheme represents then the main course of the interaction of ethylene and oxygen under the conditions of our experiments:—



(Double lines show the most usual course of the oxidation in our experiments).

We have to thank Professors W. A. Bone, F.R.S., and R. V. Wheeler for their kindly criticism of our work. Both agree with the above scheme for the preponderating course of oxidation of ethylene under the conditions of our experiments.

This work was carried out for the Chemistry Research Board of the Department of Scientific and Industrial Research, to whom we are indebted for permission to publish these results.

THE CORROSION OF CAST IRON AND LEAD PIPES IN ALKALINE SOILS.

BY J. W. SHIPLEY.

Part I.

The Corrosion of Iron by Soil.

The corrosive destruction of underground metal structures in western Canada has become a matter of real concern to the public as well as to the engineering profession. The disintegration of concrete foundations, aqueducts, and sewers, when exposed to the alkaline salts found in the soils of the western prairies, has led to an investigation conducted jointly by the Engineering Institute of Canada and the Industrial Research Council assisted financially by several western cities, the Canada Cement Company, and the Governments of Saskatchewan and Alberta.

The corrosive destruction of steel and iron structures when buried in these soils led to an investigation of the problem, primarily, in the interests of the Winnipeg Electric Street Railway, in order to determine whether such destruction took place in the absence of stray electric current. Field observations indicated severe corrosion remote from railway tracks or in localities where current would be flowing into the metal structures, and not out of them. Such was the case at the Mental Hospital at Selkirk, Manitoba, where the flanges on the bells of the cast-iron water main could be whittled off with a jack knife to a depth of a quarter of an inch or more. Soft areas on the pipe were marked by patches of rust, on removing which the iron could be dug into with a knife blade. At one spot where a limestone pebble was in contact with the pipe the deepest pitting was observed, the pipe having softened to a depth of about a quarter of an inch. This pipe line had been in the ground for eight years, and was located 1¼ miles beyond the northern extremity of the trolley line that runs to Winnipeg, the nearest sub-station being over five miles further south. The hospital water-pipe system had no connexion with the town water pipes, and the observed corrosion was on that part of the system farthest removed from the electric railway. A delicate galvanometer failed to show any trace of stray current.

Other instances of this graphitic softening of cast iron were found in the C.P.R. yard at North Transcona, almost three miles from the nearest electric railway track, and in St. Boniface at the stock yards, half a mile outside the area of electric railway operations.

Before the construction of the concrete aqueduct from Indian Bay water from artesian wells to the north-west of the city was conducted into Winnipeg. Steel water pipes, first laid, were so badly damaged by external soil corrosion after three years that they were replaced by cast-iron pipes, well covered with a coat of tar. About half a mile of these pipes was dug up in the autumn of 1921, and examination indicated that they were remarkably well preserved. Corrosion was only apparent where the protective coating had been abraded, *e.g.*, beneath the sling with which the pipes had been lowered into the trench. The pipes had been in the ground for eight years.

Breaks in the cast-iron water main system within the city of Winnipeg are frequently occurring, and a number of these show the characteristic graphitic softening clear through the pipe. Laboratory experiments showed that this softening is produced alike by soil salt solutions acting on the iron, or by an electric current leaving the pipe. Consequently, it is impossible to determine what damage should be attributed to stray current electrolysis and what to soil action. The problem is further complicated by the fact that the very conditions most conducive to soil corrosion are also most conducive to stray current electrolysis. A concentration of salts in the ground water makes a path of low resistance for the electric current.

The soils of the Winnipeg district.

The soils of the Winnipeg district consist of layers of lacustrine and alluvial silts and clays overlying glacial till. The first three to four feet below the surface loam is quite porous and rich in finely-divided limestone. The next layer is a dense, colloidal, chocolate-coloured clay containing a considerable percentage of limestone, but quite impervious to the flow of water. Beneath this lies a narrow, dark yellow layer of limy silt, frequently filled with crystals of selenite. This narrow layer rests upon the so-called blue clay or "gumbo." This last is very similar in composition and texture to the 5—6 feet of chocolate-coloured clay overlying the 18 inches of silt impregnated with selenite. The water pipes lie in the first or second clay layers, while the back fill is composed of a mixture of all layers. Crystal aggregations of salts occur in the three lower layers. These are disseminated along the bedding planes, in the vertical cleavages and particularly along roots and rootlets, where the spaces are frequently completely filled with crystals. These consist largely of calcium sulphate containing a little magnesium sulphate.

The water-soluble salt content of the soil is frequently more than 1% of the total weight of soil, while, in some instances, it is as high as 10%. The ground waters contain the sulphates, chlorides, and carbonates of calcium and magnesium, and are saturated in respect to calcium sulphate and carbonate.

Through the clay layers there is practically no lateral movement of the ground waters, and the use of the term "water table" has no significance. A difference of 4—6 feet in the ground water level has been observed over a horizontal distance of 30 feet, and this difference persisted through several months. The moisture content of the soils varies between 20% and 30%. The average electrical resistance of eighteen samples was 570 ohms per c.c., the lowest being 206 ohms, the highest 1085. A gravel back fill saturated with water gave an electrical resistance of 12,750 ohms per c.c. Below is given an analysis of three of the soil layers described above. The samples were dried at 105° C. and treated with hydrochloric acid.

	SiO_2 insol. in HCl	Fe_2O_3	Al_2O_3	P_2O_5	CaO	MgO	Na_2O	CO_2	SO_3	Cl	H_2O and organic
	%	%	%	%	%	%	%	%	%	%	%
Yellow limy silt	43·0	1·9	5·6	0·15	17·0	7·8	0·41	23·8	0·4	0·07	0·2
First clay layer	59·2	6·3	11·1	0·30	5·7	3·3	0·95	5·5	3·6	0·05	3·8
Second clay layer or "gumbo" ..	59·4	5·0	10·2	0·26	7·6	3·3	0·26	5·2	4·7	0·04	4·4

The clay layers in the above table contain a higher sulphate content than the average of these layers, but represent what is frequently encountered.

Composition of corroded material.

The graphitic softening of cast iron differs entirely from the destruction of steel and wrought iron. The two latter are pitted, and the material of the pipe is completely carried away, but cast iron corrodes without affecting the form of the pipes. No pitting appears on the surface, and a casual inspection indicates an undamaged condition. Much of the iron passes out into the surrounding soil, leaving a soft, spongy mass of residual graphite, silica, and iron, and frequently, secondary deposits of sulphide, carbonate, and phosphate appear in the corroded mass. This softening may extend entirely through the pipe without affecting its functioning as a conduit.

Table I.

Composition of matter in soft areas on cast iron pipe.

Location of pipe	Metallic iron. %	Ferrous iron. %	Ferric iron. %	Silicious-graphitic residue. %	Remarks.
Portage and Hargrave	26·2	23·0	2·2	30·4	Pitting 3/8″ deep.
Edmonton and Qu'Appelle	35·2	16·6	10·4	25·6	Pitting 3/8″ deep.
Stock Yards, St. Boniface	52·0	17·4	8·9	13·2	Pitting 1/8″ deep.
Stock Yards, St. Boniface	41·4	·24·6	4·2	18·4	More than 1/8″ deep, and sulphur 1·1%
Selkirk Mental Hospital	49·2	18·4	9·1	17·8	Pitting 1/4″.

The proportion of residual metallic iron decreases as the corrosion progresses, while that of the silicious-graphitic residue increases. The proportion of the components in the graphitic mass bears little relation to the original ingredients of the cast iron and the state of oxidation varies within wide limits. Sometimes the corroded material lifts completely out of the pipe. An analysis of one of these "fillings" gave metallic iron 2%, ferrous phosphate (vivianite) 18%, and carbon and silica 42%. The specific gravity of the mass is often reduced to one-third of that of the original cast iron.

Besides this graphitic corrosion, scale sometimes appears on the pipe. A full analysis of this material was not attempted, since it was more or less incorporated with the soil in contact with the pipe. The large proportion of iron in the ferrous condition was the most remarkable feature in the composition of this scale.

Table II.

Nature of iron in pipe scale.

Location of pipe.	Metallic iron. %	Ferrous iron. %	Ferric iron. %	Remarks.
Ellice and Donald ..	1·4	30·0	7·4	Slightly magnetic.
Manitoba Gypsum Works	4·2	9·7	13·0	Slightly magnetic.
Bannatyne and Princess	0·4	12·5	0·2	Non-magnetic.
Stock Yards, St. Boniface	1·1	23·1	12·5	Slightly magnetic.

The field observations covered practically the entire city of Winnipeg, together with adjacent municipalities, and included the examination of half a mile of water mains along River Avenue, Fort Rough, and half a mile of pipe from the old water district, north of the city.

Laboratory investigation.

The laboratory investigation was carried out with the object of determining (1) what salts were most active in promoting the corrosion of cast iron, and (2) what was the probable cause of the corrosion. Pieces of cast iron immersed in salt solutions, dilute and concentrated, to which distilled water was added as evaporation proceeded, were kept under observation for a period of 40 days.* During the day some of these were heated to 80° C. or higher. Graphitic softening was produced in more than half the samples, the sulphates and chlorides of calcium and magnesium attacking the iron most actively. Calcium carbonate saturated with carbon dioxide also proved to be corrosive, but the salts of magnesium were the worst. In general those salts which formed acid products of hydrolysis were most corrosive, while those giving basic products were least.

Heating did not appear to hasten the corrosion. This would indicate that the corrosive action is electro-chemical rather than chemical in nature, and the usual doubling of the chemical action for a 10° C. rise in temperature does not follow. That is, we are dealing with the chemical action produced by a difference in E.M.F., and consequently the temperature coefficient for voltage, which is relatively small, is alone concerned.

A set of experiments in which samples of soil were used instead of salt solutions was made simultaneously with those just described. Corrosion of the cast iron was of the same nature as that observed from the salt solutions, but the softening was not so clearly defined. The most marked local softening was observed in a sample of soil taken from the thin, yellow layer known to contain much calcium sulphate in the form of selenite.

Concentration cells.

Several concentration cells were set up on freshly polished pieces of cast iron. These were made by "diking" off portions of the surface of a cast iron pipe with paraffin. Then adjacent sections were filled with dilute and concentrated salt solutions, and liquid electrical connexion made by an inverted glass U-tube containing a wick saturated with the dilute solution. Rusting was observed to take place on the surface containing the dilute solution. Here the iron was going into solution under the influence of the galvanic action of the concentration cell. The iron ions soon became hydrated and rust appeared.

A striking manifestation of the flow of current and of the migration of iron was afforded by the passage of colloidal ferric iron up the wick of the U-tube. After a few hours the reddish-coloured colloid passed completely through the glass tube and was being deposited on the iron in the other division of the cell. This phenomenon complicated the interpretation of the observed results and limited the time during which an experiment could run.

Three experiments were carried out in cells similar to those just described with solutions of unlike salts.

Table III.

Galvanic electrolytic cells in diverse concentration on cast iron.

1. NaCl dilute to NaCl conc.	Rusting on dilute only
2. $MgSO_4$ dilute to $MgSO_4$ conc.	Rusting on dilute only
3. $MgCl_2$ dilute to $MgCl_2$ conc.	Rusting on dilute only
4. Na_2SO_4 dilute to Na_2SO_4 conc.	Rusting on dilute only
5. $CaSO_4$ dilute to $CaSO_4$ sat.	Rusting on dilute only
6. Na_2SO_4 solut'n to $CaSO_4$ solut'n ..	$CaSO_4$ rusted.
7. Na_2SO_4 solut'n to $MgSO_4$ solut'n. ..	Na_2SO_4 rusted.
8. $MgCl_2$ solut'n to $CaSO_4$ solut'n	$CaSO_4$ rusted.

A second kind of concentration cell was constructed by tightly stoppering the lower end of a glass tube and suspending in it a cast-iron bar. The tube was half-filled with a concentrated salt lution, and then the upper half filled with a arm dilute salt solution, care being taken not to ix the two. The difference in density kept the lutions from mixing for a considerable period. ight such cells were constructed and allowed to and for 9 months. Table IV. contains the results this series of experiments.

---

* Smith and Shipley, Report, Engineering Institute of Canada, Saskatoon, Sask., Aug. 10, 1921. Eng. Inst. of Canada, Oct. 1921.

Table IV.

Corrosion of cast iron gravity cells for nine months.

Salt solution.	Area of exposed iron.	Weight of iron removed by corrosion.	Nature of surface corroded.
	sq. cm.	g.	
NaCl above .. $MgCl_2$ below ..	84	2·0	Some soft areas.
$MgSO_4$ above .. NaCl below ..	98	1·8	Soft areas above surface. Pits could be excavated ¼ in. deep. Cone and crater effect.
Same as 2, but mixed	132	1·9	Graphitic areas above.
Na_2SO_4 above .. $MgSO_4$ below ..	90	0·7	Graphitic areas over surface.
$MgSO_4$ above .. Na_2SO_4 below ..	112	3·2	Graphitic areas with a few deep pits.
Na_2SO_4 above .. $MgCl_2$ below ..	132	2·4	Softening quite general in patches.
$MgSO_4$ dilute ..	112	0·6	Uniform corrosion with little localisation.
$MgSO_4$ above .. NaCl below ..	112	1·2	Corrosion fairly well distributed.

Corrosion was most marked on the upper half of he cast iron bars. Reddish oxides of iron formed n the upper part of the solution, but on sinking to he bottom these became reduced to bluish-green ompounds. Graphitic softening occurred and some uite deep pits could be dug out with a knife blade. xperiment 7 was carried out with the iron immersed in a dilute magnesium sulphate solution nly. The loss in weight was less than in any of he other cells.*

The results of these experiments showed conclusively that concentration cell effects will bring about raphitic corrosion of cast iron. Such concentraion cells would be formed by the salt-impregnated oils in contact with the cast iron water pipes buried rom 6 to 10 feet beneath the surface. The impervious nature of the soil prevents the ground ater having a uniform concentration, and this ifference in concentration over short lengths f pipes must give a concentration cell effect. Vherever crystals of gypsum are in contact with he pipe, there the solution must be saturated. At hort distances removed from this point of contact, he soil solution will be less concentrated. Consequently, iron may pass out from the pipe into the ilute solution, and, as it is almost immediately emoved as insoluble hydrate, polarisation does not ccur. The reduction of the ferric iron to ferrous ron was observed in the cells constructed as above, hen the ferric oxide entered the cathode areas. This reduction would depolarise the cathode. If we ombine with this the migration of the colloidal erric hydroxide from anode to cathode, it is readily een how the whole process might continue indeinitely. Granted a concentration cell, the continuance of the reaction is dependent only upon a supply f oxygen, and this supply is provided by the oxygen eld in solution in ground waters.

Electric battery effect of a cell consisting of two cast iron electrodes in contact with two different soils.

Two cells were so constructed as to provide two ieces of cast iron not in contact with each other, ut both in contact with moist soils, the anode being in contact with limy silt and the cathode in contact with a clay soil, both soils being kept moist. One of these cells had an initial E.M.F. of 2·1 millivolts and the other 9·2 millivolts, which latter became 7·6 millivolts when filled with distilled water. Within the first three hours No. 1 rose 10 millivolts, and No. 2 rose 40 millivolts. In about three days No. 1 had reached 14 millivolts and No. 2 63 millivolts, which were reduced respectively to 12 and 48 millivolts after adding more water. The voltages varied for two months, alternately rising and falling. At the end of about two months, the cells having stood on open circuit, and without any addition of water, the polarity showed a reversal in both cells. Upon adding water once more, No. 1 recovered its original polarity and voltage, but No. 2 increased its negative polarity to 64 millivolts negative, while No. 1 rose to 66 millivolts positive.

These results show that soils of Winnipeg and vicinity, when in contact with iron, can of themselves set up an appreciable E.M.F. like that of a primary battery amply sufficient to decompose the iron.

The effect of gypsum.

Medinger (J. Gasbeleucht., 1918, **61**, 73, 89) noted the autocorrosion of cast iron pipes buried in a soil heavily charged with calcium sulphate during the occupation of Esch in the Grand Duchy of Luxembourg in 1916. The condition of the pipes and the nature of the corrosion products were almost identical with those found in Winnipeg. Direct action of stray currents or of free acids was known to be absent in this Luxembourg case. Apparently, the presence of calcium sulphate had something to do with the corrosion of the iron pipes.

The usual explanation for the autocorrosion of cast iron lies in the galvanic action set up by differences in composition of the metallic structure. The electric potential between graphite and iron is relatively high, and so, if in contact with an electrolyte, the E.M.F. of this cell would tend to drive the iron into solution. This tendency would be much enhanced should hydrogen ions be present. The clay soils of the Winnipeg district possess a high content of limestone, and since calcium carbonate gives basic products of hydrolysis, the ground waters would tend to be alkaline. But such waters in clay soils are impregnated with carbon dioxide, and this is sufficient to overcome the basic hydrolysis of calcium carbonate, so that a slightly acidic condition results. If now, gypsum be present, it will drive the equilibrium still further into the acidic region. Although calcium sulphate is a neutral salt, the effect of the added calcium ions is to cause an increase in the concentration of the hydrogen ions. The ionic products concerned are the following:—(i.) $(\mathrm{Ca})(\mathrm{CO_3})=\mathrm{K}$, (ii.) $(\mathrm{H})(\mathrm{CO_3})=\mathrm{K}$, (iii.) $(\mathrm{Ca})(\mathrm{SO_4})=\mathrm{K}$. When calcium sulphate is added, the (Ca) content in solution is increased and $(\mathrm{CO_3})$ must diminish proportionately. This affects the equilibrium in equation (ii.), for in order to satisfy the ionic product K when $(\mathrm{CO_3})$ diminishes, (H) must increase a corresponding amount. Consequently, gypsum causes an increased acidity in ground waters containing free carbon dioxide in contact with calcium carbonate.

This, probably, is the explanation of the fact that the ground waters of the Winnipeg district are slightly acid to phenolphthalein. Moreover, the presence of calcium sulphate would keep the ground waters continuously acid, and thus the corrosion of the cast iron due to the graphite-iron couple would proceed apace.

Summary.

(1) The corrosion of cast iron by soil salts is of the graphitic softening type.

---

* A ninth experiment in which a copper strip replaced the iron n a sodium chloride cell, gave a bluish insoluble precipitate of a copper alt and in time beautifully formed crystals of metallic copper ppeared on the lower end of the copper plate immersed in the oncentrated sodium chloride solution.

(2) Magnesium salts are the most corrosive of the soil salts, and magnesium sulphate is the most effective of the salts experimented with.

(3) Local action induced by naturally occurring concentration cells may easily be a factor in the soil corrosion of cast-iron pipes.

(4) The presence of calcium sulphate in a limy silt soil gives a slight acidity to the ground waters.

(5) Autocorrosion of the cast iron is promoted by this acidity of the ground waters due to the stimulation provided to the graphite-iron galvanic couple by the presence of the hydrogen ion. Iron more readily displaces hydrogen when the latter is present in the ionic condition.

The soil corrosion of iron structures is thus seen to be an electro-chemical process, complicated by its dependence upon several variables, of which the composition of the metal in the structure, the nature of the soil in contact with the metal, and the movements of the ground waters are the most important.

Part II.

The Soil Corrosion of Lead.

During the field investigation concerned with the damage of cast iron water-mains, it was observed that the lead service pipes showed evidence of corrosion. This disintegration usually took the form of pock-marked cavities incrusted with carbonate and sulphate of lead, but sometimes black, wart-like protuberances appeared on the lead pipe. Where the lead pipes were bent or in the neighbourhood of joints, criss-cross fissures occurred on the surface, together with the characteristic pock-marked cavities. Yellow and red oxides of lead appeared on the surface of the pipe, the transformation varying in depth but usually being about as deep as the fissures. There did not appear to be any special relation between the corrosion on the cast iron mains and the service pipes, as sometimes the lead was found deeply pitted and no corrosion on the iron pipe to which it was connected. The damage was frequently found in electrically negative and neutral areas and was quite marked on the lead pipe connected to the Mental Hospital water works system at Selkirk, Manitoba.

Laboratory investigation.

A series of experiments with lead plates immersed in salt solutions and in soils was carried out, extending over a period of fourteen months. Sodium carbonate was found to be the most corrosive salt, with magnesium sulphate and calcium carbonate next. Calcium carbonate saturated with carbon dioxide was the least corrosive. The soils also attacked the lead, one in particular, a sample of limy silt from Glasgow Street, standing next to the sodium carbonate as a corrosive agent. Several instances of corrosion in which the lead pipe was completely perforated had been reported from this neighbourhood. An analysis of the ground water and of the soil itself did not give any clue as to the cause of the virulence of this particular soil.

Lead plates exposing 37·5 sq. cm. surface immersed in salt solutions and water-saturated soils for 14 months:—

Solution.	Loss of weight in grams.
$CaCO_3$	0·32
$Ca(HCO_3)_2$	0·21
Na_2CO_3	0·82
$MgSO_4$	0·34
Soil—Man.-Gypsum	0·24
„ Glasgow Street	0·60
„ Stock Yards, St. Boniface	0·25

Corrosion of lead anodes and cathodes.

Three experiments were carried out in which lead anodes and cathodes were immersed in saturated soils contained in beakers. A current of ten milliamps. was passed continuously for three days, after which the series was discontinued, owing to the disintegration of the anodes. The loss at the anode was 150%, 210%, and 350% respectively, of that required by Faraday's law. This extra loss wa due to mechanical disintegration of the anode accompanying the formation of the oxides of lead. Such extensive losses indicate how futile it is t apply "corrosive coefficients" to the electrochemical decomposition of metals, whether it be b stray current, salt solutions, or soils.

The cathodes did not appear to be attacked at all in fact they showed a slight gain in weight. I order to find out whether cathodic corrosion woul occur at all, nine experiments were allowed to ru continuously for 60 days. The cathodes were plate of lead exposing 37·5 sq. cm. of surface, and th anodes, carbon brushes. These electrodes wer immersed in salt solutions of the carbonates, chlorides, and sulphates of calcium, magnesium, an sodium, and were set up in series and a current o from 4 to 10 milliamps. passed continuously for 6 days. The lead cathodes showed no evidence o corrosion, but the carbon anodes were badly decomposed.

Salt solution corrosion in the presence of nitrate.

Lead corrosion is frequently attributed to the presence of nitrates. Five experiments with lead immersed in salt solutions containing nitrate were carried out, the lead being immersed i 400 c.c. of the solutions for eight months. Saturated solutions of calcium sulphate and calcium carbonate, saturated with carbon dioxide, together with $N/10$ solutions of magnesium chloride, magnesium sulphate, and calcium chlorid constituted the series. To each was added one gra of ammonium nitrate. In every case the surface o the lead became immediately covered with a coating of black oxide of varying thickness. This coat wa very heavy in the case of the lead immersed in th magnesium sulphate solution, and quite thin in th calcium sulphate solution. Spots of lead carbonat with pits beneath were very marked on the plat immersed in the calcium carbonate saturated wit carbon dioxide. A few little nodules of lea sulphate formed here and there, over the surfa of the lead, in the calcium sulphate solution, whi quite deep pits were found beneath mixed deposi of lead carbonate and chloride in the chloride sol tions. These incrustations had formed at the poi of contact of the lead with the glass.

The attack on both lead and cast iron was fr quently observed to be more pronounced where t metal was in contact with a foreign substance, su as a pebble or the glass of the containing vessel, above.

The total loss of lead in the above experime was of the same order as that found in solutions the same salts, without the addition of the nitra Possibly the formation of the black oxide protect the lead from further corrosion, but whatever t cause, the nitrate did not markedly accelerate t corrosion under the conditions of the experiment.

Corrosion of lead plates and lead foil in soils.

Three lead plates and four wax-supported str of lead foil were buried in moist soil and left t disturbed for several months. The plates a strips were about six inches long and two inc wide, placed vertically in large glass tubes with soil packed closely around them. Each tube c tained two samples of soil, the upper half of lead strip being in one kind of soil and the lo half in another. The tubes were corked in order prevent evaporation. The lead strips remained the soils for almost eight months.

Examination at the end of this period disclo extensive corrosion. The following observati were made at the end of eight months:—

No. 1. Lead foil badly attacked at the upper d, completely perforated. Lower end of foil also rroded and blackened.

No. 2. All foil beyond end of wax completely stroyed. Lower end of foil also corroded and ickened.

No. 3. Corrosion completely through at upper d and lead disappeared. Lower end also per-ated. White lead salt formed.

No. 4. Both protruding ends of foil completely stroyed. Elsewhere perforations especially when soil found its way between the wax and the foil.

No. 5. Lead plate deeply pitted in portion buried surface soil. Pits $\frac{1}{32}$″ deep or more. Lead phate incrusted over pits.

No. 6. Slightly incrusted but not badly attacked.

No. 7. Badly corroded and incrusted. White rustant of lead carbonate $\frac{1}{32}$″ thick on both sides the upper end of the lead strip. Lower end not dly attacked. No sulphate.

The results of this series of experiments were cidedly illuminating. They established without ubt the autocorrosion of lead by the action of the l alone. The nature of this corrosion was quite nilar to that observed on the lead service pipes eady described, the same crater-like cavities rusted with lead carbonate and sulphate being med.

Cause and course of the corrosion.

The amphoteric character of lead as regards its emical reactions and the varied nature of the ssible products of corrosion, even under one set conditions, prevents the adoption of any one eory, to the exclusion of all others, as to the use and course of the corrosion. The lack of finite basic or acidic properties makes this metal ool of its environment. The end products of the rosion are determined by the relative solubility the compounds possible under the particular nditions under which the corrosion proceeds. ese possibilities are also conditioned by the idising or reducing nature of the environment. One of the first products found in the corrosion lead is the oxide, PbO. A coating of this oxide adily forms upon the surface of metallic lead, d is commonly believed to protect it from rrosion. This coating, however, is actually uble in water, the more so if the water is quite re, or if it carries much oxygen in solution. e sulphate of lead is slightly soluble in water, and e carbonate much less soluble, so that in the esence of the acid radicle of sulphuric or rbonic acid the lead hydroxide is easily transmed into carbonate or sulphate, and the sulphate y be transformed into the more insoluble rbonate.

According to several authorities lead has a culiar physical property of occurring in more an one physical modification, even in the same ece of metal, and these allotropic modifications y occur quite near together in the same metal. ese variations of the physical structure of the d possess different physical and electrical prorties, and these differing properties may persist a long time. Consequently adjacent portions lead in the same piece of metal may set up a lvanic couple when in contact with an electrolyte, d provide all the conditions required for eleclytic self-corrosion. This property of lead has en investigated by Lambert and Cullis (J. Chem. c., 1915, 107, 210), who have observed as follows:

" The electrolytic theory of corrosion is applicable lead. The passing of the metal into solution ich precedes corrosion is due to electrolytic tion between the electrically different parts of e mass of lead. In the case of chemically pure d the physical heterogeneity due to the presence different allotropic modifications of lead in the mass of the metal causes some parts of the mass to be electrically different from other parts, and these electrical differences persist for a long time after the preparation of the metal."

The practical effect of this allotropic property of lead is met with in practice by users of lead pipe. This property was observed, for instance, by the engineer of the Mental Hospital at Selkirk, who exhibited a piece of lead pipe taken out of the earth, where it had been buried for some years, which he said had " lost its life." That is to say, it was very brittle, had a different appearance from ordinary lead, and was no longer suitable for being worked.

Lambert and Cullis found that the purest lead that it was possible to produce by distillation in a vacuum was immediately corroded when immersed in water containing oxygen. The first product of corrosion under such circumstances is evidently lead hydroxide which, when there are no salts present, will appear as a precipitate.

It has also been ascertained by a number of observers that when lead, water, and oxygen are brought together hydrogen peroxide is formed. This is a strong oxidising agent, and accordingly might well account for the presence of the higher oxides of lead which are sometimes found amongst the corrosion products of lead pipe. We have observed several such transformations of lead. A lead union from a service pipe in Moose-Jaw, Saskatchewan, sent in for examination, was found to be almost wholly transformed into a red oxide of lead. A similar case was shown us by Mr. A. Blackie, City Chemist of Winnipeg, in which a considerable portion of a piece of lead pipe consisted of a red oxide of lead. Black oxide of lead was also observed on service pipes from River and Glasgow Avenues in Winnipeg. The corroded lead pipe taken from Selkirk had an insoluble lead compound adhering to the matrix of clay that surrounded the pipe, which was probably lead peroxide. There was not enough of it to make an analysis.

L. A. Stenger (Chem. and Met. Eng., 1920, 22, 965) attributes the soil corrosion of lead pipes as observed by him to two probable sources:—(1) The action of a concentration cell produced by differences of concentration of a salt in the soil in contact with the pipe, and (2) the presence in the soil of a substance subject to a change in valence, the bi-electrolyte causing corrosion in the cathode areas.

The first of the two causes above méntioned is similar to that described by the author in that section of this paper dealing with the self-corrosion of cast iron.

The effect on lead pipe would be similar to that observed on iron pipe, that is, the lead would pass into solution where the metal was in contact with the more dilute electrolyte. Both of these causes of corrosion, as outlined by Stenger, are external to the pipe, and not in any way dependent upon the lack of homogeneity in the lead.

In a recent article in " Metall und Erz," on the destructive action of mortar on zinc and lead, it is stated that lead is attacked by the limestone alone, and by mixtures of limestone and gypsum. This is substantiated by the work of R. H. Gaines, mentioned above, as well as by the case of corrosion noted at Charlottenburg, Germany.

H. S. Rawdon (U.S. Bureau of Standards, Bulletin No. 377, April, 1920) describes the results of a series of experiments on lead corrosion which show that the so-called allotropic modifications of lead are produced by corrosion in an electrolyte by the solvent action of the salt solution removing the foreign metals lying between the crystals of metallic lead in the mass of the lead. Even the purest commercial lead is subject to this attack, and since the metallic impurities removed lie above lead in the electrochemical series, this form of corrosion is quite parallel with the galvanic action brought about between graphite and iron in cast iron, when iron goes into solution and graphite remains in the pipe. In the case of lead pipe, the impurities are removed and the lead in unsupported crystals remains, imparting to the pipe that characteristic crystalline structure and brittleness which eventually destroys its usefulness.

These observations of Rawdon, supplemented by a later investigation* in which he used lead of 99·99% purity, subjected under tensile stress to the corrosion of salt solutions, clearly demonstrate the possibility of electrochemical destruction due to the presence of almost infinitesimal amounts of an impurity in the metal structure, when such a structure is in contact with water containing salts in solution. Rawdon also observed that the corrosion of lead was more rapid in an acid solution. Recent investigations in the laboratory of the University of Manitoba (not yet published) indicate that the soil waters of Winnipeg in the presence of calcium sulphate and carbonate are slightly acid, especially when they contain free carbon dioxide. Moreover, the function that mechanical stress plays in promoting the corrosion of lead would lead to widely diverging observations on the extent of the corrosion at different places on the same lead pipe, buried in the same soil. Whenever the pipe is bent, there the pipe may be considered to be under stress, and there intergranular cracks, as described by Rawdon, will first appear, the rapidity of the disintegration depending on the amount of the stress and the character of the soil solution.

We thus see how complicated is the whole matter of the corrosion of lead. Not only does the peculiar amphoteric character of lead enter into it, but also the physical character of the crystalline metal structure, the infinitesimal amounts of intergranular impurities present, and the stress to which the structure is subjected. These factors, combined with the complexities of the salt content of ground waters, make the whole question of the soil corrosion of lead a matter for most intensive study.

Summary.

(1) Salt solutions attack lead, a carbonate of lead being the final product when exposed to the air.

(2) Sodium carbonate was the most corrosive of the salts experimented with.

(3) Lead cathodes are not attacked by currents of from 4 to 10 milliamps.

(4) "Coefficients of corrosion" are not applicable to electrochemical decomposition.

(5) The presence of ammonium nitrate appears to inhibit corrosion by the formation of a protective coating of lead oxide over the surface. Such a protective coating may only be temporary.

(6) The soils of the Winnipeg district have a decidedly corrosive action on lead, the nature of the corrosion being usually that of a crater-like pitting of the surface, with or without an adhering deposit of lead sulphate or carbonate.

(7) Contact with a foreign substance localises the corrosion.

(8) The cause of the corrosion may be attributed to local galvanic action due to differences in the physical structure of the lead, to the presence of impurities lodged between the crystals of the lead, or to concentration cell effects.

GOLD METALLURGY OF THE WITWATERSRAND (TRANSVAAL).

BY W. CULLEN.

Although there have been frequent references to the metallurgy of gold on the so-called Rand (short for Witwatersrand), the only comprehensive paper in the Journal is that of H. de Mosenthal (J., 1894, 326). It was thought that possibly the best method of recording the changes or advances made since that date would be to describe a modern plant—one acknowledged to be almost the last word in gold metallurgy. But even since this paper was started revolutionary proposals have been made and have already been put into practice. The outstanding difference between 1894 and to-day is this, that whereas in the former year the value of the Transvaal gold output was £7,500,000, to-day it is almost five times as great, and in 1916 it amounted to £39,500,000. It may be mentioned that the Transvaal output of to-day is just 50% of the world's production.

"Banket," or the ore in which the gold occurs, is principally composed of silica. It is in the main a mass of silicious pebbles imbedded in a silicious matrix. The following is a typical analysis of deep level "banket"[1]:—SiO_2 86·76, FeS_2 2·75, Fe_2O_3 2·65, Al_2O_3 6·91, CaO trace, MgO 0·70%. The composition is, of course, not precisely the same throughout the field, though the uniformity is greater than one would expect.

The distribution of the gold in the ore is somewhat remarkable. The pebbles are barren, or practically so. Contrary to expectation the pyrites also carries comparatively little gold, *i.e.*, in the same manner as galena carries silver. Weight for weight, pyrites certainly contains more gold than the pyrites-free ore, but not very much more. The following table is interesting as showing the relationship between "pyrite" and gold in a graded sample of sand:—[2]

Grade.	% Pyrite (FeS_2).	Dwt. gold per ton.	Dwt. gold per 1% pyrite.
+ 60 Mesh	0·36	1·57	4·36
— 60 + 90 "	0·62	1·36	2·19
— 90 + 125 "	2·46	2·30	1·07
—125 + 200 "	1·20	1·80	0·67
— 200 "	2·94	3·44	0·86

There has been great controversy as to the distribution of the gold, but nothing has been discovered which would invalidate the following statement:— "Although rarely visible in the hand specimen, the gold can be easily studied under the microscope if specimens known to be rich in it are examined. In the slides which we have examined the noble metal occurs in irregular angular particles often lying on the periphery of individual pyrites crystals or in the interstices between aggregates of that mineral. We have seen no instance of the gold lying inside a homogeneous crystal or piece of pyrites. In many cases perfectly round pieces of pyrites may be observed to be bounded by gold particles."[3]

The subject of mining hardly comes within the scope of this paper, but it is noteworthy that whereas in 1894 Mr. Mosenthal stated that the deepest workings were about 400 ft., to-day plans are being matured to mine at a depth of 7000ft.[4] Several mines are drawing ore to-day from 5500 to 6000 feet, *i.e.*, below sea level, for the Rand in places is almost 6000 feet above sea level. Along the row of mines there are several of the largest and the deepest in the world. Mining at this great depth has introduced problems which have not yet been satisfactorily solved.

[1] "Rand Metallurgical Practice," Vol. I., p. 382.

[2] *Ibid.*, Vol. I., p. 349.

[3] Geological Society of S. Africa, Nov., 1904 (Hatch and Corstorphine).

In the year 1920 there were forty-seven producing companies on the Rand. The smallest milled 57,000 tons during the year 1921 and the largest 2,200,000 tons; the total amount milled was 24,000,000 tons, and the mining operations absorb the products of three very large explosives factories, the combined output of which is from 800,000—900,000 cases or, rather over 20,000 tons of high explosives per annum. At no other centre in the world is to be found such a concentration of mining and metallurgical operations.

In 1884, when the first record of gold production was made, the value was only £10,096. This had become £16,240,000 by 1898, and £39,500,000 by 1915—the year of greatest production.[5] In 1921 the production had fallen by rather more than 10% as compared with 1915, but owing to the gold premium the declared value was £42,000,000.

Under ordinary circumstances it takes from three to six years to develop and equip a mine, the period depending on the size of the proposition, the depth of the workings, and many other factors. Prior to the great war the capital involved in equipping a mine of economic size was about 1½ million sterling. To-day it would be doubled, and this expenditure includes practically nothing for power, for it is now generally purchased in bulk from a large power company.

I shall now proceed to describe in general terms the metallurgical plant of the modern section of the New Modderfontein Gold Mining Co., which produced gold to the value of £2,800,000, including premium, during the year 1921. This plant is in two sections, and for the present I only propose to deal with the section which has been quite recently erected.

When the ore reaches the surface it is tipped into huge storage bins. These discharge on to two conveyor belts, each of which is 193 feet long, and which run at a speed of 200 feet per minute. These belts convey the ore to a building in which the following operations, (*a*), (*b*), (*c*), and (*d*), take place:—

(*a*) The ore is first sprayed with water to free it from dust and so-called "fines." Unless this is done it is difficult to distinguish ore proper from barren rock in subsequent operations; the "fines" amount to about 40% of the total.

(*b*) The ore is discharged into cylindrical screens or trommels, which separate the "fines" from the coarse ore. These "fines" miss several of the subsequent operations. Nowadays they generally go to storage bins, and are fed either direct to the crusher stamps or to the tube mills. A plant milling 2000 tons of ore per day will therefore handle 800 tons of "fines."

(*c*) The bulk of the ore, which consists of the large pieces, is discharged from the interior of the screens on to long, continuously moving sorting belts which are slightly inclined. Along their whole length are the native sorters, who are very expert at their work. The waste rock is thrown into shoots, and is carried away by suitable transport arrangements to the waste dump. The amount of sorting varies very greatly. Some mines do not sort at all; others reject nearly 20%. Waste dumps, when carefully sampled, seldom go as high as 1 dwt. per ton=4s. 2d. The sorting depends very largely on the width and nature of the reef mined. It is, of course, impossible to sort the "fines."

(*d*) The large pieces of ore in due course reach four gyratory crushers, each driven by a 60-h.p. motor. These reduce the ore to a size suitable for the crusher plant. At the same time a certain proportion is set on one side in the form of pebbles for the tube mills and conveyed to bins in their neighbourhood by long belt conveyors.

(*e*) The crushed ore on leaving the gyratory crusher drops on to another conveyor belt, 3 ft. wide and 130 ft. long, which runs in an upward direction and delivers the ore by subsidiary belts to the stamp mill bins. From these the ore is discharged by feeders to stamps of the Nissen type. The crushed product is discharged as a pulp through the stamp screens; the coarser the mesh of these discharge screens the coarser the product and the higher the tonnage per stamp. A stamp has generally a drop of 8½—9 in., and the number of drops per minute is about 90. They are generally arranged in batteries of five, the five dies on which they drop being contained in one so-called mortar box. An 1850-lb. stamp on one mine crushes 28·5 tons per 24 hours through a screen aperture of 0·625 of an inch square. At the particular mine now being described a 1900-lb. Nissen stamp crushes 31·5 tons per 24 hours through a somewhat finer screen.

(*f*) The crushed ore, or pulp as it is now called, since it is mixed with several times its weight of water, is carried away from the stamps by launders or open channels and discharged into conical vessels called classifiers, which automatically separate out the finest pulp, usually called slime. This slime by-passes the immediately succeeding operation and goes direct to the slime department. The slime floats off at the top, while the coarser portion is discharged from the bottom of the cones direct to tube mills.

(*g*) Tube milling, the next operation, is perhaps the most important of all the mechanical processes connected with the treatment of the ore. Tube mills now do a great deal of the crushing work formerly done by stamps, and to a very large extent are displacing them altogether. The standard tube mill of to-day is 22 ft. long and 5 ft. 6 in. diameter, lined with a special steel or other material to resist wear. They make 28 revolutions per minute. The pebbles referred to under (*d*) are fed into the tube mill along with the coarse pulp, and by attrition reduce it to the required degree of fineness. The general practice is to have one tube mill for every ten stamps so that each tube mill has a grinding capacity of 200—300 tons per day, but the actual amount passed through is very much greater. The tube mill product nowadays is so fine that 90% passes the 90 linear mesh screen. As in the case of stamps, the output depends on the required degree of fineness.

(*h*) The crushed product now reaches the first stage in extracting the gold. This consists of amalgamation, and accounts for 45—65% of the precious metal. At a lower level than the tube mills there is a series of amalgamating tables which in the main consist of copper plates 53 sq. ft. superficial area. These slope away from the tube mill; there are five such plates for each mill. The preparation of these plates and their subsequent dressing or cleaning during operation require a high degree of skill. The process described by Mosenthal (*loc. cit.*) for the treatment of the amalgam is, apart from minor improvements, the same as is carried out to-day. In the early days of the Rand, and indeed up till about 1893, amalgamation was the only process in use for extracting the gold. The returns were so good that 40% of the gold content contained in the tailings could be neglected altogether. Later on those dumps of tailings, which survived the disintegrating effects of wind and rain, made a fine treasure trove to many an adventuring metallurgist.

---

[4] Institution of Mining and Metallurgy, 1921 (Clifford).
[5] Report of Transvaal Chamber of Mines, 1921, p. 187.

(*i*) The cyanide process in the aggregate treats 24 million tons of ore per annum at an over-all cost of only 2d.—3d. per ton for cyanide of sodium.[6] One mine in particular has reduced its consumption of cyanide to 0·18 lb. per ton of ore treated. On leaving the amalgamating plates the pulp, from which most of the coarse gold has been extracted by amalgamation, falls to a series of so-called sand pumps (centrifugal pumps of special construction to resist the abrasive effects of the sharp-edged pulp particles). Each pump is capable of lifting 1300 tons per hour to a height of 65 ft., and it discharges its contents into conical classifiers. These reject a certain proportion of their charge as being too coarse, and it goes back to the tube mills for re-grinding, appearing again in the same classifiers after undergoing further attrition.

(*j*) The uniform pulp from these cones is next sent to other cones, where it is separated into a coarse and fine product termed "sand" and "slime." These are treated separately with cyanide. The fine product is brought into intimate contact with an aerated dilute alkaline solution of sodium cyanide which dissolves the gold.

The sands are pumped to very large steel tanks. In the plant under discussion there are six such tanks each measuring 52½ ft. diam. by 10½ ft. deep. By appropriate appliances the cyanide solution is made to percolate through the contents, and is circulated by centrifugal pumps to aerate solution and sands. The great distinction between sand and slime is that the latter does not permit percolation. In practice sands present no treatment difficulties; they contain anything from 2·5 dwt. of gold per ton and upwards, depending on the grade of the original ore, and an extraction of 90% is easily obtained.

The slimes as they leave the cones gravitate to six special settling tanks—Dorr thickeners. In this plant, as its name indicates, the surplus water is removed, leaving a thick, easily manipulated slimy mass, which is pumped along with dilute cyanide solution to so-called Brown tanks. These are tall cylinders 45 ft. in height provided with air-agitating appliances which have the effect of bringing the minute particles of slime into most intimate contact with the dissolving solution. When all the gold is dissolved the contents of the Brown tanks are discharged into an immense storage tank in which there is air agitation to keep the contents fluid. From here the slime is fed to a Butters vacuum filter installation consisting of 300 filter leaves capable of handling 20,000 tons of dry slime per month. The extraction of gold is very high, as the residual slimes are practically barren. Before treatment they contain 1·5 dwt. per ton upwards.

The huge quantities of barren sand and slime produced are handled very cheaply by mechanical contrivances.

One of the features of the Rand is the immense sand dumps made up of untold millions of tons of tailing. They have formed the basis of certain small industries, but nowadays immense quantities are made up into a pulp and sent back into the stopes or mine workings, from which the material originally came as ore. In time it consolidates into a sort of friable sandstone which supports the roof or hanging wall and thus renders the workings much more safe. At the same time it permits more ore to be drawn from the mine than would otherwise be the case, for in mining at depth, so-called pillars have to be left to support the roof, otherwise the whole mine would collapse.

The wonderful developments of flotation within recent years have suggested the possibility of applying it to the ore of the Rand for the concentration of the gold. The proposition from the economic point of view is exceedingly attractive. According to the Minerals Separation Co., experiments have been very satisfactory. I quote the following:[7] *Crude ore from mine.* Assay value 9·9 dwt.; concentrate 14·8% of total; value 65·9 dwt.; residue value 0·42 dwt.; extraction 98·5%. *Slimes (untreated).* Assay value 1·34 dwt.; concentrate 16·4% of total; value 7·2 dwt.; residue value 0·20 dwt.; extraction 88·1%. *Old sand residues.* Assay value 1·75 dwt.; concentrate 10·3% of total; value 12·6 dwt.; residues 0·45 dwt.; extraction 74·1%. This looks poor, but it is in effect extraordinarily good under the circumstances, for through oxidation of the pyrites old tailings or residues are always very difficult to treat. No details are given as to how these results were obtained, but they indicate the possibility of entirely revolutionising all the intermediate stages of current metallurgical practice for certain classes of ore.

I now come to the alternative processes to which reference has already been made. On one point practically everyone is agreed nowadays—viz., that in the long run it pays to grind the ore as fine as possible. Gold is made more accessible, whether in the silicious matrix or in the pyrites and whether amalgamation is retained or not. To give an idea of what this means, I may say that 1d. per ton increased or decreased working costs or improvement in extraction, or the reverse, means to the industry rather more than £100,000 per annum.[8] Twenty years ago a 90% extraction of the total gold content was considered very good work. To-day anything lower than 95% is considered poor and this will certainly be improved upon. This means, translated into practice, that residues are being sent to the dumps which only contain gold to the value of 1s. per ton or about 0·25 dwt. These excellent results have not been brought about through radical departures, but by slow, persistent effort.

Early attempts to concentrate the gold into one product of small bulk in order to minimise treatment costs failed, as they were bound to do in the light of the distribution of gold in the ore. A good many years ago, however, G. A. and H. S. Denny suggested two radical departures from the orthodox practice—viz., (*a*) sliming the product from the stamps instead of segregating it into sands and slimes; (*b*) continuous circulation of cyanide solution from the stamps onwards.[9] These were to a certain extent carried into practice, but they did not commend themselves to the orthodox school.

No one has suggested that alternative processes will give much better extraction results. Indeed it would be difficult to conceive any process which could improve on the figures just quoted. The whole question, therefore, resolves itself into one of economics.

Metallurgical plants per ton of ore treated per day cost £215 in 1903.[10]. In 1914–15 this had been reduced to £107, but probably to-day the cost is higher than it was in 1903. The main claim for the alternative process is that while reducing working charges it will also materially reduce capital outlay. The problems involved belong essentially to the domain of the engineer, for Rand metallurgy being comparatively simple, costs depend mainly on the efficient and rapid handling of large masses of material.

The fact that there are three definite steps in the extraction of gold—viz., amalgamation, treatment of sand by cyanide, and treatment of slime by cyanide, leads to complication of plant, and moreover, although about 60% the free gold is won at a very early stage of the treatment process by amalgamation, gold amalgam is easily stolen, and there is a considerable leakage from this cause. Another undesirable feature of the orthodox process is the fact that the treatment of the sands, for instance, involves immense outlay in the way of tanks, for, from the beginning to the end of the process, it takes 10-12 days. The brothers Denny suggested the use of tube mills as a substitute for stamps a good many years ago.[11] Their contention was that on the one side ore breakers were encroaching on the domain of the stamp, while on the other side the tube mill was equally aggressive. Although the duty of the stamp was being gradually increased through the production of a coarser pulp, this was really being accomplished in a machine which was unsuited for the purpose from every point of view, and moreover the capital expenditure for stamps was very high. I now come to the latest scheme which is already working on a fairly large scale. There has been a good deal of general information about the new process in the technical press, but I am indebted to Mr. Carl Davis, consulting engineer to the Anglo-American Mining Corporation, for the details which follow. Associated with him in working out the process were Messrs. J. H. Willey and S. E. T. Ewing. Mr. Davis has had the courage of his convictions and has put his ideas into practice. In these days of high capital costs this is a far greater act than the bald statement would indicate.

[9] S. African Assoc. of Engineers, Vol. XI., p. 215 (Denny).

[10] "Rand Metallurgical Practice," Vol. II., p. 337.

"The original plant is laid out on standard lines, viz: separation of the ore hoisted into oversize and undersize by means of a grizzly; the undersize being sent direct to the mill storage bin and the oversize passing to sorting belts, where the waste and the tube mill feed rock is taken out; the balance is then passed through single stage gyratory crushers to the mill storage bin.

"From the mill storage bin the ore is crushed by heavy gravitation stamps, the ratio of stamps being ten to one tube mill; after leaving the mortar box the crushed ore is sent to a de-watering cone, the underflow of which enters the tube mill; the tube mill discharge is joined by the overflow from the de-watering cone, and the combined pulp is then passed over the amalgamating plates; from thence the total pulp is elevated to the primary classifiers, the underflow of which is returned to the tube mill circuit for re-grinding, whilst the overflow, which is the final pulp, passes to the secondary classifiers, which separate the pulp into sand and slime.

"The sand is caught in collecting tanks, and is then transferred in cyanide solution to the treatment tanks. The slime is caught in the slime collecting tanks and is then transferred to Pachuca (Brown) tanks for treatment and thence to the Butters plant for recovery of the gold-bearing solution.

"In the extension of the Springs Mines plant, the alteration from existing practice is as follows:—The average size of the fines is smaller on account of the total run of the mine ore being passed over a finer set grizzly, and the oversize after leaving the sorting belts goes to a steady head bin which will maintain a 'choked feed' to the crushers.

"This crusher portion, together with the 'fines,' passes to the tube mill storage bin, from which it is fed direct to the tube mills. The tube mill discharge flows into a Dorr classifier, the oversize returning to the mill for re-grinding, whilst the overflow, which is the final pulp, is elevated to the slime collectors, and is then transferred to the Pachuca tanks and the Butters plant as already described.

"With direct tube milling as above, the amount of reject pebble is very large, roughly about 20% of the total feed. This reject pebble is separated from the tube mill discharge by means of a trommel attached to the mill, and is then returned to the stamp mill bin by means of conveyor belts and a bucket elevator. In a new plant it would be necessary to instal a small breaking plant to deal with the reject pebbles, but the stamps being available, it was decided to utilise them.

"In the suggested plant the main differences compared with the new plant at Springs are as follows:

"Firstly, crushing in cyanide solution, and zinc dust precipitation (the Merrill process) and secondly, using a tube mill of very much larger capacity than the present standard 22 ft. by 5 ft. 6 in. tube mill—this mill to have a capacity of, say, 600 tons per 24 hours, and then stage classification by Dorr classifiers.

The saving in capital cost is very considerable, probably in the neighbourhood of 20—40%, and it is estimated that the saving in working costs will be from 20 to 25%. A plant of this design lends itself very readily to grinding in cyanide solution. This, in conjunction with zinc dust precipitation in Merrill presses, reduces the possibility of gold theft to a minimum.

"In addition to the foregoing, the above method, which renders finer grinding economically feasible, will, it is confidently anticipated (as a result of lengthy full-scale trials) result in a higher total extraction of the gold contents of the ores of the Far East Rand district."

The radical departures from orthodox practice consist in:—(*a*) The elimination of the stamp mill as a crusher. (*b*) The elimination of amalgamation. (*c*) The elimination of sands treatment by cyanide and the substitution therefor of one product "slimes," which is treated by cyanide. (*f*) The continuous presence of cyanide solution within a closed circuit right from the tube mills onward.

With reference to (*a*) the accepted practice is to crush in two stages after the breakers have done their work, viz., stamp milling followed by tube milling. In the "tubes" the main crushing is performed by selected pebbles of the ore itself consisting of 6 in. to 7 in. cubes which are withdrawn on the sorting tables before the ore reaches the breakers. The breakers are called upon to do more work than they did formerly and the capacity of the tube mill has also been increased through the feeding to it of a coarser product. With regard to (*b*) no comment is required.

Item (*c*) involves much finer grinding than was practiced before, and to this extent will probably be slightly more costly, but on the other hand will make for higher extraction of the gold content.

In regard to (*f*) as the cyanide will be in contact with the ore all the time, maximum extraction should be secured and there should be a minimum loss of cyanide through oxidation.

When the cyanide process was introduced, it was found that the slimes, which formed about 25% of the product (Mosenthal says 40%), could not be leached, and they were therefore discarded, but this meant the construction of expensive slime dams. Moreover they contained anything from 1½ dwt. per ton of gold upwards, equal in value to rather more than 6s. As the difficulties of treating slimes were gradually overcome these slimes became in turn treasure troves, as the tailings did before them, and treatment of accumulated slimes has assisted in swelling the profits of many a mine, whose profits from ordinary sources were commencing to dwindle. In the early days it was found advisable to add lime at the earliest possible stage, in the first instance to counteract acidity, but it was subsequently found that it assisted in the settling of the slimes and protected the cyanide. Indeed, it was along the lines of settling and decantation that the problem was solved in the end, and apart from improvements made in settling, there has been little change in slimes treatment for many years.

---

[11] Chem. Met. and Min. Soc. of S. Africa, Vol. IV., p. 217 (Denny).

To-day slimes are not only treated more cheaply than sands, but, as might be inferred, the extraction is also better.

As showing the changes brought about by improvement and modifications in the processes, the following tables are of interest.[12]

		1903	1905	1910	1917
		%	%	%	%
Work done by	stamp mill	100	95	65	50
„	tube „	Nil.	5	35	50
„	concentrating	5·5	4·5	1·0	Nil.
„	sand plant	75·0	72·5	67·0	60
„	slime „	19·5	23·0	32·0	40

Thus, so far as crushing is concerned, nineteen years ago the stamp did all the work: in 1917 it did only 50%, the tube mills being responsible for the rest. To-day tube mills do even more, and as has been indicated, it is proposed that the stamp should be eliminated altogether. Concurrently, and owing to finer grinding, the percentage of slime produced and treated had risen to 40% by 1917. To-day the figure must be considerably higher, and if the new processes are generally adopted, sands, as such, will not be produced at all.

The solution of gold by cyanide takes place according to the equation:—

$$2Au+4NaCN+O+H_2O=2AuNa(CN)_2+2NaOH.$$

Working cyanide solutions contain, in addition to sodium cyanide, potassium and calcium cyanides, as well as thiocyanates and most probably ferrocyanides. Efficient aeration is essential for the success of the reaction. The gold in solution is precipitated or deposited on zinc shavings:—

$$2NaAu(CN)_2+2NaOH+Zn=2Au+Zn(OH)_2+4NaCN.$$

Compared with other wet metallurgical processes, that of gold extraction on the Rand can be classed as simple, for, apart from pyrites, there are no ingredients which can cause complications. The ore can be classed as free milling, for with the fine grinding which is now universal, even pyrites yields up its gold without trouble. Successful extraction depends in the main on fine comminution with consequent exposure of the gold particles. Moreover, the gold does not exist in an ultra-fine form, otherwise the physical process of amalgamation would not have been so successful in the past. Such complications as do arise in practice are mainly due to weathering of the ore underground or when stored at the surface in dumps; before the ore reaches the mill one or several of the following reactions are possible.[13] $FeS_2=FeS+S$; $S+O_2=SO_2$; $SO_2+O+H_2O=H_2SO_4$; $H_2SO_4+FeS=FeSO_4+H_2S$; $2FeSO_4+H_2SO_4+O=Fe_2(SO_4)_3+H_2O$; $Fe_2(SO_4)_3+2H_2O=Fe_2O_3SO_3+2H_2SO_4$; $Fe_2O_3SO_3+4H_2O=2Fe(OH)_3+H_2SO_4$. All these reactions actually take place and the mine water is invariably acid. This causes great wear and tear on pipes, pumps and machinery generally, notwithstanding a generous employment of lime. The free acid also decomposes the silicates present in the ore and the liberated gelatinous silica interferes with the subsequent slime settling.

Later on when the ore reaches the stamps and the tube mills the pyrites seems liable to reduction to ferrous sulphide by metallic iron. This serves as a starting point for a series of reactions similar to the above, but later on in the process.

That the amount of sulphuric acid produced is great is indicated by the fact that during cold weather the service pipes become choked with calcium sulphate which is very difficult to remove. However, the presence of calcium sulphate in these relatively large quantities apparently does no particular harm chemically.

Theoretically one pound of cyanide dissolves one and a half pounds of gold in the presence of one ounce of oxygen, but in practice the consumption of cyanide is much greater, for the oxygen is used up in other directions, as is also the cyanide itself. The following reactions are indicative of these possibilities[14]:—

(*a*) $FeS+6NaCN=Na_4Fe(CN)_6+Na_2S.$
$Na_2S+NaCN+O+H_2O=NaCNS+2NaOH.$
(*b*) $2FeS+9O+3H_2O+2CaO=2Fe(OH)_3+2CaSO_4.$
(*c*) $Fe(OH)_2+6NaCN=Na_4Fe(CN)_6+2NaOH.$
(*d*) $2Fe(OH)_2+O+H_2O=2Fe(OH)_3.$

So far no reference has been made to the presence of soluble sulphides, but that this is a possibility is indicated by equation (*a*). Moreover, all commercial cyanide contains sulphide in small quantity. These sulphides are rendered partially innocuous by sprinkling the sands or slimes with lead acetate or nitrate, but the lead sulphide also uses up available cyanide and oxygen; the alkali sulphides which escape the action of the soluble lead salts most likely behave as follows:—$Na_2S+NaCN+O+H_2O=NaCNS+2NaOH$. All of the foregoing indicate that the working cyanide solution is a much more complicated affair than it is generally supposed to be.

In the precipitation of gold from the sodium auro-cyanide by means of zinc nascent hydrogen is in reality the active precipitant. The process is therefore a reducing one, whereas the solution of the gold in cyanide is an oxidation one. About forty times the theoretical quantity of zinc is used up during preciptation, but as lead-coated zinc in filiform condition is very readily oxidised both in the moist and wet state the explanation for this excess consumption is not far to seek. In this connexion the Crowe process is now being generally introduced into modern plants. It consists in getting rid of the dissolved oxygen by evacuation and through this means the zinc consumption has been very considerably reduced; indeed, the reduction is so great that it is not necessary to treat the zinc-gold slime with acid.

Zinc hydroxide readily dissolves in fairly strong cyanide solution forming double zinc cyanide and sodium zincate—the so-salled "white precipitate" which is so troublesome in cold weather; but even zinc itself is attacked by cyanide as follows:—

$$Zn+4NaCN+2H_2O=Na_2Zn(CN)_4+2NaOH+H_2.$$

This sodium zinc cyanide is itself a solvent for gold in the presence of alkali which, however, is always produced as has just been shown.

Now the gold-bearing solutions do not readily part with their gold to the zinc even in the form of very fine shavings, 0·002 in. thick, and from what has just been said the reasons are not far to seek. One pound weight of zinc in the form of shavings exposes thirty square feet of surface and one ton has therefore a surface of 1·4 acres. An ordinary precipitation plant has from 10—20 tons of shavings in the "boxes" and this cannot be materially reduced, for the actual zinc surface available for precipitation is small. A great advance in acceleration of precipitation was made when the zinc-lead couple was introduced. The zinc shavings are merely dipped in a solution of a soluble lead salt such as nitrate or acetate, when a coating of metallic lead is formed. This facilitates the evolution of hydrogen from the decomposition of the water, for the essential requisite for the precipitation of gold from the sodium aurocyanide is intimate contact with the nascent hydrogen.

We have now reached the stage of having the gold precipitated on the zinc. In the subsequent operations the mixture of zinc, gold, base metals, and impurities generally is treated with sulphuric acid or nitre cake; the residue is filter pressed, calcined, melted down with appropriate fluxes and cast into ingots which, until quite recently, have been shipped to London for refining.

In 1894 the lowest consumption of cyanide per ton of tailings was 1·16 lb.; the quantity occasionally exceeded 2 lb. per ton. To-day the amount, in a few mines at any rate, is just one-tenth of this. In 1894 the strength of the cyanide solutions seemed to vary between 0·3 and 0·6%. To-day the solutions are only one-fifth to one-tenth as strong. There are naturally no figures available for zinc consumption, but in 1914 the consumption was only 0·32 lb. per ton, and to-day it is even lower, with every prospect of becoming lower still. Mercury—another somewhat expensive item on the "stores" side—disappeared to the tune of ½ lb. per ton in 1894; to-day's figure is the remarkably low one of 0·1 oz. per ton milled. Then in 1914 caustic soda was the protective alkali used, and sometimes the consumption was as much as ½ lb. per ton. To-day lime has taken its place, and besides being equally effective as a protector it has the great advantage, as already pointed out, of facilitating the settling of the slimes.

[12] "Rand Metallurgical Practice," Vol. II., p. 12.

[13] Chem. Met. and Min. Soc. of S. Africa, Vol. II., pp. 98, 112; Vol. VII., p. 315.

As on the mechanical side, there have been no epoch-marking developments in the cyanide process during the last twenty years. Indeed, the figures just quoted indicate rather steady and continuous improvement in detail, and this process still goes on. Some years ago J. S. McArthur,[15] the father of the cyanide process, suggested the substitution of zinc wafers or strips for the shavings, as he had found them an improvement in another connexion. Practical trials proved very unsatisfactory. Mention has been already made of the Merrill process of precipitation, which is perhaps the most radical departure within recent years. In essentials it consists of emulsifying zinc dust with the gold-bearing cyanide solution and forcing the mixture through a filter-press of special construction. In the case of fairly strong solutions 80% of the gold is precipitated at once, and the balance is precipitated completely on the leaves where the zinc-gold mixture has already accumulated. It is claimed that by this method the zinc consumption is materially reduced; but as the total is now only about 0·3 lb. per ton of ore crushed, the actual saving under this head cannot be very great.

Prior to the Boer War the old Transvaal Republic had its own refinery and mint at Pretoria. Naturally, it was on quite a small scale. When war broke out in 1914 it was decided that both refining and minting should be revived. Fortunately much of the old Boer plant was available, and it was indeed put into working order, but was never worked. The idea, however, of South Africa having its own refinery and mint caught the popular fancy. The refinery, which started up quite recently, is situated on the Rand a few miles from Johannesburg, but the mint is at Pretoria. It is the largest of its kind in the world, but the mint is not on such an ambitious scale.

In the refining process the bullion[14] is first melted in a plumbago crucible with suitable fluxes, which gives a preliminary purification. The ingot produced is next assayed, and if it contains too much refractory metal, or metal which would interfere too much with the ordinary refining process, it is submitted to a second and more drastic fusion, treatment with air, chlorine, nitre, or possibly all three. For the final stages batches of about 700 oz. are melted with a borax flux in clay crucibles, standing in plumbago guard crucibles for safety. When the bullion is melted a clay pipe-stem is introduced and chlorine and air passed through the molten mass. The base metals and the silver are converted into chlorides, which float on the surface and are baled off. The end-point is much the same as in a gold assay. This fine gold is re-melted in a large tilting furnace and cast into bars of about 400 oz. each for export.

Communications.

ORGANIC IMPURITIES IN COMMERCIAL NITRIC ACID AND THEIR EFFECT IN THE MANUFACTURE OF NITROGLYCERIN.

BY F. A. F. CRAWFORD, B.A., A.I.C.

The following investigation was undertaken for the purpose of explaining certain irregularities in the manufacture of nitroglycerin.

In the manufacture of nitroglycerin which is to be used in the preparation of either blasting explosives or cordite, it is usually stipulated that the finished nitroglycerin shall stand the Abel heat test for not less than 10 minutes. Practically every nitroglycerin factory has, at one time or other, experienced periods during which the nitroglycerin produced failed to pass this test, and although many efforts have been made to ascertain the cause of the low heat test, no explanation has been put forward which would satisfactorily account for all the variations which have been noted. A very pronounced period of low heat tests has recently been experienced at the Ardeer nitroglycerin factories of Nobel Industries, Ltd., and as most careful analyses failed to detect any abnormality in the materials used, and as no modification had been introduced into the process of manufacture, the following investigation was instituted in order to determine the cause of the trouble.

Tracing cause of low heat test.

Since no help could be obtained from analysis, the only method of attack was to duplicate the manufacturing results by experiments on the small scale and then by a process of elimination to determine the factor or factors causing the trouble.

Nitroglycerin is manufactured by adding glycerin to strong mixed acid of the composition, HNO_3 40—44%, H_2SO_4 55—59%, H_2O 0·5—2·0%. After nitration is complete the mixture is allowed to stand and the nitroglycerin, which separates above the acid layer, is removed and washed with water and sodium carbonate solution.

It was found that when plant materials were used on a small scale the resulting nitroglycerin showed low heat tests; the tests, however, varied with the washing process, so that washing conditions had to be standardised to give results similar to the manufacturing figures and these conditions were then kept constant throughout the investigation. Nitroglycerin made with chemically pure materials gave good heat tests, and by gradually substituting plant instead of chemically pure materials it was ascertained that the introduction of plant nitric acid invariably lowered the heat test, as shown in the following table:—

Average heat tests of nitroglycerin made on small scale with various materials.

Mixed acid composed of.		Glycerin.		Average heat test of N/G. min.
Plant mixed acid No. 1	..	Plant No. 1538	..	9½
" " " No. 2	..	" "	..	5½
Pure oleum and pure nitric acid	..	Price's treble distilled glycerin	..	14½
Pure oleum and pure nitric acid	..	Plant No. 1538	..	14½
Plant oleum and pure nitric acid	..	" "	..	15½
Pure oleum and plant nitric acid	..	" "	..	8

The heat tests given by mixed acid No. 2 were so exceptionally low that it was decided to investigate the acid as well as the plant nitric acid and for convenience the results with mixed acid are described first.

[16] S. African Mining J., Dec. 3rd, 1921, p. 467.

Investigation of a mixed acid which gave nitroglycerin of low heat test.

Mixed acid No. 2 was distilled and the nitric acid driven off was collected in four equal fractions, sufficient acid being distilled to enable small-scale charges of glycerin to be nitrated with each fraction. The heat-tests of the nitroglycerins for the respective fractions were 3½, 9, 13½, and 13½ mins. respectively, the last figure being obtained for the residual nitric acid. These results show that the impurity causing the low heat test passed over almost completely with the first fraction, very little being present in the second fraction, and practically none in the last two fractions. The next question was whether the substance actually causing the low heat tests was formed during nitration or whether it was present as such in the acid before nitration. Some first fraction nitric acid, obtained as above, was diluted with water to 5% strength; nitroglycerin of good heat test was then shaken with this dilute acid and the nitroglycerin separated and given the standard washing treatment. The nitroglycerin before treatment gave a 14 min. heat test, whereas after treatment the heat test was only 5 min.; now, as it is highly improbable that any reaction would have taken place with this dilute acid, the impurity must be present as such in the original acid and is merely extracted by the nitroglycerin in the nitration process.

Distillation of the first fraction nitric acid alone did not effect a further concentration of the impurity, but it was found that if the nitric acid were carefully diluted by means of ice below 68% strength and then distilled, the first portion of the distillate had a very marked effect on the heat test of nitroglycerin. About 300 lb. of mixed acid was gradually treated in above manner, namely, 25% of the nitric acid was distilled over; this nitric acid was then poured on to ice and again distilled. The first fractions obtained in this last operation were then fractionated, particular care being taken during all the operations to allow no volatile matter to escape, when finally a distillate was obtained which contained drops of oil. One part of the oil added to 20,000 of nitroglycerin lowered its heat test from 16 to 5 min. The oil had a peculiar odour and responded to the qualitative tests described later, but owing to the small amount of oil available a full analysis could not be made on this sample. A more convenient source of supply of this oil was found in plant first runnings and therefore experiments on mixed acid were discontinued.

In addition to the oil mentioned above, a small amount of a white solid was isolated in the distillation of the nitric acid. This solid distilled over after the oil, but as it had no effect on the heat test of nitroglycerin, its properties have not yet been investigated.

Isolation of impurity from plant nitric acid.

The nitric acid used in making mixed acid is manufactured by distilling sodium nitrate with 94% sulphuric acid; samples of nitric acid from the receivers were drawn throughout a large-scale distillation, and small-scale nitrations were then performed and gave products with the following heat tests: Product from first runnings 3, middle runnings 10, end runnings 11, absorption tower 10 mins. These results are similar to those obtained by the distillation of mixed acid and show that the impurity passes over in the first stages of distillation. The plant "first runnings," however, contain a considerable quantity of iodine, and when the acid is diluted iodine is liberated and passes over with the distillate and contaminates the oily impurity, from which it cannot be separated. To overcome this difficulty the nitric acid was mixed with sulphuric acid and one third of the nitric acid distilled off. This treatment was useful for two reasons, viz., the iodine remained behind, probably as iodic acid, and a distillate richer in impurity was obtained. The dilution and subsequent distillation of the nitric acid was carried out in one continuous operation by means of a small glass tower partially packed with glass beads. The nitric acid was mixed with water at the top of the tower, and then the introduction of a jet of steam supplied sufficient heat to distil off the impurity, while the diluted nitric acid passed to the bottom of the tower and was run away by means of a swan-neck tube. The distillate obtained in this latter operation was fractionated and yielded drops of oil. The oil was collected, washed with sodium carbonate solution and water, dried, filtered, and subsequently distilled *in vacuo* in a special micro-apparatus. The yield of oil from the nitric acid was about 0·005%.

Identification of impurity causing low heat tests.

Attempts were made to fractionate the oily im- that of tetranitromethane, but with a very satisfactory; evidence was, however, obtained that the oil was a mixture, but owing to the small quantity available this method of separation was abandoned.

The oil is colourless, with an odour resembling that of tetranitromethane, but with a very unpleasant action on the eyes and nose; it is insoluble in water and in sodium carbonate solution, but dissolves slowly in caustic potash, giving a yellow solution; the yellow colour gradually disappears on addition of a strong mineral acid, indicating the presence of a pseudo-acid, and the solution obtained gives the tests for a chloride. The oil quickly evolves nitrogen with hydrazine and caustic potash in accordance with the reaction for tetranitro- and monochlorotrinitro-methane described by Macbeth[1], it dissolves in sodium sulphite solution, liberates iodine from potassium iodide, and forms a yellow crystalline precipitate with alcoholic potash similar to potassium nitroform. The sp. gr. of the oil is 1·6646 at 15·5° C. At −10° it deposits a few crystals and freezes to a white solid when placed in a freezing mixture of solid carbon dioxide and ether. The oil boils at 119° C. (Siwoloboff's method) with decomposition and is very volatile. It gives a red coloration with anisol (tetranitromethane gives an intense red, monochlorotrinitromethane a deep yellow, dichlorodinitromethane a very pale yellowish green, and chloropicrin none.)

The impurity also gives the following colour reaction which denotes the presence of dichlorodinitromethane: 2 c.c. of 50% caustic potash is placed in a test tube and 1 drop of impurity and 1 c.c. of absolute alcohol added; the tube is gently shaken, but not sufficiently to mix the two layers, and the whole warmed. A deep wine-red colour appears at the junction of the two liquids.

Difficulty was experienced in the estimation of carbon in the impurity, the rapid evolution of nitrous fumes tending to give results more than 10% too high; with a specially long combustion tube and careful regulation of the combustion, however, good results were obtained. No special precautions were taken with the nitrogen estimations and the figures are therefore probably a little low. The analyses are shown in comparison with theoretical figures for compounds which might be present.

The molecular weight shown for the impurity was determined by the freezing point method, using benzene as solvent. The low molecular weight, low carbon content, and physical properties preclude the presence of anything but methane derivatives—except in small amounts—and as the oil does not react with sodium carbonate solution and is stable in hot strong nitric acid, nitroform and unsaturated compounds must be absent. The oil must therefore be a mixture of chloronitro derivatives of methane, and the analysis agrees with the supposition that it is a mixture of approximately 40% of tetranitromethane with 60% of chlorotrinitromethane, but it could also represent a smaller percentage of dichlorodinitromethane or chloropicrin with a correspondingly larger proportion of tetranitromethane.

---

[1] Chem. Soc. Trans., 1921, 119, 354.

Elementary analysis of impurity and possible constituents.

Substance.	H %	C %	N %	Cl %	O (Diff.). %	Mol. wt.
Impurity	—	6·22	24·4	11·12	58·24	189
Tetranitromethane ..	—	6·12	28·57	—	65·31	196
Monochlorotrinitromethane	—	6·47	22·64	19·12	48·23	185·46
Dichlorodinitromethane	—	6·86	16·01	40·54	36·59	174·9
Chloropicrin	—	7·30	8·52	64·73	19·45	164·38
Nitroform	0·6	7·95	27·81	—	63·64	151
Monochloropentanitroethane	—	8·29	24·18	12·24	55·29	289·5

It is very difficult to separate or estimate the various constituents of a mixture of chloronitromethanes with tetranitromethane owing to their closely allied properties, but an approximate estimate of the composition was obtained as follows: Samples of the chloronitro derivatives of methane were prepared, as will be described in a subsequent paper, and the formation of the potassium salts by means of potassium ethoxide was studied. When a strong alcoholic solution of tetranitromethane is mixed with potassium ethoxide an almost theoretical yield of potassium nitroform is precipitated as a yellow powder mixed with a small percentage of potassium nitrate[2]; with chlorotrinitromethane the potassium nitroform is mixed with potassium chloride. Dichlorodinitromethane gives a precipitate of potassium chloronitroform, $KCCl(NO_2)_2$, mixed with potassium chloride, but chloropicrin is completely decomposed, giving a precipitate of potassium chloride mixed with potassium nitrite, tetra-ethyl orthocarbonate remaining in solution.[3]

The percentage of dichlorodinitromethane in a mixture of tetranitromethane and chloronitromethanes can be roughly determined by treating the mixture with potassium ethoxide and analysing the precipitate. The potassium chloride is determined by direct titration with silver nitrate and the total chlorine by Carius' method; the difference between these two results gives the organic chlorine which represents one half of the chlorine originally present as dichlorodinitromethane. Experiments with pure dichlorodinitromethane and with synthetic mixtures gave low figures for the amount of dichloro compound, but by applying a correction an approximate idea of the dichloro compound present in the impurity can be obtained, as shown below. It should be noted that these determinations were carried out in strong solution, under standard conditions, and the salts were analysed as quickly as possible, as they decompose very readily.

Analysis of mixed potassium salts from impurity:

Mixed potassium salts; yield on weight of oil 99·0%, potassium chloride in salts 4·6%, total potassium in salts (actual) 22·7%, total potassium in salts (theoretical) 22·2%, organic chlorine 2·12%, dichlorodinitromethane in oil 10·6%, dichlorodinitromethane in oil (corrected result) 13—14%.

In calculating the theoretical percentage of total potassium in the salts it has been assumed that the ionic chloride is present as potassium chloride, the organic chlorine as the salt obtained from dichlorodinitromethane and the remainder of the salt is calculated as potassium nitroform; it will be seen that both the actual and calculated figures are close, although the "actual" figure is slightly high, due to the presence of a small amount of potassium nitrate. The results show 13—14% of dichlorodinitromethane to be present in the oil. The remaining chlorine may be present as the monochloro-derivative or as chloropicrin, and to decide this point the effect of these compounds on the heat test of nitroglycerin was tried. The method employed was to add known weights of these substances to nitroglycerin of good heat test and then subject the nitroglycerin to double the normal washing process, the heat test being taken before and after each washing. The results are given below.

Effect of nitrochloro compounds of methane on the heat test of nitroglycerin:

Substance added.	Percentage added.	Heat test of nitroglycerin. Before addition. min.	After addition. min.	After 1st wash. min.	After 2nd wash. min.
Tetranitromethane	0·01 ..	16	2	7	13
Monochlorotrinitromethane ..	0·01 ..	16	1½	2	2
Dichlorodinitromethane ..	0·01 ..	17	17	—	—
Chloropicrin	0·01 ..	16	16	—	—
Impurity	0·01 ..	16	2	5	7

The above results are very interesting; chloropicrin and dichlorodinitromethane in the concentrations used have no effect on the heat test, whereas monochlorotrinitro- and tetranitro-methane have a marked effect. There is, however, an essential difference between the last two compounds in that tetranitromethane can be fairly readily removed by washing, but the monochloro compound is very difficult to remove and it is undoubtedly this last compound which causes the worst trouble in manufacture. The low heat test caused by the presence of the impurity is more difficult to improve by washing treatment than that shown by the presence of tetranitromethane, and it may therefore be inferred that practically the whole of the remaining chlorine, after allowance has been made for the dichloro compound, is present as monochlorotrinitromethane, although a trace of chloropicrin may also be present. The approximate composition of the impurity is therefore: Tetranitromethane 50—55%, monochlorotrinitromethane 30—35%, dichlorodinitromethane 12—15%. It should be understood that although the above represents the impurity actually isolated, the relative proportions of the constituents will vary from time to time, according to circumstances as described in the next section.

Origin of impurity in nitric acid.

As already mentioned, the impurity passed over with the first runnings in a large-scale distillation, and to ascertain what gave rise to its formation, small-scale distillations were carried out using pure and also plant material, sufficient nitric acid being distilled to enable nitroglycerin to be made and washed, as previously described.

One sample of sodium nitrate gave good tests (14 min.) even with plant sulphuric acid. The other two samples gave low tests with this acid (5 and 2 mins.), and the tests were not improved by the substitution of pure for plant sulphuric acid; there is little doubt, therefore, that the cause lies with the nitrate.

In a paper by Datta (J. Amer. Chem. Soc., 1916, 1813) it is stated that chloropicrin and chloronitromethanes were obtained by treating a large number of substances with *aqua regia*; now commercial sodium nitrate always contains chlorides and traces of organic matter, and when it is considered that during the distillation process there is a large excess of nitric acid present, it is not surprising that tetranitromethane and chlorotrinitromethane should be formed. Further evidence on the formation of the monochloro compound will be given in the subsequent paper. Sodium nitrate No. 3, which gave good tests, was a very "clean" sample, while sample No. 2, which gave the worst tests, contained a considerable amount of visible organic impurities such as pieces of wood, bag, etc.; starch was also found in certain portions of it, and any of these in the presence of chloride would be capable of giving rise to the impurity. It is highly probable that traces of chloronitromethanes will be formed in almost any nitric acid prepared by distillation of sodium nitrate and sulphuric acid, as it is almost impossible to exclude a small amount of organic matter. The relative proportion of the various chloro compounds will, of course, depend on the relative proportion of chlorine and organic matter present and possibly also on the nature of the organic matter.

Summary.

An oil has been isolated from commercial nitric acid and has been shown to be composed of a mixture of tetranitromethane, monochlorotrinitromethane, dichlorodinitromethane, and possibly a trace of chloropicrin.

The formation of these compounds is probably due to the presence of traces of chlorides and of organic matter in the sodium nitrate from which the nitric acid is made, and these substances are therefore probably present to a greater or less extent in all samples of commercial nitric acid. The question of the occurrence and possible effect of organic matter in certain types of sulphuric acid used for the preparation of nitric acid is being investigated.

The above oil has been shown to cause very low heat tests of nitroglycerin in concentrations of 1 in 20,000; the active ingredients are tetranitromethane and monochlorotrinitromethane, the latter causing most trouble in manufacture owing to the difficulty experienced in washing it out of the nitroglycerin. Dichlorodinitromethane and chloropicrin in small concentration have no effect on the heat test of nitroglycerin.

In conclusion I wish to express my thanks to Messrs. Nobel Industries, Ltd., and particularly to Mr. Wm. Rintoul, O.B.E., for permission to publish this paper.

My thanks are also due to Mr. W. J. Boyd for carrying out experimental work in connexion with the identification of the compounds.

STUDIES IN VULCANISATION.

SOME FURTHER EFFECTS OF ACCELERATION ON THE RUBBER STRESS-STRAIN CURVE.

BY P. SCHIDROWITZ AND P. L. BEAN.

In a previous paper,[*] the effect of an active organic accelerator on the vulcanisation properties of rubber-sulphur mixings in the presence or zinc oxide was dealt with. A section of this paper dealt particularly with the effect of varying the amount of the accelerator, using a constant proportion of sulphur to rubber. The present communication deals with the reverse conditions, the proportion of accelerator to rubber being kept constant, with varying amounts of sulphur.

The accelerator employed, as before, was piperidyldithiocarbamate of piperidine, dispersed on colloidal clay, the proportion of the organic compound being 25%.

The rubber used was throughout the same batch of a standard thin pale crêpe. The base mixing consisted of rubber 100, zinc oxide 2½, accelerator 0·5, colloidal clay 1·5, and on this basis six mixings were made up, the amount of sulphur added varying from 1 to 4 parts. The mixings were made in the usual way on open rolls, the accelerator being added last, mixed with the zinc oxide, the temperature of the rolls being kept as low as possible. The total sulphur in the mixings was then estimated by a standard method. 24 hours elapsed in every case between mixing and vulcanisation, which was carried out in ring moulds in the press, at a temperature of 141° C. (=40 lb. steam), the plates being heated before introduction of the moulds, and no rise given. After resting for five days, ring test pieces were cut and tested on the Schopper machine. Simultaneously estimations of the free sulphur were made by the usual method, the combined sulphur being estimated by difference. The times of cure were 1, 2½, 5, 10, 20, 30, 40 minutes. Finding that mixes A and B were greatly undercured at both 20 and 40 minutes, shorter cures were not employed; similarly, E and F were found to be greatly overcured at 10 minutes, and therefore longer cures were not carried out in these two cases.

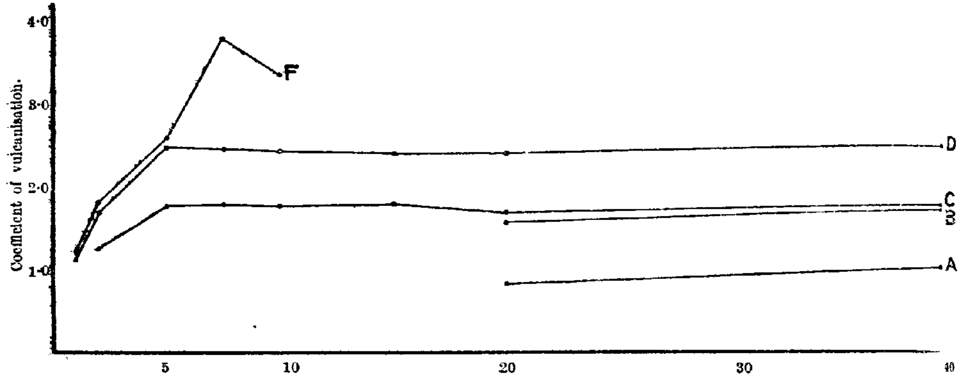

Fig. 1.

The results obtained were as follows:—

Table I.

Total sulphur in mixings.

Mixing.	A	B	C	D	E	F
Total S %	1·01	1·59	1·79	2·33	3·38	4·10
% S to rubber	1·07	1·69	1·90	2·49	3·66	4·49

Coefficient of vulcanisation.

The coefficient of vulcanisation results will be found in Fig. 1. The curves in this figure show the progress of curing so far as combination with sulphur is concerned for mixes A, B, C, D, and F. Curve E is omitted as the results obtained obviously involved some experimental error. It will be observed that in all cases, as has been noted by previous workers, combination is comparatively

[1] E = elongation % at a load corresponding to 600 g. per sq. mm. of cross-section.

[2] E_1 = elongation % at a load corresponding to 1040 g. per sq. mm. of cross-section.

[3] Type (slope) = $(E_1—E)/2·5$.

[4] B = breaking strain in lb. per sq. inch.

[5] E at B = elongation at break, taking the original length as = 1.

[6] Total sulphur calculated to 100 of rubber.

rapid in the early stages, the steepness of the curve increasing with the total sulphur. The sulphur figures are not put forward as being exhaustive, inasmuch as gross over- or under-curing was not desired.

Mechanical properties.

Fig. 2 indicates the progress of curing illustrated by means of extensions at loads of 600 g. and 1040 g. per sq. mm. respectively. Fig. 3 shows the progressive effect on the breaking load. The figures obtained for tensile strength, type, etc. will be found in Table II.

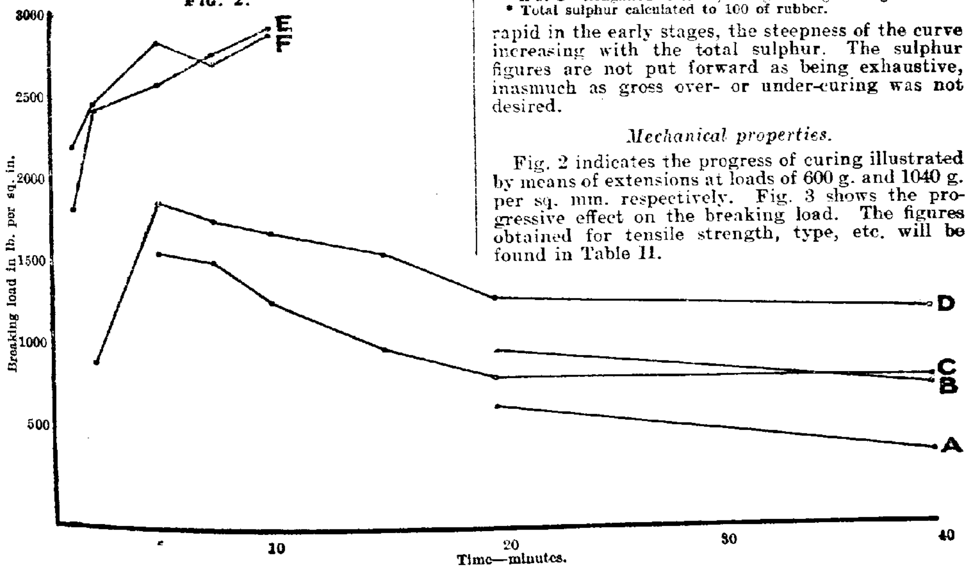

FIG. 3.

The following observations may be made on the results recorded above:—

1. As is evident from Fig. 2, and the data in the tables, "reversion" occurs at a comparatively early period when the quantity of sulphur does not exceed, in round numbers, 2½%.

2. As is evident from Fig. 3, and the data in the tables, moderate curing takes place with a sulphur content of 2½%, but below this results are poor.

3. In a previous paper,* it was shown that excellent results could be obtained with a minimum of 2% of sulphur. It would appear, therefore, that the accelerator used required 2 to 2·75% of sulphur (allowing for variations in materials and conditions) to attain reasonably full activity.

The work described above was carried out at the Northern Polytechnic Institute, N. 7, and we wish to express our thanks to the Governors for facilities afforded.

THE EFFECT OF THE ACETONE-SOLUBLE CONSTITUENTS OF RUBBER ON THE VULCANISING PROPERTIES.

BY HENRY P. STEVENS.

Much time has been devoted to the study of the accessory substances present in Para rubber which are believed to give rise to variations in rate of cure (or vulcanisation), but the position remains obscure and progress is slow. It is the object of this paper to summarise briefly the present position, particularly as regards the acetone-soluble constituents, and at the same time to publish certain results which have been obtained by the author in a recent investigation while working on behalf of the Rubber Growers' Association.

Mainly as the result of the work of D. Spence, L. Weber, and the author,† it was shown ten years ago that the rate of vulcanisation and physical properties of rubber were dependent upon certain active ingredients present in small amounts in the crude rubber. These could be removed (1) with the insoluble matter (mainly nitrogenous) or (2) with the acetone-soluble portion. This latter also contains nitrogen but in relatively small amount. The complete removal of the insoluble constituents resulted in a rubber which, when mixed with sulphur, would hardly vulcanise (as shown by the physical properties and small proportion of the sulphur combined). Extraction with acetone had little or no effect on rate of vulcanisation of this rubber-sulphur "mix," whether the rubber had been previously freed from the insoluble constituent or not. If, however, vulcanisation be carried out with a "mix" containing litharge as well as sulphur, it was found that previous extraction of the rubber with acetone has a profound effect on rate of vulcanising; the rubber shows very inferior mechanical properties and a low percentage of combined sulphur. The acetone-soluble constituents appear to play the same part in a litharge mix as do the insoluble (nitrogenous) constituents in a simple rubber-sulphur mix.

It should be noted that the process of extraction of the constituents, whether insoluble or acetone-soluble, is not the cause of differences in behaviour as the rubber regains its normal properties on putting back into it the constituents which have been removed.

The next stage was the discovery of the rapid vulcanising properties of "matured," that is putrefied coagulum (Eaton and others), and the separation from such rubber of the nitrogenous bases which were apparently the cause of the rapid vulcanising properties. These bases were not found, or were present in a very small proportion, in crêpe as ordinarily prepared. Little doubt exists that these bases are putrefaction bases, as such are known to act as vulcanisation catalysts. These observations threw some light on the variations noted in the rate of vulcanisation of Para rubber, but it soon became evident that much still remained obscure. For instance, rubber normally prepared contains but little nitrogenous base, and removal of this base by extraction with acetone, or treatment with weak acid, has relatively little effect on the rate of vulcanisation. It is obvious that the insoluble matter (as removed by benzene treatment) must contain the bulk of the substances which enable the ordinarily prepared rubber to vulcanise normally and that these substances are not readily soluble bases like the putrefaction bases extracted from "matured" rubber.

As already stated, these acetone-soluble bases* account for the fast vulcanising properties of "matured" rubber. Ordinary crêpe contains little or no soluble bases, consequently acetone extraction has only a slight effect on the rate of cure. Crêpe will, however, vary in this respect, and accordingly it is not surprising to find that some samples do respond to a greater extent than others to acetone extraction when vulcanising with sulphur only. Martin and Elliott in a recent paper (J., 1922, 226 T) have shown that sheet rubber is more susceptible than crêpe rubber in this respect, while "matured" (slab) rubber is markedly affected. The rate of vulcanisation of ordinary crêpe rubber can be almost doubled by the addition of 2% of acetone extract from "slab" rubber. These authors also show that there is probably some correlation between the amount of acetone extract and rate of vulcanisation.† These results fall in very well with the foregoing conclusions that slab rubber owes its rapid rate of vulcanisation to putrefactive bases. On the other hand, there are certain published data which are difficult to reconcile with the views expressed. Kratz and Flower, in the course of their work on accelerators, record an instance in which the coefficient of a sample of rubber was *increased* from 0·58 to 0·83 as a result of 36 hours' acetone extraction. Another sample of rubber treated in the same manner gave a negligible decrease (J. Ind. Eng. Chem., 1920, 12, 971).

As already explained, the insoluble constituents must contain a catalyst or catalysts insoluble both in benzene and acetone, and these probably consist of nitrogenous substances more complex than the acetone-soluble bases. It is well known that rubber obtained by evaporating latex to dryness on a steam bath vulcanises rapidly, and in this respect is comparable with "slab." As, however, the temperature employed excludes the possibility of putrefaction, the fast vulcanisation properties of evaporated latex cannot be attributed to putrefaction bases; moreover, extraction with acetone or water, as will be seen from the figures recorded below, has no appreciable effect on the coefficient. This applies to latex whether air-dried, sun-dried, or steam-oven-dried. So prepared the rubber vulcanises approximately three times as fast as ordinary crêpe. The specimens examined were as follows:—(A) Air-dried and sun-dried. Evaporation was accompanied by some putrefaction. (B) Steam-oven-dried. (C) As A, but with 0·2% of boric acid added to the latex before drying. This did not prevent putrefaction, nor did a much larger proportion of boric acid do so. (D) Crêpe rubber as a control prepared from the same latex as the three foregoing samples. (E) Rubber prepared by pouring latex into alcohol.

---

* Loc. cit.

† For references see "Plantation Rubber and the Testing of Rubber," by G. S. Whitby.

* Soluble in acetone such as commonly used for extraction. The bases might not dissolve in carefully dried acetone.

† This had already been found by van Rossem, who calculated the correlation coefficient for 315 samples. (Comm. Neth. Govt. Inst., 1917, 196.)

Samples of each were treated as follows:—(1) Dry êped, that is, run out into crêpe on dry rollers; small amount of sticky substance was deposited on he rollers, but it may be assumed that no subantial loss ensued and that the dry crêped rubber ontained practically all the original ingredients.) Crêped and washed in a stream of water on the ollers, so as to remove as much as possible of the ater-soluble ingredients. After this treatment the ubber was air-dried. (3) Part of the rubber which ad been dry crêped as in (1) was extracted with hot cetone in an all-glass Soxhlet extraction apparatus s in the determination of "resin."

The fifteen specimens thus obtained were mixed ith sulphur in the usual proportion of nine parts f rubber to one part of sulphur, and vulcanised ogether for the usual time and temperature (2 ours at 138° C.). The resulting specimens were xhaustively extracted with acetone and the comined sulphur estimated in the residue in the usual anner with the following results:—

Coefficients.

	1. Dry crêped.		2. Crêped and washed.		3. Acetone-extracted.
. Air-dried and sun-dried	6·28	..	6·00	..	6·18
. Steam-oven-dried ..	7·16	..	5·48	..	6·94
. As A, but with 2% boric acid	5·75	..	4·70	..	5·60
. Ordinary crêpe as control	2·20	..	2·38	..	2·22
. Alcohol-coagulated ..	3·94	..	4·43	..	4·65

A comparison of columns 1 and 2 for samples A, , and C shows that washing had the effect of reoving a little of the accelerating ingredients. If olumns 1 and 3 be compared it will be seen that cetone extraction had practically no effect on amples A, B, and C, or at the most reduced the ure very slightly.

The control sample of pale crêpe as ordinarily repared shows a slight increase in rate of vulcanisation after wet crêpeing, possibly due to slight utrefaction of the rubber on account of moisture aken up, although no odour of putrefaction was oticeable. Acetone extraction was without effect n the rate of vulcanisation.

The alcohol-coagulated rubber vulcanises appreiably faster than the control. Wet crêpeing ncreased the rate of cure which, as before, may be ttributed to putrefaction, but it is difficult to ccount for the increased rate of cure of the acetonextracted rubber. The case is analogous to the bservations of Kratz and Flower already referred o.

The acetone extracts were examined, but the mounts of base and the precipitates obtained with he phosphotungstate reagent were very small. It an only be said that A, B, C, and E gave rather eavier precipitates than the control sample D. he following figures give the weights of the queous and acetone extracts of the dry crêped ubbers:—

		Aqueous extract. %		Acetone extract. %
A	.. ..	0·0035	..	4·47
B	.. ..	0·0140	..	4·95
C	.. ..	0·0320	..	5·80
D	.. ..	0·0170	..	2·40
E	.. ..	0·0140	..	3·80

The figures for acetone extract for A, B, C, and are high, due no doubt to the retention of the reater part of the serum. The main constituent f these extracts is methylinositol or allied subtances.

Portions of the dry crêped rubbers were placed to oak in water in separate stoppered bottles with the ddition of a little chloroform in each case to revent putrefaction. The soaking was continued or some weeks, and the water changed two or three imes. The rubber was dried, mixed with the rdinary proportion of sulphur, and vulcanised under the same conditions as before. The combined sulphur was then estimated in the vulcanisates.

The following figures give the coefficients for the dry crêped rubber (from the previous table) and the coefficients after soaking and drying:—

Coefficients.

		1. Dry crêped. %		2. Same after soaking in water. %
A	.. ..	6·28	..	6·42
B	.. ..	7·16	..	7·16
C	.. ..	5·75	..	5·34
D	.. ..	2·20	..	2·58
E	.. ..	3·94	..	5·27

The figures show that for samples A to D but little change is produced by long soaking. The small increase shown by some of the samples may have been due to putrefaction, for although the presence of chloroform would inhibit these changes during the soaking process, the chloroform would soon pass off when the crêpe was hung up to air-dry, and putrefaction might then ensue. The increase in rate of cure of sample E is remarkable. The alcohol-coagulated rubber gives, in the first place, a coefficient of 3·94, which is increased to 4·65 by acetone extraction, and to 5·27 by soaking in chloroform water and drying. Alcohol, acetone, and chloroform would all presumably inhibit bacterial changes. It might be assumed that putrefaction would set in at the last stage of drying after the chloroform had evaporated. This, however, could not apply in the case of the acetone-extracted sample, which was not moistened. Moreover, the alcohol-coagulated specimen, which was washed with water and air-dried, showed a smaller increase in coefficient than the acetone-extracted specimen (4·43 as against 4·65). Also the effect of water washing or soaking on samples A to D was to reduce rather than to increase the rate of vulcanisation. The behaviour of the alcohol-coagulated rubber is therefore exceptional, and the increase in rate of cure resulting on aqueous or acetone extraction cannot be attributed to putrefactive changes.

Attempts to characterise the putrefactive change have not met with success; we do not know whether the bacteria are aerobic or anaerobic. The interior of a mass of putrid coagulum is acid, but the exterior is covered with an alkaline slime. It is in this alkaline slime that the putrefactive base should be found. Experiments were undertaken to compare the rato of vulcanisation of the interior and exterior portions. Omitting some earlier experiments, the following figures may be quoted:—

	Crêped and air-dried.			Smoke-dried.	
	Time of cure, min.	Rate of cure,* %		Time of cure, min.	Rate of cure,* %
Acetic acid coagulated—					
(1) Inside portion ..	75	272	..	48	430
(2) Outside ,, ..	142	143	..	75	272
Spontaneously coagulated—					
(1) Inside portion ..	161	127	..	99	206
(2) Outside ,, ..	127	160	..	141	145

* Ordinary pale crêpe taken as standard.

In the preparation of these samples the surface portions were thin slices so as to comprise as large a proportion of the actual surface as possible, and the mass of coagulum was dried down so as to include any basic substances present in the slimes on the surface of the rubber. It will be noted that there is a considerable difference in the rate of vulcanisation. Except in the case of the air-dried spontaneously coagulated specimen the interior portions vulcanise much faster than the exterior.

To carry the inquiry a stage further, a quantity of this alkaline slime was collected and forwarded for examination. It consisted of a thick, greasy liquid with an abominable odour. A small quantity (5 c.c.) was distilled in steam (1) alone, (2) with the addition of magnesia. The latter was added to

B

facilitate the decomposition of any salts of basic volatile constituents, and enable them to pass over into the distillate. In both cases the distillates and the residues gave copious precipitates with the phosphotungstate reagent (after suitable treatment), showing the presence of simpler nitrogenous bases, such as are normally present in the products of putrefaction. The mixed bases were separated from the phosphotungstates by the appropriate procedure and dried in a vacuum desiccator. The effect on the rate of vulcanisation of rubber was then ascertained by mixing the separated bases (each from 5 c.c. of slime) with the same quantity of ordinary pale crêpe rubber (90 g.) compounded with sulphur in the usual proportion (10 g.). Part of the pale crêpe, without addition of bases, was taken as a control, and to a further portion was added 5 c.c. of slime. This was added gradually to the rubber and worked in on the rollers before mixing in the sulphur. All samples were vulcanised together under the same conditions. The samples were then analysed, and the combined sulphur determined. The distillate in the case of (1) was lost and therefore does not figure in the table.

	Description.	Combined sulphur, %		Rate of cure, %
(1)	Control, pale crêpe	3·09	..	100
(2)	Control with the addition of the bases (amounting to 0·0280 g.) from the residue of steam distillation	3·25	..	105
(3)	Control with the addition of the bases (amounting to 0·0073 g.) from the distillate of steam distillation with magnesia	3·29	..	106
(4)	Control with the addition of the bases (amounting to 0·0398 g.) from the residue of steam distillation with magnesia	3·21	..	104
(5)	Control with the addition of 5 c.c. of slimes.	4·43	..	143

These figures show that the bases separated from the slimes have a negligible effect on the rate of vulcanisation. The slimes untreated have an appreciable effect. The separation of the bases used in (2), (3), and (4) seems to have resulted in the loss of the active ingredients, as the slimes alone (5) have a much greater accelerating effect.

Similar distillation experiments were made with sample A (air-dried and sun-dried latex) by allowing the dry crêped rubber to soak in water and distilling the extract. This yielded an alkaline distillate, and both distillate and residue (after extraction of the base with lime and acetone) yielded fairly copious precipitates with phosphotungstate in contrast with the amounts of precipitate yielded by the acetone extract.

Similar tests were carried out by steam distillation in the presence of magnesia. Twenty g. yielded bases from the distillate requiring 4·1 c.c. of $N/10$ acid to neutralise and from the residue 5·1 c.c. of $N/10$ acid for neutralisation. The separated bases from 20 g. of the sample were incorporated with 20 g. of a control pale crêpe and the usual proportion of sulphur and vulcanised. The following figures were obtained:—

	Coefficient.		% Control.
Control (pale crêpe)	3·09	..	100
Steam and magnesia distilled, bases from distillate	3 29	..	107
Steam and magnesia distilled, bases from residue	3·21	..	104
Residual rubber from steam distillation	6·53	..	211
Original rubber as dry crêped ..	7·16	..	232

It appears that the bases separated, whether volatile or not, had but a slight effect on the rate of cure. The rubber (sample A, dry crêped) lost slightly in rate of cure by the treatment. Generally, therefore, the experiment confirms the previous conclusion that the separated bases do not account for the fast vulcanising properties of rubber obtained by evaporation of latex.

As further proof I may recall experiments made some years ago with latex treated with formalin. An appreciable amount of formalin was added to the latex, which showed the usual premature coagulation and was full of minute clots. This latex could not possibly have undergone putrefaction after the addition of the formalin. Yet when evaporated to dryness on a water-bath it gave a very fast vulcanising rubber.

Conclusions.

(1) Extraction of evaporated whole latex with water or acetone either causes a small decrease in rate of vulcanisation or it is without effect.

(2) Extraction of ordinary pale crêpe may increase or slightly decrease the rate of vulcanisation or may be without effect. The specimen examined on this occasion was unaffected by acetone, but showed a small increase as the result of water extraction.

(3) Extraction of alcohol-coagulated latex with water or acetone results in an appreciable increase in rate of vulcanisation.

(4) The alkaline slimes from the surface of matured rubbed contain appreciable quantities of organic bases, part of which is volatile. Similar bases are obtained by soaking evaporated latex in water. The accelerating effect of these bases is small.

(5) The surface and interior portions of putrefied coagulum may show considerable differences in rate of vulcanisation.

(6) The formation of putrefaction bases is probably sufficient to account for the high rate of vulcanisation of "slab" or other "matured" rubber, but does not account for the high rate of vulcanisation of evaporated "whole" latex or of alcohol-coagulated latex.

(7) The correlation between the amount of acetone extract and rate of vulcanisation is not directly connected with the presence of putrefaction bases, as acetone extraction, which should remove the bases, may result in a more rapid vulcanising rubber.

THE TRANSFORMATION OF METHYL α-ELÆOSTEARATE INTO METHYL β-ELÆOSTEARATE.

BY R. S. MORRELL, M.A., PH.D., F.I.C.

K. Bauer and K. Herberts (Chem. Umschau 1922, **29**, 229) have published the results of an investigation on tung oil, from which they conclude that α-elæostearic acid is transformed during esterification into the β-modification, but if the α-acid be heated with acetic anhydride and the excess of anhydride distilled off at 110° C. *in vacuo* subsequent saponification with alcoholic potash gives the α-acid (m.p. 46° C.) only. In 1918 I communicated a paper to the Birmingham Section of the Society (J., 1918, 181 T) in which I proved that methyl α-elæostearate was transformed into the β-variety on distillation *in vacuo*. The undistilled methyl α-ester, prepared from thickened tung oil by the action of sodium methoxide at the ordinary temperature, gave on saponification a syrupy acid from which a cerium salt soluble in ether was obtained, indicating the absence of the β-acid. I would not have called attention to my communication if Bauer and Herberts had acknowledged my work on methyl elæostearate or on the bromination of β-elæostearic acid. I am of the opinion that the conclusions drawn from their results are incorrect. There is the possibility that the formation of solid tetrabromide obtained from α-elæostearic acid is due to the transformation of the α-variety into the β-variety by the action of bromine. Nicolet (J. Amer. Chem. Soc., 1921, **43**, 938) considers that this suggestion requires confirmation, but it seems plausible. The yield of solid tetrabromide from the α-acid is small. Bauer and Herberts had difficulty in obtaining the solid tetrabromide and make no mention of the fact that the β-acid yields a solid and fluid tetrabromide on bromination.

DR. E. ARDERN IN THE CHAIR.

NOTE ON THE CAUSE OF THE "SPLITTING" OF A POTTERY BODY.

BY MAY B. CRAVEN, M.SC.TECH., A.I.C.

The following is a brief account of an investigation carried out during the war in connexion with the "splitting" of a pottery body. The investigation concerned an English ring support required to carry incandescence mantles, which ring split off, or splintered, under the effect of heat, whereas the German rings, which were used almost exclusively before the war, withstood perfectly much greater variations of temperature. Having regard to the use of the rings, it was obviously essential that the pottery body, of which the ring was made, should withstand heat suddenly applied.

When made, the highest temperature which the ring has to withstand is reached during the manufacture of the mantle. The mantle, which is made from knitted material (cotton, silk, ramie fibre, etc.), is tied on to the ring, dipped into the solution of rare earth compounds, and then put on to a gas fitting and fired by compressed gas at about 1100° C. This treatment burns off the fibre and eaves the framework of thorium oxide which carries the essential cerium oxide (98% ThO_2, 2% CeO_2 approx.). It is during this firing that the quality of the ring shows itself. If it be a poor ring, either it breaks, or small splinters fly from it, and usually some of these pierce the mantle. In either case there is a loss—in the former case complete, n the latter case partial, because the pierced mantles cannot be sold as perfect ones.

During use the heat effect is as a rule that of urning ordinary gas, and "splitting" from the lay ring is not so likely to occur, although with a poor ring the life of the mantle is comparatively hort; the greatest damage, however, is incurred during manufacture. Where the mantle is used with a compressed gas supply the piercing takes place each time the mantle is in use owing to the nability of the ring to withstand the temperature o which it is subjected.

The delicate form of the ring, with its tying groove and three lugs, by which it is supported on he burner, preclude the use of any pottery material incapable of delicate treatment. The material must be fine in grain and coherent, and he more homogeneous the mixture the fewer trains there will be.

It was considered probable that the difference etween the English body and the German one was chemical difference, that is, one of chemical composition, and this was rather indicated by the name f the German body, "Magnesia." A bone-ash body would also withstand heat well. So, having regard o the possibilities of bone-ash and magnesia bodies, xceedingly careful chemical analyses were made. The porosities of the bodies were also determined. At the same time, for the purpose of comparison, n analysis was made of an English clay ring, made y a different firm; this was certainly better than he ring first examined though inferior to the German one.

Chemical analyses.

In the following statement, A refers to the German body, B to the superior English body, and C o the body first under investigation.

The porosities (weights of water absorbed by 100 grams of body) were:—A, 12·6; B, 10·2; C, 12·7 g.

The analyses show ordinary pottery bodies approximating to earthenware in type, though as a rule earthenware bodies contain at least 70% of silica.

	A.	B.	C.
SiO_2	66·25	66·17	61·00
Al_2O_3	31·93	29·40	36·06
Fe_2O_3	0·72	0·65	0·80
P_2O_5	1·03	0·77	0·18
CaO	0·03	0·35	0·08
MgO	0·70	1·41	0·39
K_2O and Na_2O (by diff.)	—	2·00	1·44
Loss on ignition	0·22	0·25	0·05

The alkalis were not determined separately because they were present in the usual small percentage. TiO_2 was estimated, but it also was present in the usual small percentage, and has no significance in this instance, so the figures are omitted.

It is evident from the analysis that the German body is not specially a "magnesia" body, neither is it a bone-ash body, for the lime content is low, even unusually low.

The good English body approximates in composition to the German body, and the body under investigation differs from it, the silica content being about 5% lower and the alumina content about 4% higher than that of the German.

The porosities are much the same, and are not remarkable.

The usual earthenware materials are ball clay, china clay, and flint.

The analysis showed that the German raw materials were extremely well washed—the almost complete absence of alkali (0·12%, and this is probably experimental error) shows this. The difference in chemical composition is not enough to account for the success of the German and the failure of the English body, *i.e.*, conclusions drawn from the analyses are mainly negative.

Ordinary visual examination of the fractured rings showed a great difference, the German fracture being granular and the English one striated.

Sections were cut and examined, and the cause of the trouble was plainly to be seen.

At a magnification × 30 the German body, Fig. A, showed finely ground, evenly sized particles. There were no stratifications, the mass being homogeneous throughout. Black iron stains, due to ferri-ferrous silicate, occurred here and there, but as the ring was almost perfect when in use the presence of the iron oxide was evidently not detrimental. The good English ring approximated to the German in texture, though where the lugs join the ring there was not perfect cohesion, and slight striations were faintly visible.

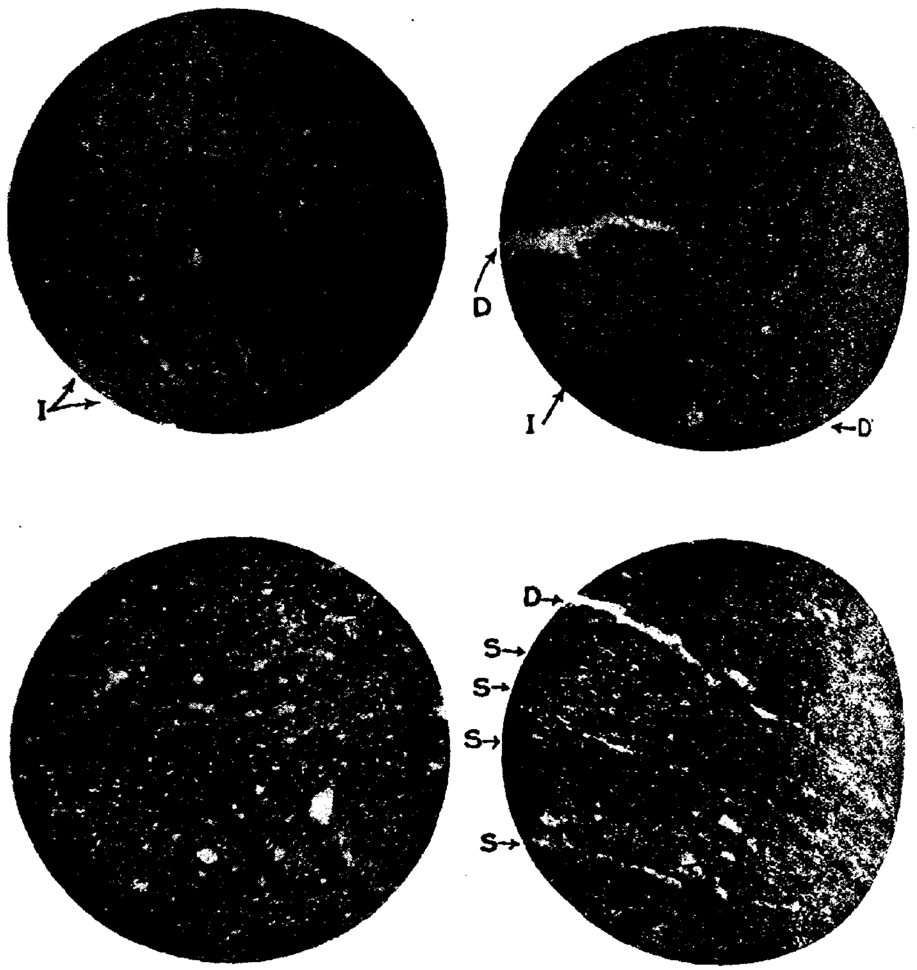
Two sections of the inferior English body are shown, Figs. C1 and C2. The former is a section cut at 45°, and the latter is a vertical section. Both photomicrographs show plainly the extremely unevenly sized particles. Figure C2 shows layers of material and air spaces running more or less transversely. In fact, the ring is striated throughout.

The difference between the German ring and the English one is thus a difference of mechanical treatment of the material. The actual pressing of the rings had evidently taken place in three operations —first ring, then ring with lugs, and then the complete shape with the tying groove.

The direction of the striations in the English ring showed plainly that they were the result of pressing. If the die is not working in perfect mechanical adjustment this would at once affect the stresses in the presser ring. The English die is certainly not "true." A die mechanically more perfect would prevent the formation of the layers in the ring.

The unevenly sized particles of the English body indicated that the raw materials had not been evenly ground. Of the raw materials the ball clay and china clay present no difficulty; they are soft and are very easily ground. The third body, flint, is the most difficult to grind to an impalpable powder. The imperfect grinding of the flint is another cause of the trouble. The best grinder for flint is the old chert mill and this type of mill—where a homogeneous material is required—should certainly be used. Silica occurs naturally in a fine state of division as diatomite or kieselguhr. The fine, even texture of the German body might be due to the use of kieselguhr, and all the sections examined under polarised light (D×360) showed crystalline particles in the English body and no crystalline particles in the German one. In the former body silica is certainly introduced as flint but it could not be positively asserted that the German body contained kieselguhr. In any case the silica here, whether derived from flint or kieselguhr, was extremely finely ground, and that fact helped considerably to ensure the success of the German body.

Photomicrographs of ring sections. ×30.



Vertical section.—A. German body.

Vertical section.—B. Good English body.

Oblique section.—C1. English body.

I. Staining due to iron oxide.
D. Crack where the foot joins the ring.

Vertical section.—C2. English body.

D^1. Air spaces.
S. Striations.

There can be no doubt that the superiority of the German body was due to the superiority of the mechanical treatment of the German raw materials. They were much better washed, better ground, and better pressed than were the English raw materials.

Where a body has to withstand heat treatment no precaution should be spared to ensure homogeneity and to have arrangements for pressing such that the product has no laminations, air films, or strains of any kind.

Communications.

THE ACTION OF OZONE ON HYDROCARBONS WITH SPECIAL REFERENCE TO THE PRODUCTION OF FORMALDEHYDE.

BY T. SHERLOCK WHEELER, B.SC.(LOND.), A.R.C.SC.I., A.I.C., AND E. W. BLAIR, B.SC.(LOND.), D.I.C., A.I.C.

Part I. The action of ozone on methane.

The action of ozone on methane was first investigated by Otto (Ann. Chim., (7), 13, 109), who proved that at 100° C. a very slow reaction takes place; he detected formaldehyde and formic acid among the products. His results were afterwards confirmed by Drugman (Trans. Chem. Soc., 1906, 89, 939). Both these researches, however, were purely qualitative; accordingly the present authors, having completed a quantitative investigation of the production of formaldehyde from ethylene by interaction with ozone, decided to study the interaction of methane and ozone on similar lines.

Experimental methods.

The methane and oxygen for these experiments ere prepared and stored as described by Bone and Vheeler in their paper on the slow oxidation of ethane (Trans. Chem. Soc., 1903, 83, 555); the nalysis of the gaseous mixtures obtained is also escribed therein. The ozoniser employed gave bout 4% ozone from oxygen under the conditions f our experiments; the ozone was estimated by ieans of neutral potassium iodide.

In our first experiments mixtures of methane and xygen which had been dried over sulphuric acid nd phosphorus pentoxide were passed through the zoniser and led into a hard glass tube 80 cm. long y 2 cm. diam., placed in an electric furnace so that lmost its whole length could be heated to any esired temperature. The volume of the tube was 50 c.c., and as the gas mixture was in each experinent passed at the rate of 1 litre in 10 mins. the eriod of heating was about 2½ minutes. The issung gas was washed in two water-worms and with ieutral potassium iodide to remove any residual zone, after which it was collected in a gas-holder illed with 50% glycerin and water. Ground glass oints were used in all portions of the apparatus in ontact with ozone.

Before starting an experiment the apparatus was illed with pure oxygen—at the end of the experinent it was washed out into the final gas-holder vith several litres of the same gas. The pressures, emperatures, and volumes of the initial and final gases were measured and compared as described in our paper on the production of formaldehyde from ethylene (J., 1922, 303 T). Our methods of estinating solutions containing formaldehyde, formic acid, and hydrogen peroxide will be described in another paper.

In a second series of experiments oxygen alone was passed through the ozoniser and methane was mixed with it before entering the reaction tube. To each 5 litres of oxygen 1 litre of methane was added. The oxygen was passed at the same rate as before to obtain the same concentration of ozone; to have the heating period the same a slightly wider tube was used.

Finally in a third series of experiments equal volumes of methane and ammonia were mixed in a 500-c.c. bulb and the mixture added to the ozonised oxygen at the rate of 2 litres of mixture to 5 litres of oxygen. The reaction tube was further correspondingly increased in size so as to ensure the same time of heating. The volumes of the gases were compared as before.

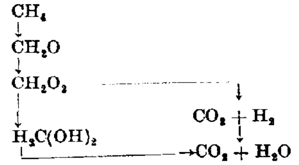
Experimental results.

Ozonisation of mixtures of methane and oxygen.—In these experiments in which methane and oxygen were passed directly through the ozoniser, it was necessary to use mixtures outside the explosive limits, which are 4% and 60% of methane. The following is a summary of some of our experiments using mixtures of oxygen 97% and methane 3%. It is to be noted that in these and in all our experiments more or less white fumes were present in the gases issuing from the reaction tube. They probably consisted of water in a finely-divided form.

Experiment ..	1	2	3	4	5
Temp., °C ..	15	100	200	300	400
mmg. CH_2O per litre of mixture used ..	0·3	0·8	1·5	2·2	0·5
CH_2O_2 ..	Trace	Trace	Trace	Trace	Trace
c.c. CO_2 per litre mixture used	—	5	7	6	5
%$CH_4 \rightarrow CH_2O$	—	9	14	20	9
%O_3 reacting	5	53	76	68	52
%O_3 directly decomposed..	Nil	15	15	32	48

At 15° C. the action is very slow; it increases with temperature until at 100° C. 53% of the ozone present reacts in about 2 mins. The rate of decomposition of ozone also increases; above 400° practically all the ozone decomposes. It is probable that at these higher temperatures the oxidation is rapid and that any that does occur takes place during the period of heating up the gas, for even at 250° the decomposition rate of ozone is very rapid.

The first isolated product of the interaction is formaldehyde. It is quickly further oxidised by ozone but its oxidation rate does not at first increase as fast as that of methane, so there is an initial slight rise in the percentage isolated on the methane oxidised. At all temperatures, however, the greater portion of the methane oxidised is obtained as carbon dioxide. No carbon monoxide was detected in any experiment, so probably little is formed as it would not be completely oxidised. This can be explained by assuming that the ozone oxidises formaldehyde to formic acid which is then rapidly oxidised *via* carbonic acid to carbon dioxide and water. At 200° formic acid decomposes mostly to carbon dioxide and hydrogen (it may be noted that at 500° it decomposes to carbon monoxide and water)—above 100° ozone attacks hydrogen. The action of ozone on methane may then be represented—



Owing to the low concentration of carbon dioxide in the residual gases the quantities given are only approximate. The percentages of ozone decomposing are obtained by estimating the ozone absorbed in the potassium iodide solution and assuming that formaldehyde and carbon dioxide are formed according to the following equations:

$$CH_4+2O_3=CH_2O+H_2O+2O_2$$
$$CH_2O+2O_3=CO_2+H_2O+2O_2$$

While the first equation is probably correct, all three atoms of the ozone molecule may go to oxidise formaldehyde. This of course increases very largely the amount of ozone decomposing. It is difficult to decide this point, as at low temperatures where ozone can be safely assumed not to have decomposed, the amount of carbon dioxide formed is difficult accurately to estimate (*cf.* Z. Elektrochem., 17, 634).

Experiments were also made using mixtures containing over 60% of methane; similar results were obtained, but less interaction occurred as the concentration of ozone was low, and owing to the dilution of the oxygen. Some transformations of the methane to unsaturated products by the discharge was noticed.

Addition of methane to ozone.—In the next series of experiments methane was added to ozone as described above. The results were similar to those quoted, the amount of interaction being slightly increased owing to the greater concentration of methane. Thus at 300° C. 2·5 mmg. of formaldehyde was obtained per litre of the mixture in a yield of 17% on the methane burned. The percentage yields of formaldehyde were throughout some 5—10% lower. In these experiments no special precautions were taken to dry the methane added to the ozone; this was done later, and the yields rose to the figures obtained with the dried mixtures of methane and oxygen.

Experiments were then made using catalysts and surfaces to try if the interaction of ozone and methane could be accelerated without accelerating the action of ozone on formaldehyde. It was found that surfaces such as ignited pumice had very little if any effect. Catalysts such as nickel oxide pumice, aluminium oxide pumice, ferric oxide pumice, platinised asbestos, etc. accelerated the decomposition of ozone even below 100° so that very little oxidation of methane occurred.

In some further experiments methane preheated to 500° was added to 4% ozone in the hope that all interaction to formaldehyde might take place before the ozone could decompose or carbon dioxide be formed. The results, however, did not differ appreciably from those of the previous experiments.

Experiments using ammonia.—In a third series of experiments mixtures of ammonia and methane were added to ozone and passed through the furnace as described above, the ammonia being added to stabilise the formaldehyde as hexamethylenetetramine. In each experiment dense white fumes were formed and deliquescent white crystals were deposited at the entrance to the furnace tube. On examination these proved to be ammonium formate, mixed with a little hexamethylenetetramine and ammonium carbonate. On dismantling the apparatus a smell of formamide was noted. The reaction tube was washed out thoroughly with distilled water and the washings added to the water from the worms. The liquid was distilled with moderately dilute sulphuric acid and formaldehyde and formic acid estimated in the distillate.

There were never more than traces of hydrogen peroxide or of nitrates or nitrites present. The yield of formaldehyde at various temperatures was much the same as in experiments where ammonia was not added but the yield of formic acid was very much increased, the quantity at each temperature being about equal to the formaldehyde isolated. It varied slightly directly as the amount of ammonia used and rose slightly if both ammonia and methane were thoroughly dried before adding to the dry ozonised oxygen. The non-stabilising of formaldehyde is due to the necessity of ten molecules interacting to form hexamethylenetetramine; this does not readily occur especially at low temperatures and with such low concentrations of formaldehyde. On the other hand, to stabilise formic acid as ammonium formate only a bimolecular reaction need take place.

These experiments with ammonia support the oxidation scheme set out above. It is to be noted that methyl alcohol was never detected among the products in our experiments, but it is so very readily oxidised in comparison with methane that it is not unlikely that it is first formed, more especially as it would result from the interaction of 1 mol. of methane and 1 mol. of ozone. The oxidation scheme is similar to that put forward by Bone for the interaction of oxygen and methane (Trans. Chem. Soc., 1903, 86, 1074); since the ozone oxidises by means of atomic oxygen, it would appear that in the interaction of oxygen and methane, atomic oxygen also comes into play. The fact that moisture increases the amount of formaldehyde slightly corresponds with the observations of Bone and Andrew on the interaction of hydrocarbons and oxygen in the absence of moisture (Trans. Chem. Soc., 1906, 89, 652). They note that in their experiments the accumulation of aldehyde was somewhat greater in the dried than in the undried gases. They formed the opinion that the greater accumulation was due to a slight increase in the initial rate of oxidation of the hydrocarbon, the further rates of oxidation being unchanged. The slight increase in formaldehyde in our experiments when both gases were dried may be due to the same cause, but it is also possible that the absence of moisture does not affect the rate of interaction of ozone and methane, but inhibits slightly the oxidation of formaldehyde. It may be that absolutely dry formaldehyde and oxygen would not react.

This work was carried out for the Chemistry Research Board of the Scientific and Industrial Research Department to whom we are indebted for permission to publish our results.

THE DETERMINATION OF SULPHUR IN VULCANISED RUBBER.

BY J. W. W. DYER, M.SC.(LOND.), AND AMY E. WATSON, B.SC.(LOND.).

With reference to the method described for the determination of combined sulphur in vulcanised rubber (J., July 31, 1922, 251—252 T), our attention has been called, by Mr. A. R. Pearson, to his prior description of the method and application to the determination of total sulphur (Analyst, 1920, 45, 405). We were not aware of this at the time of publication of our paper and regret the oversight. Although we published our method only recently, it was in constant use in our laboratory in the autumn of 1920. We prefer to use it for combined sulphur only and not for total sulphur, unless the amount of free sulphur is small.

ERRATUM.

In the paper on "Organic impurities in commercial nitric acid and their effect in the manufacture of nitroglycerin," by F. A. F. Crawford (J., Sept. 30, 1922), an error occurs on page 322 T, col. 2. Line 19 "that of tetranitromethane . . . very" should be replaced by "purity by distillation but the results were not."

TES ON A MANCHURIAN COAL FROM FUSHUN.

BY GODFREY W. HIMUS.

he Fushun colliery is situated in the Fushun fecture, Fengtien Province, some twenty miles t of Mukden, on a branch line of the South nchurian Railway, and is administered by the lway company. The coalfield has an area of ut 24 square miles, being some ten miles in gth from east to west, by 2·4 miles in width from th to south. The colliery is on a table-land 600 700 feet above sea level, which descends pre- itously to the Hun Ho River on the northern e, and on the south side somewhat less steeply.

The lowest formation in the coalfield is granite eiss, which is overlain by reddish-green tuffs longing to the Cambrian system which are lowed by alternate layers of tuffaceous sand- nes and shales of Mesozoic age. The coal-bear- g strata occur in Tertiary rocks consisting of eccia, sandstone and shale, and comprise a number seams of which the aggregate workable thick- ss averages 130 feet, rising to a maximum of 0 feet.

Later intrusions consisting of porphyritic dykes d basalt laccolites occur which cause a certain nount of alteration in the coal deposits.

The coal deposits are dated as of Miocene age, the ajority of the associated organic remains being lants, amongst which the following may be men- oned:—*Osmunda* sp., *Parrotaia* sp., *Salix* sp., *yptostrobus ungeri*, *Populus glandulifera*, *Styrax* ., *Tilia* sp., *Thuja* sp., *Quercus* sp., *Sequoia* sp., *agus feroniæ*, *Aphnantha* sp., *Ginkgo* sp.

The estimated reserves of coal are eight hundred llion tons, and the output has risen from 233,325 ns (British) in 1907, to 3,158,000 tons in 1920.

The coal is a poorly-coking gas or almost a sand al, the amount of volatile matter being over 40% d the coke presenting a somewhat sandy rather an a well-fused surface.

The average of the analyses given by the Publicity partment of the South Manchurian Railway mpany is:—Volatile matter 39·2%; fixed carbon 3%; ash 4·5%; B.Th.U. per lb. 12,900. Another of averages from the same source is:—Volatile tter 43·9%; fixed carbon 53·0%; ash 3·1%; Th.U. per lb. 12,530. C 74·15%; H 6·41%; 1·98%; O 13·59%; S 0·77%.

Analyses made in the author's laboratory of mples from consignments aggregating some 10,300 ns of Fushun dust coal, and about 100 tons of shun unscreened coal gave:—

	Dust. %	Unscreened. %
Volatile matter	41·8	41·7
Fixed carbon	47·3	48·5
Ash	10·9	9·8
B.Th.U. per lb.	12,345	12,410
Sulphur	0·5	0·5

he calorific values are gross, and were deter- ed in a Berthelot-Mahler bomb calorimeter in e two cases. The calorific value of the coal stance is somewhat less than that of the general of Far Eastern coals of similar proximate lysis.

t was observed that the unscreened coal con- ned a large percentage of lumps, varying in size m about two inches to six inches cube, many of ch showed yellow transparent or translucent mmy drops and bands resembling resin; other ps appeared to be practically free from these ps. By extraction with chloroform the gummy material could be isolated as a dark brown substance with an odour of heavy petroleum. The two sets of lumps in the coal contained very different amounts of material soluble in chloroform, those with much "gummy" material giving 10·5% of extract, the other lumps giving 2·8%, and the average sample of the coal, 3·3%.

Analysis of the extracted material showed:—Volatile matter 97·3%; fixed carbon 1·1%; ash 1·6%; B.Th.U. per lb. 16,550. C 79·22%; H 9·60%; O 10·19%. No sulphur or nitrogen could be detected. The above ultimate analysis was kindly made for the author by Mr. R. Bachrach, of the Shanghai Chemical Laboratory.

This analysis agrees fairly well with that given by Carrick Anderson and Roberts for the resinic constituents of certain Scottish non-caking coals, which they obtained by heating to 300°—315° C. in a current of carbon dioxide (*cf.* J., 1898, 1019).

A sample of ordinary rosin gave volatile matter 98·5%; fixed carbon, trace; ash 1·5%; B.Th.U. per lb. 15,710. Saponification value 177.

The resin-like material from the Fushun coal had a saponification value of 130 and melted at about 140° C.

The two sets of lumps into which the coal could be separated differed considerably in proximate analysis and in calorific value, as will be seen from the annexed table:—

	Coal. %	"Resinous" lumps. %	"Non-resinous." %
Volatile matter	41·7	51·5	46·0
Fixed carbon	48·5	28·8	49·2
Ash	9·8	19·7	4·8
Sulphur	0·5	0·15	0·75
B.Th.U. per lb.	12,410	12,530	13,920

If the results be reduced to dry ashless coal, the figures are more striking and can be seen in better perspective:—

	Coal. %	"Resinous" lumps. %	"Non-resinous" lumps. %
Volatile matter	46·3	64·1	48·3
Fixed carbon	53·7	35·9	51·7
B.Th.U. per lb.	13,780	15,660	14,670

Analysis of the "resinous" lumps after extraction with chloroform gave:—Volatile matter 45·6%; fixed carbon 33·4%; ash 21·0%. B.Th.U. per lb. 10,810.

Examination of the powdered coal or of the powder derived from either the "resinous" or "non-resinous" lumps, in water under the microscope, showed a considerable proportion of lemon to orange-yellow irregular lumps most of which vanished after extraction of the powder with chloroform.

Following the observation recorded by Wheeler and Burgess (Trans. Chem. Soc., 1913, **103**, 1704, 1705), pieces of the coal, one of which showed a prominent light-coloured band, and which was therefore classified as a "resinous" lump, and the other of which showed only one or two small gummy drops, were smoothed on one face and placed on a photographic plate in a light-tight box in an incubator at about 40° C. for 48 hours. On development, it was found that the "non-resinous" lump had had a considerable photographic action on the plate, a number of streaks and bands being shown, none of which corresponded to any obvious markings on the original lump. In the case of the "resinous" lump there was scarcely any action.

Summary.

The Fushun coal is a high-volatile coal of Miocene age formed apparently of the remains of coniferous plants, and, in common with many other coals, contains appreciable quantities of comparatively little altered resin-like substances which are ex-

tractable with chloroform. These substances make up about 3·3% of the coal, there being a tendency for them to be concentrated in certain bands and lumps together with a considerable amount of mineral matter. On the other hand, other lumps of the coal contain only about one-fourth the amount of chloroform-soluble material, and these lumps are much freer from mineral matter and have a strong action on a photographic plate. The calorific value of the resin-like material is very high, the contribution of the 3·3% of resinous substances to the heat value of the coal amounting to 4·4% thereof.

The author desires to express his thanks to Professor Hiroshi Yamada, of the Tung Wen College, Shanghai, China, for the information regarding the Fushun coal mine.

DETERMINATION OF PHENOL IN MIXTURES OF TAR ACIDS.

BY W. H. HOFFERT, M.A., B.SC.

Owing to the similarity in properties of phenol and its homologues, the accurate determination of phenol in a mixture of tar acids is a matter of considerable difficulty.

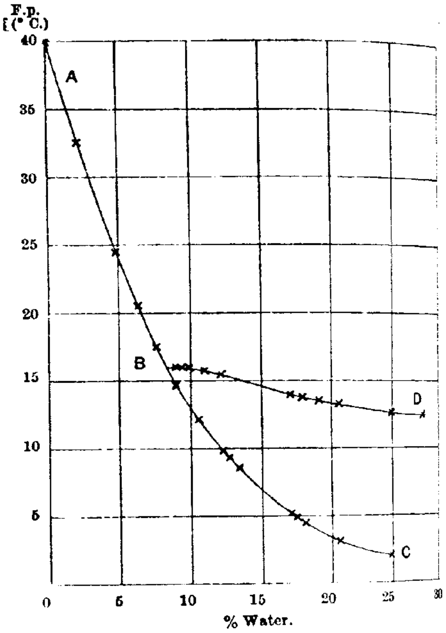
Numerous methods have been proposed from time to time. The most important papers dealing with this subject, recently published, are those of Fox and Barker (J., 1917, 842; 1918, 265 T; 1920, 169 T), and Dawson and Mountford (Chem. Soc. Trans., 1918, 113, 923). A fairly complete summary of important papers previously published is given in the second of the papers by Fox and Barker referred to above.

The above authors utilised the freezing point relations of phenol and the cresols in determining the phenol in a mixture of phenol and its homologues. Since, however, the lowering of the freezing point of phenol by equal weights of the three cresols differs considerably, owing to the variable tendency of the three cresols to form mixed crystals with phenol, they found it necessary first to separate the whole of the phenol originally present in the mixture, entirely or almost entirely in conjunction with *o*-cresol.

The method worked out by Fox and Barker was devised for the determination of the residual phenol in cresylic acid. The cresylic acid is first fractionated with an efficient column up to 210° C., when all the phenol, practically all the cresols, and a little xylenol come over. This distillate is then again fractionated up to 195° C., after the addition of sufficient *o*-cresol (if necessary) to bring over all the phenol in the fraction up to 195° C. The phenol in this fraction is then determined by application of the freezing point curve for mixtures of phenol and *o*-cresol, which was shown to be practically identical, for mixtures containing more than 80% of phenol, with that obtained from mixtures of phenol with the distillate collected up to 195° C., obtained from commercial cresylic acid free from phenol. Accordingly, if to an aliquot part of the distillate up to 195° C. sufficient pure phenol is added to yield a mixture containing at least 80% of phenol, and the freezing point of the mixture so made is determined, the percentage of phenol in the distillate up to 195° C. and hence in the original cresylic acid can be calculated.

The method gives fairly good results for mixtures having a low phenol content (less than 10%). When, however, the phenol content is high, a preliminary fractionation with an efficient column is necessary, in order to reduce the percentage of phenol in the mixture, two fractions being thus obtained:—(1) consisting chiefly of phenol and *o*-cresol, the phenol content of which can at once be determined by application of the freezing point curve of phenol and *o*-cresol; (2) consisting chiefly of *o*-cresol, *m*-cresol, and *p*-cresol, with only a small percentage of phenol, the phenol content of which is determined, after the addition of sufficient *o*-cresol to bring over all the phenol in the distillate up to 195° C., as already described.

The method proposed by Dawson and Mountford (*loc. cit.*) for the determination of phenol in a mixture of phenol and the three cresols, is similar to the above, the mixture being mixed with about half its weight of *o*-cresol, so as to yield on distillation with an efficient column two fractions:—(1) consisting of a mixture of phenol and *o*-cresol, and (2) consisting of a mixture of *o*-cresol, *m*-cresol, and *p*-cresol. The percentage of phenol in (1) can then be determined by application of the freezing point curve of phenol and *o*-cresol.



Freezing points of mixtures of phenol and water.

FIG. 1.

Experiments carried out by the author to separate a mixture of phenol and cresols in this way were, however, not in general successful, since even when using an efficient column it was only when the phenol content was very low that all the phenol passed over in the distillate up to 191° C., the boiling point of *o*-cresol.

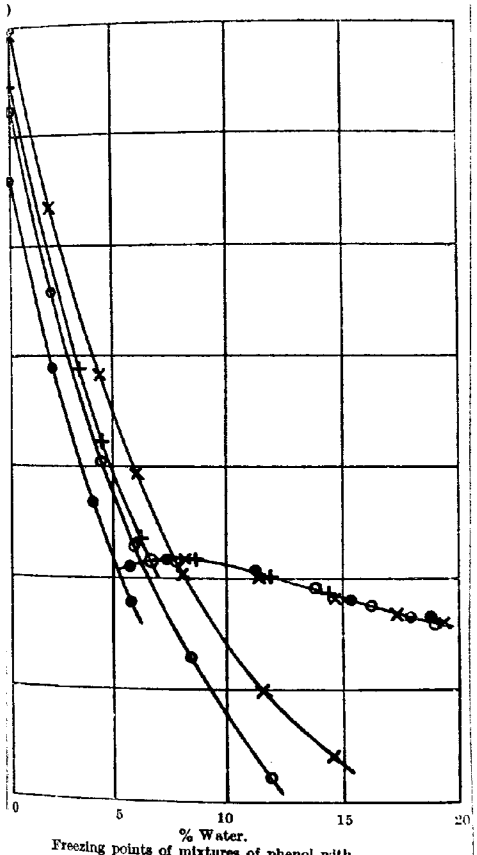
The method to be described enables the phenol, in any proportion, in a mixture containing any or all of the three cresols to be directly determined, and depends on the fact that the lowering of the freezing point of phenol hydrate by equal weights of each of the three cresols is the same.

Phenol hydrate.—It has long been known that phenol forms a definite crystallisable hydrate with water, m.p. +16° C.

The freezing points of mixtures of phenol and water were determined in an apparatus of the Beckmann type, the freezing points recorded being the temperatures at which liquefaction is complete, since these temperatures would correspond with those at which crystallisation of the liquid would gin in the absence of supercooling. The results e plotted in Fig. 1.

It will be seen that a continuous curve, A C, is tained for the lowering of the freezing point of enol by addition of water. When, however, the rcentage of water exceeds 8·5%, phenol hydrate n crystallise out (as shown by the branch curve, D) at temperatures considerably above those rresponding to the freezing points of phenol and ater. The hydrate curve is fairly flat, and reaches maximum at 16° C., with 8—9% of water (*cf.* also ig. 2), corresponding to the formation of phenol drate $2C_6H_5OH,H_2O$ (water 8·75%). The ends of e curve, C and D, indicate approximately the mits of solubility of water in phenol at these mperatures.

With mixtures of phenol and the cresols, it was und that phenol hydrate could be crystallised out hen the proportion of phenol was greater than out 55%, the limiting proportion depending on e nature of the admixed cresol or cresols.



Freezing points of mixtures of phenol with
(1) *o*-Cresol, 25% by weight, o—o—o
(2) *m*-Cresol " " ×—×—×
(3) *p*-Cresol " " ●—●—●
(4) Cresylic acid and water. " " +—+—+

Fig. 2.

The freezing point curves of various mixtures of enol and the cresols with water were also deter- ined. These curves showed that the lowering of e freezing point of phenol hydrate by each of the three cresols was the same within the limits of experimental error. As an example, the curves obtained with mixtures containing 75% of phenol in admixture with (1) *o*-cresol; (2) *m*-cresol; (3) *p*-cresol; (4) commercial cresylic acid free from phenol (fraction to 203° C.) are given in Fig. 2.

The freezing points of the above anhydrous mixtures of phenol and the cresols were very different, owing to the fact that the lowering of the freezing point of phenol by equal weights of the three cresols varies considerably, as already indicated, the actual freezing points obtained being in close agreement with those of Dawson and Mountford (*loc. cit.*). The lowering of the freezing points of these mixtures by addition of water is shown in the figure. It will be observed, however, that the freezing points of phenol hydrate separating from these mixtures all lie on one curve within the limits of experimental error. The maximum of the hydrate curve is clearly shown at 5·8° C., corresponding to about 8·5% of water. Similar results were obtained with mixtures containing larger and smaller percentages of phenol.

The lowering of the freezing point of phenol hydrate by addition of any or all the three cresols may, therefore, be represented by a single curve. For the application of this curve to the determination of phenol in admixture with cresols, it was found most convenient to construct the curve for mixtures of phenol and the cresols after the addition of water amounting to 10% of the weight of the mixture taken (*i.e.*, the mixture contained 9·1% of water by weight), since a definite percentage of water must be present, and the freezing point of the phenol hydrate varies least with slight alterations in the water content when the water is approximately 9·0%.

The experimental results recorded for such mixtures are given in the table below:—

(1)
Phenol + *o*-cresol (f.p. 30·5° C.).

Phenol %	F.p of hydrate. ° C.
100·0	16·0
95·0	14·25
86·2	10·8
75·0	5·8
70·8	3·9
62·9	—0·5
58·6	—3·0

(2)
Phenol + *m*-cresol (f.p. 10·4° C.).

Phenol. %	F.p. of hydrate. ° C.
100·0	16·0
90·8	12·6
80·0	8·1
75·0	5·8
62·4	—0·8
58·4	—3·2

(3)
Phenol + *p*-cresol (f.p. 34·2° C.)

Phenol %	F.p. of hydrate. ° C.
100·0	16·0
85·4	10·4
75·0	5·8
64·7	0·5
56·6	—4·2

(4)
Phenol + cresylic acid.

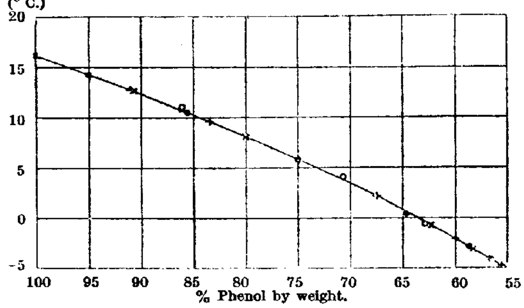
Phenol. %	F.p. of hydrate. ° C.
100·0	16·0
90·9	12·6
83·4	9·7
75·0	5·8
67·4	2·2
60·0	—2·0
55·5	—4·8

The cresylic acid used in (4) was a fraction obtained from commercial cresylic acid (b.p. 195°—203° C.), which had previously been freed from phenol by adding *o*-cresol and fractionating twice to 195° C. The results are plotted in Fig. 3.

This curve may be used to determine the percentage of phenol in mixtures of phenol and the cresols. If the percentage of phenol exceeds 55%, the determination of the freezing point of the hydrate after addition of water amounting to 10% of the weight of mixture taken, enables the percentage of phenol in the mixture to be read off at once from the curve. If the percentage of phenol in the mixture is below 55%, a known proportion of standard phenol (f.p. 40·5° C.) is added to the mixture to bring the percentage of phenol above 55%.

By a determination of the freezing point of the hydrate in this mixture it is then possible to calculate the percentage of phenol in the original mixture containing less than 55% of phenol.

Process.—The method of determining the percentage of phenol in a mixture of tar acids is as follows:—The mixture is first examined for neutral hydrocarbons and pyridine bases. If more than 2—3% of these impurities is present, a quantity of the sample is freed from them, either by steam distillation of the solution in sodium hydroxide or by extraction of the solution with ether or benzene, as described by Fox and Barker (*loc. cit.*). In recovering the tar acids by acidification of the alkaline solution with sulphuric acid, the acid layer should be extracted to recover any phenol present in the sodium sulphate solution.



Freezing points of phenol hydrate, phenol-cresol mixtures, containing 9·1% water.

FIG. 3.

If a preliminary distillation test shows that the mixture of tar acids, thus treated, distils over entirely below 205° C., the determination of the phenol may at once be proceeded with. If, however, the presence of more than traces of xylenols and higher homologues is indicated, these should first be removed by a preliminary fractionation with an efficient column to 203° C. In this connexion it may be mentioned that when a large proportion of phenol is present, the distillate obtained above 203° C., even with an efficient column, may still contain appreciable quantities of phenol. In most samples of cresylic acid, however, the phenol content is fairly low and all the phenol distils over below this temperature. Moreover fractions with high phenol content obtained in works practice (except in the case of crude carbolic acid itself) have usually been obtained by the fractionation of crude carbolic acid and are entirely, or almost entirely, free from xylenols and higher homologues. The method of determining the phenol in crude carbolic acid will be described later.

The mixture of tar acids obtained above should have been freed from water.

A known weight of standard phenol (f.p. 40·5° C.) is then added to a weighed portion of the above mixture (X), so as to yield a mixture containing at least 55% of phenol, and 10% of its weight of water is run in from a burette. For the determination of the freezing point of the phenol hydrate, 12—15 g. of this solution is required. The freezing point apparatus is similar to that described by Fox and Barker, and consists of a thin-walled test tube, inserted into another tube of slightly larger diameter acting as an air bath, at the bottom of which some dry calcium chloride is placed to keep the air dry and prevent the formation of mist.

The temperature of the solution is read on a thermometer graduated from +20° to −10° C. and reading to tenths of a degree. The liquid is stirred regularly by means of a stout spiral copper wire stirrer. A preliminary freezing point determination is first made. The apparatus is placed in a freezing mixture of ice and salt and cooled, with constant stirring, until crystals of the hydrate appear. It is advisable to seed the cooled solution with a crystal of phenol hydrate, to ensure that phenol hydrate crystallises out and not mixed crystals of phenol and the cresols. A tube containing phenol hydrate should be kept in the freezing mixture for this purpose. The crystals of the hydrate are fairly easily distinguished from those of the mixed crystals of phenol and the cresols. The apparatus is then removed from the freezing mixture and allowed to warm up, with constant stirring, and the temperature at which the crystals of hydrate just disappear is read off on the thermometer.

A more careful freezing point determination is then made. The tube is again cooled, a freezing mixture being employed, if necessary, until the liquid in the freezing point tube is a few degrees below the preliminary freezing point determined above. The cooled liquid is then seeded with a crystal of phenol hydrate and stirred rapidly. In this way a fine "cloud" of hydrate crystals is formed. The apparatus is now removed from the cooling bath and placed in a bath of water cooled with ice to a temperature 1°—2° above that of the preliminary freezing point already determined. The solution is constantly stirred and the temperature read off at which the fine "cloud" of crystals just disappears. By taking the above precaution of obtaining only a fine "cloud" of crystals, and not allowing large crystals to form, the temperature at which the crystals just disappear may be found with precision and successive determinations should not differ by more than 0·1° C.

Having obtained the freezing point of the hydrate, the percentage of phenol in the mixture is then read off from the curve $(=p)$, and the percentage of phenol (x) in the original mixture (X) of tar acids calculated from the formula:—

$$x = \{ p(a+b) - 100b \} \div a$$

where a is the weight of original mixture (X) taken and b the weight of standard phenol added.

The table below gives the data from which the phenol hydrate curve used is constructed:—

% Phenol in mixture.	F.p. of hydrate (9·1% water).
100	16·0
95	14·25
90	12·25
85	10·25
80	8·1
75	5·8
70	3·4
65	0·75
60	—2·2
55	—5·2

The above method has been used for the determination of phenol in cresylic acid, and also for the determination of phenol in the numerous fractions with higher phenol content, obtained in the working up of crude carbolic acid.

Where a comparison has been made between the present method and that of Fox and Barker, the results obtained have been in fairly good agreement, as shown in the table below:—

% Phenol determined.

Hydrate method.	Fox & Barker's method. (curve corrected for phenol, f.p.=40·5° C.).	Cresols present (approx.).
65·3	65·9	*o*-cresol, 20%; *m*+*p*-cresols, 14·5%
62·8	61·8	*o*-cresol, 19%; *m*+*p*-cresols, 19%
57·5	57·1	Chiefly *o*-cresol.
49·1	48·5	*o*-cresol, 30%.
40·8	40·4	*o*-cresol, 15%; *m*+*p*-cresols, 33%.
15·2	14·6	*o*-cresol, 16%.
13·1	13·0	*o*-cresol, 15%; *m*+*p*-cresols, 60%.
6·2	5·8	*o*-cresol, 30%.

The method described in the present paper ha the following advantages over that of Fox an

Barker:—(1) It is more rapid and more generally applicable as a works test, since there is no preliminary fractionation (or fractionations) to separate the phenol with *o*-cresol. (2) The effect of small traces of moisture left in the phenol-cresol mixture is practically negligible in the hydrate method, since the hydrate curve is almost flat (9% water). In using Fox and Barker's method, it is necessary to dry the mixture thoroughly over freshly ignited calcium chloride before determining the freezing point. (3) A greater degree of accuracy is attainable when the phenol content of a mixture of phenol and the cresols is low, since although the slope of the hydrate curve is approximately the same as that of the phenol-*o*-cresol freezing point curve, the range of the hydrate curve is more than double that of the latter curve.

In the above investigation the freezing point of the phenol used was 40·5° C., since phenol of this freezing point is readily prepared from ordinary samples of phenol. Probably the most accurate determination of the freezing point of phenol is that of Leroux (J. Pharm. Chim., 1919, (7) **20**, 88), who found that pure anhydrous phenol melts at 40·85° C.

Determination of phenol in crude carbolic acid.

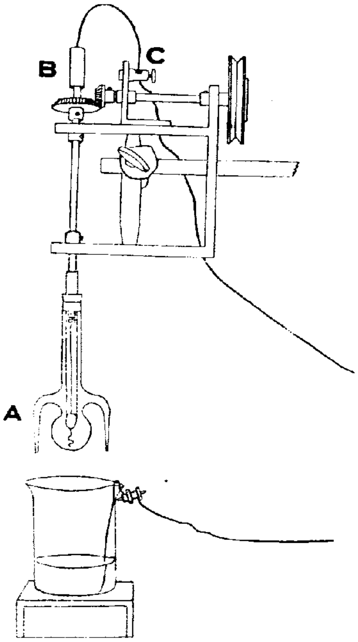
The hydrate method enables the phenol content of samples of crude carbolic acid to be readily determined. The sample should first be freed from neutral hydrocarbons and pyridine bases, if these amount to more than 2—3%. A weighed quantity of the sample is then fractionated with an efficient column. The water is collected separately, "salted out," and the oil returned to the distillation flask. The oil is fractionated to 202° C. (distillate A). To the weighed residue about half its volume of *o*-cresol is added, and the resulting mixture again fractionated to 202° C. (distillate B). In this way the small amount of phenol left in the residue boiling above 202° C. is removed. A determination of the phenol in the weighed distillates, A and B, by the hydrate method enables the percentage of phenol in the original crude carbolic acid to be calculated.

The thanks of the author are due to Messrs. Bowdler and Bickerdike, in whose research laboratory the work described in this paper was carried out, for kind permission to publish the results.

A SIMPLE APPARATUS FOR ELECTROMETRIC TITRATION.

BY W. E. GARNER AND C. A. WATERS.

During the course of a number of experiments on the methods of electrometric analysis devised by Treadwell and Weiss (Helv. Chim. Acta, 1919, 2, 680), a simple apparatus was devised which differs in certain essential details from the apparatus described by these authors. This apparatus, as may be seen from the illustration, consists of an electrode vessel attached to a rotating stirrer. The electrode vessel, A, carries a small bulb, which is convenient in the preparation of a calomel electrode, and two side tubes turned downwards and constricted at the ends. The appropriate metal used as an electrode is either fused or waxed into a thin glass tube, and attached by means of a small binding screw to a rotating spindle, electrical connexion being made through a small steel mercury cup, B, to a binding screw, C. The constricted side tubes of the electrode vessel are packed with asbestos as described by Treadwell, and the vessel completely filled with electrolyte and supported from the glass tube by means of a waxed cork. To prevent the formation of small bubbles in the constricted tubes, it is advisable to store in a solution of the electrolyte of the same strength. It is also essential to avoid the presence of a bubble of air in the electrode vessel itself, for this makes it more sensitive to temperature changes and leads to leaks during the analysis. The down-turned capillaries make it possible to start a titration with 5 c.c. of solution in the beaker, whereas an apparatus of the type described by Treadwell of corresponding capacity required nearly 50 c.c. before the ends of the capillaries were immersed. The electrode is best driven at a rate of 80—90 revolutions per minute. The outer electrode may be of any convenient form such as that shown.



The electromotive force generated between the electrodes was measured by a high-resistance millivoltmeter (1000 ohm) which was connected to one of the arms of a resistance box. The electrodes were connected across the whole resistance of the box (10,000 ohms) and the resistances in the two arms of the box were so adjusted as to give the maximum deflection in the millivoltmeter.

In the case of silver titrations

$$\underbrace{\mathrm{Ag}\;\Big|\;N/10\,\mathrm{AgNO_3}}_{\text{inner electrode.}}\;\Big|\;N/100\,\mathrm{AgNO_3}\;\overset{\downarrow N/100\,\mathrm{NaCl}}{\Big|}\;\mathrm{Ag}$$

results giving an end-point within 0·05 c.c. $N/100$ NaCl were readily obtained and reproduced (see Treadwell, *loc. cit.*). Equally good results were obtained with zinc titrations with potassium ferrocyanide.

$$\underbrace{\mathrm{Pt}\;\Big|\;N/10\,\mathrm{K_4Fe(CN)_6}}_{\text{inner electrode.}}\;\Big|\;N/10\,\mathrm{K_4Fe(CN)_6}\;\overset{\downarrow N/10\,\mathrm{ZnSO_4}}{\Big|}\;\mathrm{Pt}$$

An attempt was made to apply this method to the titration of sulphates by means of barium salts but it was found impracticable except in the titration of the alkali sulphates, when it worked very well. The arrangement

$$\underbrace{\mathrm{Hg}\;\Big|\;\mathrm{HgSO_4}\ N/10\ \mathrm{H_2SO_4}}_{\text{inner electrode.}}\;\Big|\;N/10\ \mathrm{SO_4''}\;\overset{\downarrow N/20\ \mathrm{Ba(OH)_2}}{\Big|}\;\mathrm{Hg}$$

in which the mercury electrode consisted of a fine stream of mercury, gave satisfactory results.

The method is inapplicable to the sulphates of metals giving insoluble hydroxides.

CRESYLIC ACID.

BY J. J. FOX.

Corrigenda.

In a paper dealing with the composition of cresylic acid (J., 1920, 169 T) a method for determining the proportion of *o*-cresol was described depending upon the specific gravity of the cresylic acid. The formula given was calculated from the products of the percentages of the various cresols and their specific gravity, but the accurate method of calculation is, of course, to add the volumes of the constituents.

The correct formula is:—

$$8210—(8529 \div G)—(P \times 2{\cdot}942) = \%\ o\text{-cresol},$$

where G is the specific gravity of the mixture, and P the percentage of phenol; or in the absence of phenol:—

$$8210—(8529 \div G) = \%\ o\text{-cresol}.$$

In practice the results obtained with either formula do not differ greatly because it happens that the specific gravities of the cresols are fairly close together.

The table of the "Specific gravities of phenol with a mixture of *o*-cresol and *m*-cresol" (J., 1917, 845) should be deleted, as the specific gravities shown refer to an entirely different series of mixtures of the three cresols and phenol.

THE MANUFACTURE OF 1.3.5-TRINITROBENZENE.

BY ALAN A. DRUMMOND, M.SC.

This paper gives an account of an investigation of methods for the economical production of *s*-trinitrobenzene with a view to its large-scale manufacture. Several workers have examined methods of direct nitration (Hepp, Annalen, 1882, **215**, 345; Lobry de Bruyn, Rec. Trav. Chim., 1891, **13**, 149; Radcliffe and Pollitt, J., 1921, 45 T). An indirect method involving nitration has been proposed by Frankland, in which 1-chloro-2.4-dinitrobenzene is nitrated to form picryl chloride and the chlorine group subsequently replaced by hydrogen. No large-scale production has been mentioned, however.

Radcliffe's work (*loc. cit.*) showing the comparative ease of nitration of dinitrobenzene using 100% nitric acid and oleum containing 60% free SO_3, and also the good result obtained by Frankland and Garner (J. 1920, 257 T) by nitrating chlorodinitrobenzene led to the work described in this paper. Hepp obtained a yield of 45% of theory of trinitrobenzene using highly concentrated acids, whilst Radcliffe and Pollitt claimed yields of 70% of theory.

The strongest acids readily available in quantity in the factory were oleum containing about 20% free SO_3 and nitric acid containing at a maximum not more than 95% HNO_3. These acids were therefore used in the experiments and applied in the first place to the nitration of pure *m*-dinitrobenzene recrystallised from alcohol (m.p. 89·5° C.). The methods adopted in the nitration work were modelled on those employed in the nitrating factory in the nitration of mono- and dinitrotoluene (see Technical Records of Explosives Supply. 1915–1918. No. 2. Manufacture of Trinitrotoluene; J., 1921, 3 R) and on the method employed by Frankland and Garner (*loc. cit.*) in nitrating 1-chloro-2.4-dinitrobenzene. Methods for the isolation of trinitrobenzene from the crude nitration product containing dinitrobenzene were also investigated, including those of crystallisation and also formation of additive compounds (Hepp, *loc. cit.*, and Sudborough, Chem. Soc. Trans., 1916, **109**, 1339). In this connexion a setting point-composition curve was constructed for mixtures of *m*-dinitrobenzene and 1.3.5-trinitrobenzene.

Work on the following lines was carried out: The materials used were oleum containing about 22% of free SO_3 (100 parts being equivalent to 104 parts of 100% sulphuric acid); nitric acid of 90% strength, and dinitrobenzene, m.p. 89·5° C. The nitrations were carried out with systematic alteration of variables, viz., proportion of nitric acid, concentration of nitric acid and sulphuric acid, proportion of sulphuric acid, time of nitration, temperature of nitration, and mode of mixing the reaction materials. Comparative nitrations were carried out with dinitrobenzene and chlorodinitrobenzene under similar conditions.

The apparatus used was a round-bottomed nitrating flask with long glass air condenser attached to it by a ground glass joint. The flask was heated by an oil bath, and agitation was effected by periodical vigorous shaking.

Two methods were adopted in the initial mixing of the materials:—

(1) "*Hot mixing.*" The charge of dinitrobenzene, dissolved in the required amount of nitric acid and warmed to 80°—90° C., was added gradually to the required amount of oleum, also heated to 90° C., with continual shaking, keeping the temperature of the mixture at about 95°—100° C. External heating was not required to maintain a temperature of 100° C. until the bulk of the solution had been added.

(2) "*Cold mixing.*" The dinitrobenzene, dissolved in nitric acid, was run cold into oleum, also at ordinary temperature, without cooling. The maximum temperature reached was 110° C., and as the final portions of the nitric acid solution were added the temperature fell. In each method the temperature was subsequently raised at the rate of about 1° C. in two minutes. The proportion of sulphuric acid to nitric acid was chosen so that the waste acid after nitration and before dilution was not more than about 97% H_2SO_4. Dilution to 75% H_2SO_4 was found to precipitate the bulk of the nitration product. The yield was determined on the nitration product from the completely "drowned" nitration charge.

The reaction mixture after each nitration was poured into 2—3 times its weight of water with cooling. The solid product was filtered off and washed twice by steam-blowing and granulating in cold water, dried in the steam-oven, and weighed. The proportion of trinitrobenzene in the itration product was determined from the setting oint curve for **mixtures** of trinitrobenzene and initrobenzene (*cf. infra*).

* 100% H_2SO_4. † 100% HNO_2,

The effects of the two methods of mixing are hown in Nos. 1—4. A twelve-hour nitration gives he same result by both methods, but after a sixiour nitration the method of hot mixing, as might e expected, appears to have increased oxidation vith consequent loss of product.

The time factor is an important one in the itration of dinitrobenzene. It has previously been hought that long nitration, extending to a number f days, was essential. It has, however, been found hat the limit of nitration is reached in a much horter period, further action only leading to oxidaion. By reducing the time of nitration to 3 hours rom the start of mixing the materials, marked mprovement over the result of 6- and 12-hour nitraions was obtained (*cf.* Nos. 2, 4, 5, 6, 7).

The effect of temperature is seen in two experinents (Nos. 8 and 9) carried out at 120° C. (*cf.* No. 3). Nitration at this temperature evidently equires a longer time for completion.

In Nos. 10 and 11 the concentration of the nitric cid was raised to 100%, but with 4 molecules HNO_3 nd three hours' nitration no improvement was btained.

Reference to the results of Nos. 5, 6, and 12 shows hat the yield of trinitrobenzene increases with the mount of nitric acid taken. The amount of oxidaion also increases at a rapid rate. It would appear rom the figures that a further increase of nitric cid beyond 11 mols. and under the same conditions vould not effect any marked improvement in the ield.

Setting points of mixtures of trinitrobenzene and dinitrobenzene.

87·3	12·7	82·0
100·0	0	89·5

An indirect method of preparing trinitrobenzene involved the preliminary nitration of chlorodinitrobenzene, and it was therefore desirable to compare the relative ease of nitration in each method, the tests being carried out under exactly similar conditions of nitration. A yield of 68% of picryl chloride is obtained as compared with 18% of trinitrobenzene, the loss of chlorodinitrobenzene being 14—15% as compared with 35% of dinitrobenzene. The yields of picryl chloride and unchanged chlorodinitrobenzene were determined by the use of the setting point curve for mixtures of chlorodinitrobenzene and picryl chloride (Frankland and Garner, *loc. cit.*).

The above table has been obtained from the determination of setting points of artificially prepared mixtures of pure trinitrobenzene and dinitrobenzene. The curve plotted from these figures indicates that dinitrobenzene and trinitrobenzene form a compound between limits of 45% and 50% trinitrobenzene, with setting point 58° C. This compound occasions considerable trouble when mixtures rich in dinitrobenzene are being dealt with for the recovery of trinitrobenzene. It would seem to be the cause of the assumption of an isomeric trinitrobenzene made by Radcliffe and Pollitt (*loc. cit.*; see also Gibson, J., 1921, 90 T).

The yield of trinitrobenzene obtained in the various nitrations described has been determined by the use of a curve constructed from the above table. The setting point of the washed, dried nitration product was determined and the composition read off from the curve. Where there was uncertainty regarding the side of the curve to which the particular setting point referred, a known proportion of pure trinitrobenzene was added to the mixture and the setting point redetermined. The movement up or down of the setting point after the addition decided the original composition.

Separation of trinitrobenzene from mixtures with dinitrobenzene.

Attempts were made to separate trinitrobenzene from dinitrobenzene by:—

(1) Fractional crystallisation from alcohol and carbon tetrachloride. The following table gives the solubilities of dinitrobenzene, trinitrobenzene, and the 50% eutectic mixture in alcohol:—

Dissolved substance.	100 g. dissolves: At 100° C. g.	At 20·5° C. g.
DNB.	25·6	3·5
50% eutectic	18·2	—
TNB.	8·5	1·9

Mixtures of dinitrobenzene and trinitrobenzene of known setting point and composition were crystallised from alcohol, and the composition determined respectively of the portion crystallised out and that remaining in the mother liquor (by use of the setting point curve). The results of these experiments (see Table) indicate clearly the difficulty of separating mixtures of DNB and TNB by fractional crystallisation from alcohol.

Original mixture.		Crystallised out.			In mother liquor.	
Setting point. ° C.	Content of TNB. %	g. per 100 g. original mixture.	Setting point. ° C.	Content of TNB. %	Setting point. ° C.	Content of TNB. %
86·0	70	72·5	96·0	78·0	66·0	46
66·5	56	75·0	77·0	65·0	66·5	36
70·0	30	80·2	68·5	32·5	77·0	21

(2) Fractional precipitation from the nitrating acids, in which again the compound of trinitrobenzene and dinitrobenzene apparently prevents separation.

(3) Formation of compounds with aniline, α- and β-naphthylamine and subsequent recovery of trinitrobenzene. The aniline compound offered most promise, chiefly because of the readiness with which trinitrobenzene can be recovered by evaporation of aniline and simultaneous recovery of the aniline. From a mixture of dinitrobenzene and trinitrobenzene containing 50% of trinitrobenzene a recovery of 80—90% of pure trinitrobenzene was possible by this means.

The author's best thanks are due to Miss R. M. Duckham, B.Sc., for the determinations of the setting points of mixtures of trinitrobenzene and dinitrobenzene, for the determinations of the solubilities, and for the figures obtained in the recrystallisation experiments.

Conclusions.

From the foregoing work conclusions may be summarised as follows:—

(1) A yield of 29% of theory of trinitrobenzene with a 24% recovery of dinitrobenzene may be obtained by a three-hour nitration at 130° C. with nitric acid of 90% strength and fuming sulphuric acid containing 22% of free SO_3. The expenditure of nitric acid is equivalent to 7 molecules, using sulphuric acid in quantity calculated to give a spent acid of about 95% H_2SO_4. The destruction of dinitrobenzene amounts to 43% of the original weight of dinitrobenzene.

(2) Less nitric acid gives less trinitrobenzene but also less loss by oxidation; thus, 4 mols. HNO_3 gives 22% of trinitrobenzene in three hours at 130° C. and 30% loss of dinitrobenzene.

(3) A greater amount of nitric acid gives a larger amount of oxidation loss but a purer trinitrobenzene. Thus, 11 mols. HNO_3 gives 32% of trinitrobenzene in 6 hours, with about 1% of dinitrobenzene recoverable. The nitration product is a good crude trinitrobenzene of setting point 117°—118° C.

(4) From these results it appears that with the acids given the economical manufacture of trinitrobenzene by direct nitration is not practicable.

(5) The comparative nitration of chlorodinitrobenzene and dinitrobenzene shows that a yield of 68% of picryl chloride can be obtained as compared with 18% of trinitrobenzene, the relative losses of chlorodinitrobenzene and dinitrobenzene being respectively 15% and 35%. Trinitrobenzene can therefore be made more economically from chlorodinitrobenzene through picryl chloride, as the final replacement of the chlorine is readily accomplished.

The author's thanks are due to the Director of Artillery for permission to publish this paper.

MR. E. V. EVANS IN THE CHAIR.

THE STRUCTURE OF COKE: ITS ORIGIN AND DEVELOPMENT.

BY SIR GEORGE BEILBY.

In connexion with the work of the Fuel Research oard it was early recognised that for the study of ıe behaviour of different types of coal during car- nisation the ordinary laboratory methods of coal sting and analysis were quite inadequate, and ıat for the purposes of this inquiry a new method assay must be elaborated. A full description of ıe method which was ultimately devised and of ıe apparatus in which it was carried out has ready been published.* In this apparatus the ields of the principal products of carbonisation at ny given temperature are ascertained by direct eighing and measurement, while much useful formation is obtained as to the physical and other roperties of the products. Of no less importance re the opportunities which this method presents r the study of the behaviour of different types of al during carbonisation, *e.g.*, the stages in the volution of the hydrocarbon gases, the changes in mposition of these at each stage, and the influence f the fusibility of the coal on the ultimate form nd structure of the resulting coke. The last-amed study has a very direct bearing on the prac- cal side of the problem of industrial carbonisation, ot only for the production of a satisfactory smoke- ss fuel for domestic use, but also on the pro- uction of coke for metallurgical and other indus- ial purposes.

The following experimental observations were for ıe most part carried out on average samples taken om bulk deliveries of the different coals as these ere received at H.M. Fuel Research Station. The eliveries in some cases represented the whole coal om one definite seam, and in others the result f screening, or screening and washing, the small al from several seams. No attempt was made t this stage to carry out the separate examination f the distinct bands of which the seams were omposed.

The samples used were obtained by methods hich have been described in the reports of I.M. Fuel Research Station; but for the present urpose it is sufficient to note that a large bulk ample was crushed, mixed, quartered, and finally round till it would all pass through a 50-mesh ieve. The material carbonised in the assay pparatus in the laboratory and later in the trays f the horizontal retorts may therefore be regarded s a homogeneous mixture, the behaviour of which n carbonisation and the products obtained there- rom, accurately represent the characteristics of the oal as a whole.

Most seams are built up of bands of varying usibility, each of which would give different esults if carbonised by itself. When coal in the ough is carbonised in gas retorts it is often ossible to pick out pieces of the coke which have bviously resulted from bands of different fusibility. Vhen the more fusible parts preponderate, the usion may become so general as to absorb the less usible portions into one indistinguishable mass. In other cases the infusible portions retain their individuality, but are concreted by the fused material into a caked mass. The latter effect is very noticeable when a caking or partially caking coal is carbonised in continuous vertical retorts, while in heavily charged horizontal retorts, in which the charge is undisturbed from start to finish, the effects of general interfusion are more in evidence.

The results of carbonisation in the laboratory assay apparatus throw a great deal of light on the behaviour of coals of different fusibility in a fine state of division and in homogeneous mixtures. Coals for the purposes of carbonisation may be classed under two heads:—(*a*) those in which the resulting coke occupies a greater volume than the original coal, and (*b*) those in which it occupies a smaller volume. The behaviour of class (*a*) is often referred to as due to the "expansion" of the coal. This might be taken as implying that the actual coke substance, the material of which the coke structure is built up, may be less dense than the coal substance from which it is produced. This it never is, for the coke substance essentially consists of carbon in the vitreous state which in itself is structureless, and the density of which is in the neighbourhood of 1·9.

Microscopical study, which began with the examination of specimens of coke resulting from the laboratory assay of individual coals of different degrees of fusibility and of mixtures of these, naturally led to a more extended inquiry into the origin of coke structure and as to the means by which it can be modified and controlled.

In charcoal and coke, carbon appears as the non-volatile residue of destructive distillation or carbonisation. It results from the decomposition by heat of the complex organic substances of which wood, peat, lignite, and coal are composed, and the driving off by heat of the volatile products of this decomposition. The higher the temperature of carbonisation the more complete are the decomposition and volatilisation, and the smaller therefore are the percentages of hydrogen and other gaseous elements left in combination with the residual carbon. By carbonisation at 1100° to 1200° C. the volatile matter left in the residue may be reduced to less than 1%.

The non-volatile constituents of the original material are concentrated in the carbon residue, and may exercise a considerable influence on its structure. In the case of coke this influence will be traced with some detail in what follows, but it has a special significance in the case of wood charcoal, which may be referred to now. Even a superficial observation of the charcoal from various kinds of wood shows that the general features of the wood structure are preserved in the charcoal, but the microscope not only confirms this general likeness, it shows the persistence of the actual cell structure. Professor Farmer states that anyone familiar with the micro-structure of various kinds of wood can without difficulty identify the particular wood from which a specimen of finely-powdered charcoal has been prepared. It is perhaps not so generally known that this identification of cell structure can to some extent be followed to an even later stage by the study of the ash left on the combustion of wood charcoal. A piece of wood charcoal, if allowed to burn quietly away in the absence of draughts, leaves its mineral ash in the form of a delicate, lace-like skeleton in which the minute cellular structure of the wood is reproduced. This suggests that these mineral constituents may actually contribute to the preservation of the plant cell structure in the charcoal by providing infusible nuclei distributed through the cell walls, thereby minimising the obscuring effects of the fusion of the carbon compounds during carbonisation. For we must now recognise that the production of an infusible carbonaceous residue from organic materials is invariably preceded by the fusion of the compounds of carbon with hydrogen and oxygen (and in the case of coal, sulphur and nitrogen) which result from the decomposition of these materials by heat. For each type of organic substance there is a stage in carbon concentration at which fusibility ceases. In some cases the range of fusibility is extended by raising the temperature of carbonisation. This, as will be seen, is the case in coal and similar bituminous materials, while in carbohydrates like sugar and cellulose the carbon concentration, with the resulting infusibility, is definitely reached at a much lower temperature, and no fresh access of fusibility can be induced by the application of higher temperatures.

---

* Fuel Research Board, Technical Paper No. 1: "The assay of oal for carbonisation purposes," by T. Gray and J. G. King.

In sugar we are fortunately provided with a pure chemical substance from which a carbonaceous residue can be prepared which is practically free from mineral and other impurities. This residue contains only minute quantities of hydrogen and oxygen, and it approaches more nearly to elementary purity than any form of carbon other than diamond and graphite. Indeed, it is by no means certain that graphite is really carbon in the elementary state, as Sir William Bragg's work on the atomic structure of diamond and graphite indicates that in the relatively open packing of graphite there is room for a layer of hydrogen atoms between the more densely packed lamellæ which are in diamond formation. It may be, therefore, that graphite is not pure carbon but a definite compound of carbon and hydrogen.

It has hitherto been the custom to refer to all forms of carbon other than diamond and graphite as amorphous. In his work on "The Electric Furnace" Henri Moissan devotes a chapter to his study of amorphous carbon, in the opening paragraphs of which the following sentences occur:—

"Carbon is the element which presents the most interesting allotropic varieties. It has long attracted the notice of workers by its contradictory properties and by the differences existing between the specific heats of the diamond, of graphite and of lampblack. . . . Theses have often been written on the hypothetical shape of the carbon atom, but there are relatively few experiments on the physical and chemical properties of the same carbon. . . . In order to reproduce the diamond, we were led to take up again a general study of the different varieties of carbon. . . . In the first part we shall deal with the amorphous kinds of carbon."

While Moissan made full use of the microscope in the study of graphite and diamond, his references to the micro-structure of amorphous carbon are very casual, and amount to little more than the statement that the substance was "amorphous," which generally appears to mean that it was in the form of a brown or black impalpable powder. For the purpose of his experimental work on the artificial production of diamond, the study of amorphous carbon was mainly directed to its response to oxidation by oxygen and by chemical agents and its differentiation by these tests from graphite and diamond. His study of lampblack led him to the conclusion that the carbon in this substance can be polymerised by calcination. The temperature of combustion of purified lampblack in oxygen was found to be 371° C. This lampblack was calcined for five minutes in a porcelain crucible at 910° C., and its temperature of combustion rose to 440° C. After calcination for three hours the temperature of combustion rose to 476° C., and after six hours to 506° C. The density was raised by calcination to 1·87. No attempt was made to associate the increase of density and the reduction of reactivity with changes in the state of aggregation which should have been plainly seen in the micro-structure. In my opinion the changes in chemical activity may quite well be accounted for by alterations in molecular aggregation which in effect lower the reactivity of the carbon merely by reducing the surface exposed to oxidation.

The more careful study of the aggregation of solids which had already begun some years before the publication of Moissan's work, had shown that the word "amorphous" was too apt to be used to cover our ignorance of forms of aggregation in which the atoms and molecules are not in the orderly formation and equilibrium which is the essential feature of the crystalline state.

The vitreous state, to which we owe so much in our daily lives, where it is presented to us at every turn, not only in its more obvious forms as glass and porcelain, but equally in metals and alloys in the hardened state, is no longer regarded as outside the scope of physics, chemistry and metallurgy. It is a definite form of molecular aggregation which over a long range of temperature is thermally as permanent as the crystalline state, while in many cases it is physically the more stable form. We now know that the special rigidity of the vitreous state is always associated with a state of strain which impairs the elastic freedom of the individual molecules. The remarkable hardness of vitreous carbon is associated with the type of brittleness which results from this state of strain. It is by virtue of that state of internal strain that glass can be cut by the diamond. The diamond does not really "cut" glass; it cleaves it. The cleft which can be initiated by the pressure of the diamond on the surface, spreads indefinitely in the plane in which it was initiated owing to the state of elastic strain of the glass. In the crystalline state this elastic strain does not exist. A single well-developed crystal can be cleft along certain definite planes, but the cleavage in this case is due to the homogeneous aggregation of the molecules in definite lamellæ between which either cleavage or slip may occur.

My own study of the steps in the formation of carbon by the carbonisation of sugar and of the micro-structure and properties of this substance and of coke, have led to the conclusion that in most if not all of the carbonaceous residues with which we are familiar, from wood charcoal to hard coke, the carbon is in the vitreous state—it is a true glass. This glass-like character of the ultimate coke substance has from time to time been referred to by various observers, though its significance from the physical point of view and its influence on the structure and properties of coke have not so far as I am aware been hitherto recognised.

The first experiment on the carbonisation of sugar was made by slowly heating a small crystal which weighed a few milligrammes on a glass micro-slip on a hot plate heated by a ring burner. Fusion without discoloration took place at 180°—190° C. Evolution of gas—mainly water vapour—with bubbling and foaming, began at about 220°. This practically ceased about 240°—250°, and the brown viscous liquid became tranquil and remained so till about 260°—270°, when gas was again evolved with vigorous bubbling and frothing, and the colour of the residue became black except in films or layers of extreme thinness. The temperature was gradually raised to about 450° C. Fig. 11 is a photomicrograph of the carbon residue at a magnification of ×10. It is a black glass which has been blown into a sponge of communicating bubble cells. Round the edges some unburst bubbles are seen. The thinner films are transparent and brown by transmitted light. By direct inspection with the 16-mm. lens small burst bubbles were detected, the walls of which were so thin that they showed the soap bubble colours. This vitreous carbon is entirely without metallic reflection, its surface is as smooth as glass and does not scatter light even under concentrated illumination.

Mr. King, chief of the laboratories of H.M. Fuel Research Station, has carried out the carbonisation of sugar in the laboratory assay apparatus with the following results:—

Amount experimented with: 2·3 grams.

Temp. °C.	Time.	Behaviour.	
180	10.32	No gas. No change.	
200	10.34	Melting.	
220	10.36	Melted.	
240	10.40	Browning and frothing, the viscous material blown into thin films. Gas evolution: water distillate.	
250	10.43	Rapid evolution of gas.	
270	10.48	Vigorous frothing; charring of the bubble walls and films. Light brown coloured distillate.	
290	10.51	Gas evolution 9 c.c. per min.	
316	10.54	Black residue consisting of thin films. Gas evolution still strong.	
332	11.4	Gas evolution still strong. Further flaking of carbon substance.	
344	11.0	Gas 8·75 c.c. per min.	The carbon residue is becoming infusible and the blowing even of minute bubbles has ceased.
374	11.21	Gas 7·0 ,, ,, ,,	
380	11.28	Gas 7·0 ,, ,, ,,	
398	11.37	Gas 5·5 ,, ,, ,,	
400	11.44	Gas 3·75 ,, ,, ,,	
420	11.55	Gas 3·5 ,, ,, ,,	From this stage little or no fresh gas was evolved; the gas measured mainly resulting from the expansion of that in the apparatus through rising temperature.
468	12.20	Gas 3·0 ,, ,, ,,	
484	12.30	Gas 3·0 ,, ,, ,,	
495	12.35	Gas 2·75 ,, ,, ,,	
500	12.40	Gas 2·5 ,, ,, ,,	
508	12.39	Gas 2·5 ,, ,, ,,	
516	12.55	Gas 3·0 ,, ,, ,,	
528	1.0	Gas 2·5 ,, ,, ,,	
540	1.15	Gas 2·0 ,, ,, ,,	
550	1.25	Gas 1·75 ,, ,, ,,	
556	1.32	Gas 1·25 ,, ,, ,,	
562	1.38	Gas 1·25 ,, ,, ,,	

These results are not strictly comparable with my own experiments on single minute crystals, owing to the difference in scale, which was in the ratio of 1:1000, but taking into account the very great difference in the scale of the operations, and therefore in the part played by the time element, the results are in fair agreement.

Mr. King has also carried out carbonisation experiments in crucibles over a wider range of temperature to determine the density of the vitreous carbon. At a temperature of 850° C. a product of sp. gr. 1·8 was reached.

Winter and Baker* obtained a carbon of sp. gr. 1·76 by heating for 4 hours at 900° C. After heating for 40 hours the specific gravity rose to 1·84. Forster† found that sugar charcoal prepared at high temperature contained 95% of carbon and 1·1% of hydrogen.

Moissan used lampblack as a standard of comparison in his study of amorphous carbon. He states that the lampblack was purified by successive washings with benzene, alcohol and ether. "This is absolutely necessary, and the quantity of hydrocarbons so removed was considerable. After the ether washing, the air-dried powder is placed in an oven and the temperature slowly raised to 150° C. This lampblack floats on allyl iodide of 1·87 density and sinks in propyl iodide of 1·78 density. Lampblack so prepared is far from being pure. It holds tenaciously small quantities of hydrocarbons and water from which it cannot be freed. It contains also a little nitrogen.

"To analyse this variety of carbon, it is first heated *in vacuo*, at the softening point of glass, in order to cause it to polymerise and to be handled more easily. Some water and traces of hydrocarbons are set free. The black powder then gives the following figures:—

These were two different samples.

	No. 1.	No. 2.
	%	%
Ash	0·22	0·34
Carbon	93·21	92·86
Hydrogen	1·04	1·20

"If the hydrogen be expressed as water, it is seen at once that the figures add up to more than 100, which shows that a small amount of hydrogen, less than 1%, is still there in the form of hydrocarbon; the remainder comes from the water whose complete removal from lampblack is not possible."

For our present purpose the significance of the foregoing analytical results, taken in connexion with the physical properties of carbon produced from substances of known composition, is that its vitreous character becomes more marked as the state of elementary purity is approached by the driving off of hydrogen or hydrocarbons. Though the bubble sponge structure must be regarded as a survival of the fusible state and the evolution of gases, the fact remains that long after this stage of carbonisation has been passed the material retains its glass-like character and even the thinnest bubble walls are still vitreous. The micro-structure of lampblack films deposited on a glass surface has been dealt with in another connexion. ("Aggregation and Flow of Solids," page 64, Fig. 35, Plate XI.)

The hardness of vitreous carbon.

The conversion of the so-called amorphous forms of carbon into graphite by their exposure to high temperatures is well recognised not only among scientific workers but in industry. Whether this operation can be simply explained as the natural passage of the vitreous to the crystalline state, which occurs in a great variety of substances at a temperature much short of the liquefying point is, I think, still unproved. Experience in matters physical shows the need for caution in accepting what appears to be the most simple explanation of any phenomenon; and in this particular case the suggestion of Sir William Bragg that hydrogen may possibly take part in the building up of graphite supplies a definite reason for suspension of judgment. I can only refer very briefly to the significance of the suggestion that, in addition to the crystalline forms of carbon, diamond and graphite, there is a third form which is vitreous and of lower density than either of these.

If it is ultimately confirmed that vitreous carbon has a density of 1·85 as compared with 3·55 in diamond and 2·55 in graphite, interesting questions arise in regard to the atomic packing in the vitreous state which may have an important bearing on the whole theory of the rigidity of solids.

The relatively close packing of the atoms in diamond seems to fall naturally in line with the extreme hardness and rigidity of carbon in that form. The sectile quality of graphite, which causes it to flow like a liquid under moderate differential pressures and to act therefore as one of the most trustworthy of lubricants for moving surfaces under high pressure, is associated by Sir William Bragg with the alternation of closely packed layers in diamond formation with layers of wider spacing in which there is room for a layer of hydrogen atoms. The graphite which flows under differential pressure is composed of ultramicroscopic plates of diamond hardness which slip over each other with the freedom of a liquid. The question now arises, by what atomic arrangement can we account for the extreme hardness and rigidity of vitreous carbon in which the packing is on the average more open than it is in graphite?

---

* Chem. Soc. Trans., 1920, 117, 319.

† Chem. News, 86, 152.

Two points emerge very clearly from the consideration of the physical properties of the three forms of carbon. These are that the ultimate atoms of carbon in the solid state must in themselves possess great rigidity and hardness, and that the cohesive force within the molecule under the influence of which these atoms are built up in the rigidity of the vitreous state, must be used with a much higher efficiency than in the case of graphite.

The micro-structure of coke and charcoal.

The method of section cutting of coal developed by Mr. Lomax has placed in the hands of palæobotanists the means whereby the microscopical study of the constituents of coal as they occur *in situ* in the bands of which coal seams are built up, can be pursued on the well-established lines familiar to botanists and biologists: that is by the examination of extremely thin, transparent sections. From the microscopist's point of view, this method has many advantages. Not the least of these is that the examination can be made by light transmitted from below the stage of the microscope which passes through the section directly into the object glass. This means that light of any desired intensity can be used under the most critical conditions, and further that lenses of the highest resolving power can be employed, as there is no limit to the nearness of approach of the lens to the object. With lenses of high resolving power the picture as received at the eyepiece is a presentation of the object strictly in two dimensions. When lenses of longer focus and lower resolving power are used, however, the third dimension comes into the picture to a limited extent, and some idea may be gathered of the structure of the object as a solid.

For the study of the micro-structure of coke and other carbonaceous residues this method of section cutting is only available to a very limited extent. Carbon in this form is black by reflected light, but in very thin layers or films is brown by transmitted light. In the sponge-like form in which it occurs in coke it is glass-like and brittle, and is a peculiarly difficult material to prepare in the form of sections thin enough to be of any value for microscopical examination by transmitted light.

In a most interesting paper by W. Thörner in 1886 on the "Study of coal, coke, and charcoal,"[*] he describes how he succeeded in obtaining by grinding, thin sections of specimens of coke obtained from a number of different sources, and photomicrographs of these at a magnification of 50 diameters are given in the original paper. Two of these are reproduced, Fig. 1 being gas-retort coke and Fig. 2 pressed coke. These serve to show the inadequacy of this method for the study of the minute structure of coke. They are not even complete pictures in two dimensions, but are simply black and white silhouettes produced by light passing through holes in an opaque screen, which to all appearance is absolutely structureless. That Thörner did not recognise the limitations of this method of examination is quite clear, for he says:— "Coke made in gas retorts is the most unlike charcoal. It presents in various degrees massive pore walls with large cells which might almost be called caves. The coke substance is melted down until it has become an extremely close impermeable glassy mass."

My earlier work on the micro-structure of solids has shown the importance of bringing into view all three dimensions of the structure under investigation; for, however minute the elements of structure may be, they are solids of definite form which must be seen in relief if their nature and origin are to be properly understood. From the microscopist's point of view this means that lenses of great depth of focus must be used even though this necessarily involves a serious sacrifice of resolving power. Visually the heights and depths of a structure can be followed with the microscope by focussing up and down even with lenses of fairly high resolving power, but when photomicrographs are desired, only lenses of long focus and lower resolving power can be used. With this object planar lenses of 4·5 cm. and 7·5 cm. focus were used, and satisfactory photographs were obtained at magnifications from 5 to 12 diameters, the surface of the object being illuminated by a beam at an angle of about 45°. The more intimate structure was directly examined, using a 16-mm. apochromat of N.A. 0·3, the surface being preferably illuminated by reflected light from a north sky slightly condensed on the object by a double convex lens.

Carbon in the form of coke is a very difficult material to examine microscopically. As we have seen, it is a black glass, almost opaque and entirely without metallic reflection. From its glass-like surfaces light under ordinary conditions is reflected without scattering. With lenses of low resolving power the reflections from the surfaces of the more minute bubbles or cells give the effect of scattering. On examination with the 16-mm. lens it is seen that the surface of the minute bubbles or cells gives the effect of scattering, but on examination with the 4-mm. lens it is seen that the surface of the minute bubbles is still glass-like.

As grinding and polishing lead to surface flow, these operations, if resorted to, must be applied to coke with great caution, as they may obscure or even completely destroy the real structure. For this reason freshly broken surfaces are much to be preferred if these can be obtained reasonably flat. Broken edges often show details of structure which would have been missed on an unbroken surface.

The general method of examination was as follows:—

(1) The selected specimens were photographed at their natural size.

(2) They were then carefully examined in a good light with a hand lens and the portion best suited for microscopical examination was broken off and trimmed for mounting. In every case a specimen having an untouched broken surface and edges was prepared; but in some cases additional specimens were prepared by filing and grinding on fine emery, great care being taken to remove the resulting dust from the structure. All specimens were examined in this way, so that the structure was traced continuously from natural size down to the limits of resolution by lenses of N.A. 0·3 and 0·95. These limits are in the region of the one-thousandth and the forty-thousandth of a millimetre respectively.

(3) While photographs are of great value, they cannot take the place of patient and long-continued study at the microscope with gradually increasing magnification and resolution, and with varying illumination.

(4) The specimens were photographed at magnifications of from 5 to 12 diameters, using planar lenses of 4·5 and 7·5 cm. focus.

In each case the lens was stopped down till a clear picture with the necessary depth of focus was obtained.

(5) Many attempts were made to photograph the specimens using the 16-mm. and 4-mm. apochromats with the vertical illuminator, but the range of focus of even the 16-mm. is so small and the difficulty of satisfactorily illuminating a black glassy substance like coke is so great that no satisfactory results could be obtained in the time at my disposal. I hope, however, to have greater success when time permits.

These observations show that the coke structure, however minute, is due to the evolution of gas bubbles from the fused or partially fused coal

bstance. Probably the first step in this operation sults in the formation of a foam in which each bble is a self-contained cell, but by the mutual rforation of these bubble cells at their points of ntact, a sponge is produced through which the ses ultimately escape to the outside of the mass. e special characteristic of fused coal substance ich leads to the continuous development of this ructure is that its decomposition with the evolu- n of gas continues as the temperature is raised. s which begins to come off at about 400° C. is ll being evolved at 1000° or even higher; and the lls of the bubbles which are generated at lower mperatures continue to give off gas and to nerate more and more minute bubbles as the mperature rises.

Bubbles, however, can only be blown so long as e mass is sufficiently plastic. This places definite nits of time and temperature on the development this structure, which ceases when decomposition s reached the stage at which rigidity of the cell lls has set in. Though gas may continue to be olved after this stage is reached, it can only cape from the surfaces which have already been veloped and through the more intimate molecular ructure of the vitreous substance.

The complex character of the decomposition of the sible constituents of coal during carbonisation akes it difficult to ascertain the limits of time and mperature at which rigidity sets in, especially as ese vary considerably with different types of coal. e can, however, say with confidence that the rbon of which all forms of coke and charcoal are ilt up, is a fairly homogeneous, vitreous solid in hich the vitreous properties become more and more arked as the state of elemental purity is proached and further, that the bubble structure hich is developed during the fluid or plastice stage carbonisation through the evolution of hydro- rbon gases, is finally stereotyped in this rigid treous material.

The experiments on the carbonisation of sugar, hich have already been referred to, throw a useful ght on the subject, for in this case these limits ave actually been defined. Rigidity sets in at 350° ., and at 400° C. frothing and bubble-blowing have ased. No change in the minute structure occurs hen the temperature is raised to 800° C. or higher. the experiments with single minute crystals the ement of time was almost eliminated, for the ystals only weighed a few milligrammes. When e scale of the operation was raised in the assay pparatus by about 1000 times, the element of time viously played a considerable part. The assay be which under normal conditions is sufficiently rge for the carbonisation of 20 g. of coal, was mpletely filled by the frothing of the viscous aterial from 2·3 g. of sugar and the ultimate resi- ue consisted of thin films of vitreous carbon.

Even in the small assay tube it is evident that the enetration of heat through the frothing material as comparatively slow and that it did not all reach he rigid state of carbonisation at the same time. he time element therefore entered much more rgely into the operation than it did in the case f the single crystal experiments.

In the carbonisation of coal on an industrial scale, n coke ovens and gas retorts, the influence of the ime element is generally recognised and has been arefully studied by many observers. I venture to ope, however, that the definite association which as now been traced between what occurs during the usion and frothing stage in carbonisation and the ltimate structure of the coke, may prove to be a ew starting point in these inquiries.

Frothing with the formation of large bubbles only ccurs when the froth is free to expand without the ntervention of solid surfaces against which the ubbles burst and the gas they contain can escape. This was demonstrated by R. Lessing in 1912,* in the laboratory assay apparatus which he had devised. In this apparatus ground coal was carbonised in an externally-heated silica tube placed vertically, the excessive foaming of fusible coals being completely controlled by allowing a loosely fitting plunger to press lightly on the surface of the molten coal. This caused the bubbles to burst while the resulting gas escaped by the narrow annular passage between the plunger and the inner walls of the tube. Lessing's method includes the measurement of the volume of the resulting coke as compared with the original volume of the ground coal. Though this information is of value in the laboratory study of carbonisation, it is not directly applicable to works practice. The pioneering work of Lessing is of the greatest importance in connexion with this fundamental feature of carbonisation, which goes far to explain the mechanism of the production of dense coke in modern coke oven practice, where the finely-divided coal is tightly packed in the ovens by the application of pressure.

In modern coke-oven practice the advantages of fine crushing and blending of the various bands of one seam or of several distinct seams are only partially recognised as the means by which homogeneity in composition and uniformity of any desired texture in the coke can be secured with certainty. It is hoped that the detailed study of the subject which has been involved in the researches of the Fuel Research Board on carbonisation will throw useful light on the structure of coke and on the methods by which this may be modified at will, so as to adapt this fuel more perfectly to the metallurgical and other purposes for which it is produced.

Some two years ago we discovered that the excessive foaming of the more fusible coals could be completely arrested by a totally different method from that of outside restraint which results from confining the coal in a restricted space during carbonisation. This method we have generally referred to as blending. It consists in the intimate mixing of fusible with an infusible or less fusible coal. The proportions in which the selected coals should be mixed can be quickly determined by a few preliminary trials in the laboratory assay apparatus. When the proper mixture has been arrived at, little or no foaming occurs during carbonisation, and the resulting coke occupies a smaller volume than the original coal. This has already been described and is illustrated in detail in Figs. 16 and 17.

By ensuring the shrinkage of the coke one of the most serious of the difficulties in the carbonisation of fusible coals is removed. For the past two years this method has been in regular use at H.M. Fuel Research Station for the adjustment of fusibility so as to ensure that the coke will contract and occupy a smaller volume than the original coal. The idea has been taken up by other workers and is being practically applied in various directions.

As a variation on the method referred to, pulverised coke or breeze has been successfully used as the infusible material in blends or mixtures. The most obvious disadvantage in the use of coke for this purpose is that, while it contributes no gas and no oil to the output of the operation, it occupies space in the carbonising apparatus, and involves costs for handling and fuel which could be more profitably expended on the carbonisation of coal of low fusibility and high volatile content.

Mr. E. V. Evans has, however, shown that an admirable smokeless domestic fuel can be produced by carbonisation of a blend of gas-retort breeze with a fusible coal (*cf.* J., 1922, 206 T). It is a remarkably homogeneous material in which the bubble sponge structure is uniformly developed, and on just the right scale for a fuel which is to be used for domestic purposes.

---

* "A laboratory method for comparing the coking properties of coal." Inst. of Gas Engineers, June 13, 1912.

My own interest in the micro-structure of coke was greatly stimulated by the remarkable work of Messrs. E. R. Sutcliffe and E. C. Evans* on the briquetting of pulverised coal as a preliminary to carbonisation. This at once appealed to me as the logical sequence of the work on the blending of coal crushed to a moderate degree of fineness. It has been proved by these pioneers that the control of bubbling and frothing by grinding and blending which made it possible to develop the reactive surface within the mass without too great a sacrifice of density and robustness could be almost indefinitely extended by the briquetting of finely ground coal by pressure as a preliminary to carbonisation. It has therefore been a work of great interest to trace the absolute continuity of the bubble sponge structure from its most obvious appearance in the carbonisation of a highly fusible coal through all its intermediate stages to the remarkable absorbent carbon which was produced by Sutcliffe and Evans to replace the most absorbent forms of wood and nut charcoal for the gas masks supplied to our soldiers at the front.

It is stated that this material has at least three times the gas-absorbing capacity of the best wood charcoal. My belief is that the absorbing capacity is mainly if not entirely a question of surface, and that the conversion of vitreous carbon into thin films by the blowing of bubbles is the most effective known means for the development of enormous internal surfaces.

The continuity of the bubble sponge structure can be followed so far in the photomicrographs, Figs. 3 to 8, and in the enlargement of Fig. 6 on Fig 9. By direct observation with lenses of higher resolving power it has been followed down to a minuteness which is expressed in ten thousandths of a millimetre.

It is evident that Thörner's conclusion cannot be supported that the relatively large pores or cells which were disclosed by his method of examination were bounded by walls consisting of "an extremely close, impermeable, glassy mass." We have seen on the contrary that this glassy mass is possessed of a sponge cell structure which under suitable conditions may have a minute porosity which is not only comparable with that of wood charcoal, but may far exceed it.

The structure of coke has been considered by metallurgists from three points of view. These are, porosity, density, and reactivity. Reactivity appears to be generally regarded as depending on chemical rather than structural changes in the carbon. Porosity and density are treated as purely reciprocal, the ratio of the relative volumes occupied by the actual coke substance and by "pores" in any given specimen being calculated from the apparent and real specific gravities. It is obvious that this method of estimating porosity gives no indication whatever of the relative area of the internal surfaces which have been thereby developed, for this involves a knowledge of:—(1) The size of the pores. (2) Their number and distribution in the mass. (3) The thickness of their dividing walls.

Consider the case of a coke in which the ratio is as 1:1, the specific gravity of the carbon substance being 1·9 and of the coke 0·9. One cubic inch of coke will contain half a cubic inch of carbon substance and half a cubic inch of air space. Assume that the whole of the carbon is concentrated in the lower half of the cubic inch, and that this can be sliced horizontally into sections 1/1000 of an inch in thickness, and that the 500 slices so obtained are extended upwards at intervals of 1/1000 of an inch, so that they occupy the whole of the cubic inch. We should then have a block of coke the specific gravity of which would still be 0·9, and its reactive surface would be about 1004 square inches as compared with a reactive surface of 4 square inches in the solid block of carbon substance. It is obvious that by making the slices of carbon substances and the spaces between them 1/100 of an inch in thickness and width, the specific gravity of the block would still be 0·9, but its reactive surface would now be 204 square inches instead of 1004. By reducing the spaces between the slices of 1/1000 of an inch to one half the thickness, the specific gravity of the block would be raised to 1·2 and the reactive surface to 2667 square inches.

So far therefore as reactive surface is concerned, the ideal condition would be the subdivision of the whole of the carbon mass into films of minimum thickness separated by spaces of equal width. This ideal can most nearly be approached by the bubbling method, pulverising and pre-briquetting suitable blends of coal so that the sponge cells are small and their walls as thin as possible. The apparent density of coke obtained in this way may reach 1·33 sp. gr.; the air space must therefore be of the order of one fourth of the volume.

Let us turn now to the other aspect of porosity, its influence on the accessibility of the reactive surfaces within the mass to oxidising gases. The users of metallurgical coke have in the past attached great importance to this function of porosity, in the belief that full advantage of the reactivity of the internal surfaces can only be secured by free access of the oxidising gases and the equally free removal of the products of oxidation. If it be assumed that Fig. 4 may be taken as a metallurgical coke which meets this condition, it is of interest to determine the size of the larger bubble units. These range from 3 to 4 mm. down to about 0·5 mm. in diameter. We may take it therefore that free circulation of gases will mainly occur through the larger of these, as they have probably been opened up and kept open by the rapid discharge through them of the carbonisation gases. They have formed ducts through which the gases from the areas of the more minute bubbles have escaped.

In the much denser pre-briquetted coke, Fig. 8, the larger pores range from 0·5 mm. down to 0·1 mm., and it is evident that in this case also these have been the main ducts for the escape of gases, but the fact that the combustion of these briquettes proceeds definitely from the outer surfaces inwards shows that the internal circulation of the oxidising gases is much more restricted than in the case of metallurgical coke. Sutcliffe and Evans believe that the reactive surface of the coke briquette is so immensely greater than that of metallurgical coke that the increased rate of combustion more than compensates for the less free circulation throughout the mass. This question of the relation of "accessibility" of surfaces to rate of combustion is now being investigated by Mr. E. C. Evans and Dr. Wheeler, and also at H.M. Fuel Research Station.

Descriptions of photomicrographs.

Figs. 1 and 2.—Coke structure. Reproduction of micrographs at a magnification of ×50, which were published by Dr. Thörner in "Stahl und Eisen" in 1886.

Fig. 1.—Gas retort coke.

Fig. 2.—Metallurgical coke.

Sections of coke were prepared by grinding and were photographed by transmitted light. As the thickness of these sections, unlike those which can be prepared from coal, cannot be so far reduced that they become transparent.

---

* J., 1922, 196—206 T.

he resulting pictures are simply silhouettes produced by the passage of light through holes n an opaque screen. There is not even any ertainty that the holes really represent the size r shape of the pores or elements of structure, for n so fragile a material as vitreous carbon in the orm of thin films the grinding of the section might asily lead to the destruction of the more minute lements.

Figs. 3—8.—Coke structure. Photomicrographs y G. Beilby in 1922. These were obtained by the use of a planar lens of 3 inch focus stopped down o give depth of focus. The illumination was by eflected light at an angle of about 45°. The magnification was from 5 to 10 diameters.

Fig. 3 is gas coke from horizontal retorts using Durham coal.

Fig. 4 is blast furnace coke from recovery ovens. Compare with that shown in Figs. 1 and 2.

Fig. 5 is a cross section of laboratory assay coke rom Mitchell Main, a fairly fusible coal. Considerable frothing has occurred during carbonisation. Compare with Fig. 15c.

Fig. 6 is gas coke from vertical retorts using Arley, a fairly fusible coal. Compare with the enlargement of this, Fig. 9.

Fig. 7 is a cross section of laboratory assay coke from Dalton Main. Compare with Figs. 15 A and B.

Fig. 8 is the coke resulting from the carbonisation of a briquette made by the compression of pulverised coal. The structure is only imperfectly resolved by the planar lens. Compare Fig. 10.

Fig. 9.—Enlargement of Fig 6. Coke from Arley goal carbonised in vertical retorts with steaming. The continuity of the bubble sponge structure can be followed on this photograph from cells of 1 mm. down to 0·05 mm. diameter. The more minute cells in the walls of the larger bubbles which appear only as small diffraction discs, when visually resolved by the 16 mm. apochromat show the continuity of this structure down to a minuteness of 0·001 mm.

Figs. 10—14.—Coke structure. Photomicrographs by G. Beilby in 1922, prepared under the conditions described for Figs. 3—8.

Fig. 10 is coke resulting from the carbonisation of the briquetted blend of Mitchell Main and Ellistown Main at a higher temperature than that employed in Fig. 8.

Fig. 11 is vitreous carbon prepared from sugar, described on page 342 T. Though large bubbles, both burst and unburst, are seen, the more minute structure seen in coke is absent.

Fig. 12 is the broken surface of a briquette made from pulverised coal (about 60 mesh) heated to 380° C. and compressed at 2 tons per sq. in.

Fig 13 and 14 show oak charcoal across and along the grain of the wood. The structure is practically a reproduction of the natural cell structure of the wood. There is little or no evidence of fusion and bubbling.

Fig. 15.—Coke produced in the laboratory assay apparatus. Natural size.

A and B—Dalton Main, a typical coal which produces a satisfactory coke for use as smokeless fuel for domestic purposes. Compare with Fig. 7.

C—Mitchell Main, a fusible coal which froths on carbonisation. Compare with Fig. 5.

Fig. 16.—Laboratory assay coke showing the result of blending coals of widely differing fusibility.

A—The carbonaceous residue from Ellistown Main breeze is practically a non-coherent powder.

B—The coke from Mitchell Main is an open sponge.

C—The coke from a blend of 40% of Ellistown Main with 60% of Mitchell Main is relatively hard and dense and occupies a much smaller volume than the original coal.

Fig. 17.—Laboratory assay coke from blends of Mitchell Main and Ellistown Main coal.

A and B are the cokes as seen in elevation and plan of the blend, Mitchell Main 80%, Ellistown Main 20%.

C and D are the cokes as seen in elevation and plan of the blend, Mitchell Main 60%, Ellistown Main 40%.

The greater shrinkage of the 60-40 blend is very obvious.

Communications.

EFFICIENCY IN CENTRIFUGAL DRAINING.

BY THOMAS J. DRAKELEY AND LESLIE H. WILLIAMS.

In a former communication, it has been shown by Drakeley and Martin (J., 1921, 308—310 T) that the reduction of the speed at which the basket of a centrifuge was revolved from 1198 to 697 revolutions per minute failed materially to affect the separation of liquor from the crystals. An investigation has therefore been made to determine how the speed of revolution is related to the efficiency of the centrifuge. The efficiency of the centrifuge has been defined (*loc. cit.*, 309 T) as the percentage of the total mother liquor which has been extracted from the charge of crystals at any particular moment of the run.

At the higher speeds, no further separation of mother liquor occurred after the crystals had been spinning for fifteen minutes, but a small loss of moisture was noted with longer spins although no liquor separated from the crystals. No doubt the loss was due to the drying effect of the air blowing through the charge after the liquor had been extracted. Whilst the latter drying effect may assume great importance in works practice, it was decided to eliminate this somewhat doubtful factor and run the centrifuge in all experiments for fifteen minutes, so that comparable results might be obtained for the extraction of mother liquor from the crystals.

Hence in the following experiments arrangements were made to obtain widely different speeds, and in each case the centrifuge was run for a period of fifteen minutes. At the end of that period, the efficiency of the separation effected in the time was determined by the method described in the previous paper. Each result given in Table I. is the average of six individual experiments.

TABLE I.

Spratt's centrifuge (Manlove, Alliott and Co., Ltd.). Diameter of basket, 14 inches. Time for attaining stated speed, 15 seconds. Time of spin, 15 minutes.

Ref. no.	Maximum speed r.p.m.	Efficiency %
1	100	10·8
2	124	27·6
3	197	52·5
4	330	64·8
5	368	66·6
6	476	70·6
7	602	70·9
8	697	71·4
9	868	72·6
10	1198	73·5

The results plotted in Figure 1 show that the speed may be reduced to a remarkable extent before the efficiency of the separation effected in fifteen minutes is seriously diminished. Indeed it will be observed that at a speed of 476 revolutions per minute, that is, considerably less than half the maximum speed, the efficiency is only 2·9% lower than the maximum.

Whilst it may justly be contended that this 2·9% drop in efficiency may, in a particular case, represent an inadmissible addition to the moisture content of the crystals, it, nevertheless, shows that high speed is not the sole factor in centrifuge practice. Indeed the present-day tendency to advertise centrifuges which work at enormous speeds seems to be emphasising a doubtful advantage.

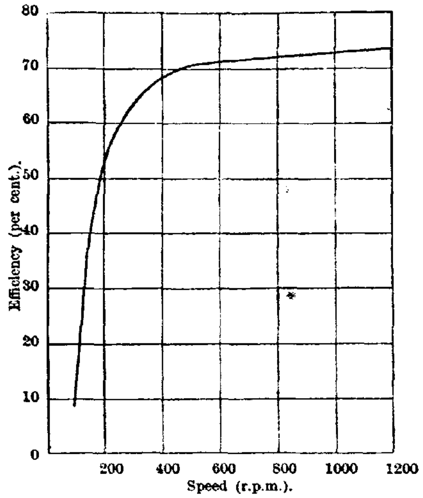

FIG. 1.

Bryson (J. Ind. Eng. Chem., 1921, 13, 993) suggests that possibly the question of the arrangement of the particles under the centrifugal force may influence the efficiency of the separation. When particles collect under the comparatively low force of gravity they assume a cubical piling arrangement. In this state, the maximum volume of interstices between the particles is afforded for the passage of the mother liquor. Even with low speeds and therefore small centrifugal force, the crystals may arrange themselves in cubical piling. However, when the speed of the basket is very great, the high centrifugal force is stated to cause the particles to assume the most stable arrangement, that is, hexagonal piling. But with hexagonal piling the volume of the voids is reduced to the utmost, and thus the exit area for the mother liquor is a minimum.

It was thought possible that the change from cubical to hexagonal piling might be sufficiently marked to give a sharply defined change in the type of the extraction or efficiency curve.

The apparent efficiency, that is, the percentage of the total mother liquor which has flowed from the drain of the centrifuge at any particular moment, was determined at various speeds and times to test this suggestion. The values are given in Table II., and the efficiency is plotted against the time in Fig. 2.

TABLE II.

Spratt's centrifuge. Diameter of basket, 14 inches. Time for attaining stated speed, 15 seconds. Size of crystals, 0—⅛ inch.

Apparent efficiency (per cent.).

Time (mins.).	Speed (r.p.m.). 100	124	197	330	368	476	602	697	1198
0·5	—	—	—	—	—	10·0	14·2	18·0	35·0
1·0	—	—	—	13·1	15·8	20·1	25·0	46·5	55·8
2·0	—	—	18·5	24·5	29·6	34·4	46·7	59·0	65·4
3·0	—	9·4	25·0	31·1	37·1	43·0	56·1	64·5	69·2
4·0	—	—	30·8	36·7	44·3	48·4	60·8	67·0	70·5
5·0	—	13·4	34·9	40·3	48·6	52·4	63·0	68·9	71·7
7·5	—	17·4	40·4	49·9	57·0	59·8	66·8	70·5	72·0
10·0	7·2	20·4	44·8	56·5	60·8	66·5	69·3	71·1	72·5
15·0	10·8	27·6	52·5	64·3	68·6	70·6	70·9	71·4	73·5

An examination of the curves in Fig. 2 shows that there is no marked change in the character of the extraction, and consequently no evidence of a change from cubical to hexagonal piling.

It should be observed, however, that before the above experiments were made the crystals in the basket were allowed to drain free from excessive liquor, so that comparable results could be obtained. When the crystals have thus drained, the fluidity of the resulting charge is far less than if they were placed in the basket with a greater quantity of liquor. This decrease in fluidity would naturally hinder any possible change in the arrangement of the particles from a cubical to hexagonal piling system, and hence this may account for the absence of the anticipated indication in Fig. 2.

Experiments were therefore made in which the charge was introduced into the basket with a sufficient excess of mother liquor to give more fluidity. It was found impossible to obtain results which could be treated mathematically, but it appeared that, as a general rule, the best treatment is to remove the major part of the mother liquor at a low speed and then, after the fluidity of the charge is thereby rendered negligible, to run the basket at a higher speed to remove the remaining liquor (*cf.* Bryson, *loc. cit.*).

The reason no results can be given, but only the general conclusion from the experiments, is due to the fact that, for no apparent reason, the charge sometimes formed an almost impervious cake on the sides of the basket which prevented the separation of the liquor. At other times, with the same speed and the same crystals, and seemingly the same conditions, the above peculiarity was not noticed.

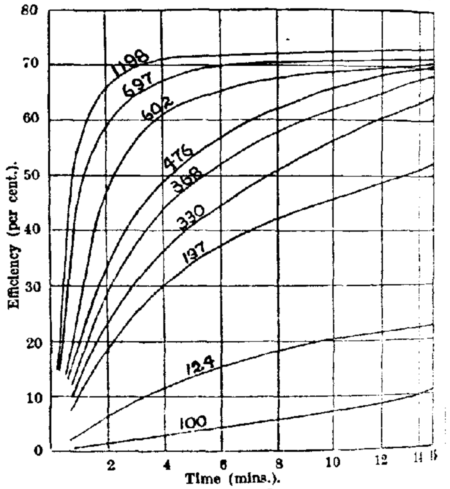

FIG. 2.

For works practice, especially with fine material, it would appear to be advisable to commence centrifuging with the lower speed, so that the initial piling is probably largely cubical and the fluidity is reduced to maintain that system of piling. Then a higher speed may be used to complete the removal of the liquor, but even in this case, the high speed should actually be the lowest speed capable of producing the required results.

The author's thanks are due to Mr. J. Reader Faul for his assistance in connexion with the plant necessary for driving the centrifuge.

Communications.

HE EXTRACTION OF GLUCINA (BERYLLIA) FROM BERYL.

r HUBERT THOMAS STANLEY BRITTON, M.SC., A.I.C.

Beryl, including the gem forms emerald and aqua- arine, is the chief source of glucinum salts. Its mposition corresponds with the formula

$$3GlO.Al_2O_3.6SiO_2$$

ıd therefore contains about 13·5% of glucina. It coloured in differing shades by traces of ferric :ide. Glucinum also occurs in the less common inerals, such as chrysoberyl, euclase, phenacite, ucophane, gadolinite, etc. Beryl is by no means ıch a rare mineral as is generally believed. It is und in America, Switzerland, Norway, Scotland, eland, Madagascar, and other countries—much of ıe supply being of no use to the jeweller. Up to ıe present, very little technical use has been made these supplies, although slight use has been made glucinum nitrate in the incandescence mantle dustry.

Metallic glucinum has many unique and useful operties. Its specific gravity (1·6) is much lower ıan that of aluminium (2·6). Besides having an :ceptionally high melting point, 1278° C., it can be loyed with many metals, for example, with uminium, copper, silver, and iron (*vide* Lebeau, ɔmptes rend., 1897, **125**, 1172; Osterheld, Z. anorg. ıem., 1916, **97**, 1).

The isolation of glucina from beryl involves the oublesome separation of the two remarkably milar oxides, glucina and alumina. The difficulty this separation may be inferred from the number ıd variety of methods which have been put forard. Many of them have been investigated by the ıthor (*vide* Analyst, 1921, **46**, 359—366, 437—445; 22, **47**, 50—60). Only four were found under rtain conditions to be quantitative, and of these, is doubtful if any one could be worked commercılly. It was decided, therefore, to try to develop method of separation which could be employed on large scale. These efforts have not been cometely successful. It has been found, however, that 'er 90% of the alumina from beryl can be separated om the glucina quite easily.

Beryl is not attacked by acids, except perhaps hen finely divided by hydrofluoric acid. In order effect its decomposition, it must first be ground the consistency of a flour and then fused with a ıitable flux. Grinding can be carried out satisctorily in an agate mortar. For this purpose, ɔy (Amer. J. Sci., 1863, **36**, 83) employed a goldıartz mill. Lebeau (Comptes rend., 1895, **121**, 641) und that fusion of pulverised beryl alone in an ectric furnace caused the volatilisation of some of s silica, after which the residue was easily attacked r a mixture of sulphuric and hydrofluoric acids. he following fluxes have been used by various vestigators: (*a*) caustic soda and caustic potash chaub, Annalen (Crell), 1801, **17**, 174), (*b*) calcium ıoride and sulphuric acid at 100°—200° C. in a ad dish (Scheffer, Liebig's Annalen, 1859, **109**, 4), (*c*) ammonium fluoride, potassium fluoride, dium carbonate, potassium carbonate, calcium cide (Joy, *loc. cit.*). The most convenient of these ıxes is potassium hydroxide. Fusion with potash ın best be carried out in a silver crucible, as was ıggested by Schaub. If care is taken to employ as w a temperature as possible, the fusion can also effected satisfactorily in a nickel crucible. When intimate mixture of finely ground beryl and an cess of potassium hydroxide is heated over a ınsen flame fusion takes place readily. Generally, half an hour will be found sufficient. If the fusion is carried out at too high a temperature, such as that attained in a gas muffle furnace, the crucible will be attacked appreciably, much nickel being found in the fused mass. The fused mass is ground, placed in a beaker and covered with water. The silico-aluminate of glucinum and potassium which has been formed, is then decomposed with a slight excess of concentrated sulphuric acid. The precipitated silicic acid is rendered amorphous by carefully heating on a sand-bath, after which the solution is diluted and filtered. The mother-liquor now contains the glucinum, aluminium, and traces of iron.

Before passing on to the isolation of the glucina from the mother-liquor, brief reference should be made to the process of isolating glucina from beryl which has been worked out recently by Copaux (Comptes rend., 1919, **168**, 610). In this method the precipitation of silica is eliminated. If one part of finely pulverised beryl is heated at 850° C. with two parts of sodium silicofluoride, the following reactions are stated to take place, due to the dissociation of the silicofluoride at 750° C. The glucina is converted into a double fluoride, thus:

$$2GlO+SiF_4=SiO_2+2GlF_2,$$
$$2NaF+GlF_2=Na_2GlF_4.$$

and similarly with the alumina to form artificial cryolite, Na_3AlF_6. Treating the pulverised fritted mass with boiling water will dissolve the sodium glucinum fluoride, which is soluble at 100° C. to the extent of 28 grams per litre, whereas the double aluminium fluoride is only very slightly soluble. The aqueous extract contains about 1% of silica and 2% of alumina. The addition of boiling sodium hydroxide solution to the extract decomposes the double glucinum fluoride, glucinum hydroxide being precipitated. Copaux claims that this method is capable of securing 90% of the glucina present.

As previously stated, fusion with potash can be carried out at a conveniently low temperature, and furthermore the removal of the silica presents very little difficulty. Besides the sulphates of glucinum, aluminium, and of possible traces of iron, the mother liquor also contains potassium sulphate and sulphuric acid. Various workers have taken advantage of the sparing solubility of alum and have tried to remove the alumina completely as alum. Pollok endeavoured to separate the last trace as alum by adding to the solution an equal volume of alcohol. He found, however, that some glucinum sulphate also crystallised out with the alum (Trans. Roy. Soc., Dublin, 1904, **2**, 8, 139). No definite information appears in the literature showing the extent to which alumina can be extracted in this way. This possibility has been investigated therefore by the author from the standpoint of the phase rule.

In the following considerations, the amount of iron which may be present will be of so small a magnitude as to be almost without influence. Hence it will be disregarded; incidentally, its removal is a matter which presents very little difficulty. Suppose that the free sulphuric acid in the mother liquor has been neutralised with potash. Such a solution would be an example of a four-component system, the components being the three sulphates and water. After concentrating and allowing to attain equilibrium at a fixed temperature, it is possible that either a single solid phase, or two coexistent solid phases, or in special instances, three solid phases may crystallise out together. Including sulphuric acid, the solution will contain five components, and therefore on crystallisation at any temperature, may yield any of the foregoing combinations of solid phases together with the possibilities of four solid phases, should the solutions contain the solutes in certain concentrations. The following are some of the solid phases which may crystallise

▲

from these solutions: alum, potassium sulphate, glucinum sulphate tetrahydrate, aluminium sulphate with eighteen molecules of water, and potassium glucinum sulphate dihydrate.

Before proceeding to investigate to what extent the alumina can be removed in the form of alum, it was considered advisable to learn something about the crystallisation of alum in the ternary system: potassium sulphate, aluminium sulphate, water, and also of the double sulphate of glucinum and potassium in the ternary system: potassium sulphate, glucinum sulphate, water at a suitable temperature. These two systems, therefore, have been investigated (*vide* Britton, Trans. Chem. Soc., 1922, **121**, 983; Britton and Allmand, *ibid*, 1921, **119**, 1463). By referring to the isotherm at 25° of the former system, it will be observed that alum attains equilibrium with solutions having a very extensive range of concentrations of aluminium and potassium sulphates. Moreover, the amount of aluminium sulphate retained in the liquid phase in equilibrium with alum is usually small. In the second system, the field at 25° of the potassium glucinum sulphate is small and the solutions in equilibrium with it contain considerably more glucinum sulphate than aluminium sulphate in the case of the alum field in the previous system. The solubility of aluminium sulphate and of glucinum sulphate in water at 25° are almost equal. Thus it appears reasonable to expect that in the quaternary system—beryllium sulphate, aluminium sulphate, potassium sulphate, water—alum will be the only solid phase to separate at 25° from solutions of a very wide range of concentrations.

In view of this, it was considered unnecessary to work out an isotherm of the quaternary system. It was decided, however, to investigate how far separations could be made when the aluminium and beryllium sulphates were taken in the molecular ratio of one to three respectively, this being the ratio in which the oxides occur in beryl. In measured quantities of water, known amounts of potassium sulphate were dissolved. These amounts were approximately sufficient to produce saturated solutions at 25°. At a few degrees above that temperature, weighed quantities in the above ratio of aluminium and glucinum sulphates were dissolved. these amounts having been arranged to bear some simple relationship to the potassium sulphate already in solution. These solutions were placed in a thermostat at 25° and mechanically stirred until equilibrium was established. Both the liquid and solid phases were then analysed. Table I. gives the results, expressed in molar proportions, obtained.

TABLE I.

Temp. 25° *C.*

1	1	0·236	3	3	1	0·246	75·4	Alum
2	2	1·194	3	3	1	0·203	79·7	"

From these results, it will be seen that almost 80% of the aluminium sulphate can be removed from aqueous solutions in the form of alum. In separation No. 2, the molar proportion of potassium sulphate taken was twice that employed in No. 1. This, however, could only be done by halving the amounts of aluminium and glucinum sulphates taken, as the solutions had been nearly saturated with potassium sulphate before the other two sulphates had been dissolved. Again, the solubility of potassium sulphate in water is by no means great, neither does it increase appreciably with rise in temperature. It appears that increasing the proportion of potassium sulphate results in a relatively greater separation of alum. On the other hand, the solutions become weaker in glucinum sulphate. This will be seen from Table II. which gives the results in weight percentages which are otherwise given in Table I.

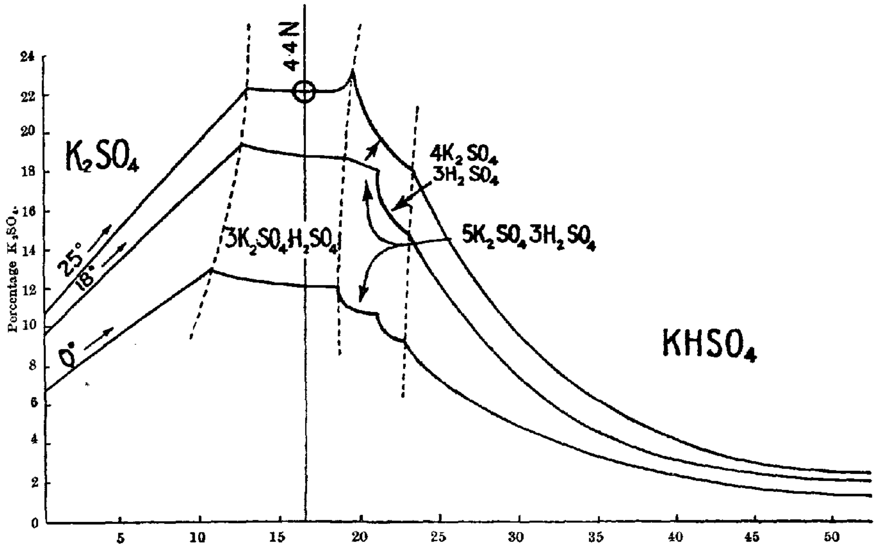
It is difficult to neutralise exactly the free acid in a solution of a glucinum salt. Any excess of potassium hydroxide beyond that required to neutralise the free acid in an aluminium sulphate solution would be indicated by the precipitation of a little aluminium hydroxide, but in the case of an acid solution of glucinum sulphate more potassium hydroxide than that required for the neutralisation of the free acid would have to be added before a precipitate of glucinum hydroxide would be produced. This is due to the peculiarity possessed by soluble glucinum salts of being able to retain in solution comparatively large amounts of glucinum hydroxide; in fact, in a concentrated solution one mol. of glucinum sulphate may cause the solution of two mols. of glucinum hydroxide (*vide* Berzelius, J. Chem. (Schweigger), 1815, **15**, 296; Parsons, J. Amer. Chem. Soc., 1904, **26**, 1433; Parsons, Robinson, and Fuller, J. Phys. Chem., 1907, **9**, 651). For this reason, it seemed desirable to employ dilut sulphuric acid solutions. Before attempting furthe separations, a few determinations were made t ascertain the effect which sulphuric acid of abou 5*N* concentration would have on the solubility o alum, potassium sulphate, glucinum, sulphate, an aluminium sulphate.

It was found that at 25° the solubility of alum i 8·81*N*. sulphuric acid was 6·23 g. of anhydrous alu per 100 g. of solution as compared with 6·75 g. i aqueous solution. In the case of both glucinu sulphate and aluminium sulphate in sulphuric aci solutions, the solubilities are also diminished. A 25°, the solubility of glucinum sulphate in wat is 29·94 g. per 100 g. of solution, whereas in 5 sulphuric acid it becomes 15·91 g. (Britton, Tran Chem. Soc., 1921, **119**, 1970). For aluminiu sulphate Würth found that the solubility fell fro 27·8 g. in water to 20·4 g. in 4·3*N*, and to 15·4 in 6·2*N* sulphuric acid (Z. anorg. Chem., 1913, 7 360). At first, no reference could be found to t solubility of potassium sulphate in sulphuric ac and consequently one solubility determination w made. It was found that at 25° C., 22·04 g. potassium sulphate was dissolved in 100 g. sulphuric acid solution, the percentage of t sulphuric acid being 16·55 and its normality 4· The solid phase in equilibrium with the solution w found to be the acid salt corresponding to t formula, $3K_2SO_4,H_2SO_4$, as the slightly moist so contained 84·0% of K_2SO_4 and 15·7% of H_2S (calculated: 84·2% and 15·8% respectively). It w then found that this compound had been prepa by several workers, and that Stortenbeker (R Trav. Chim., 1902, **21**, 400) and D'Ans (Z. ano Chem., 1909, **63**, 225) have investigated the tern system—potassium oxide, sulphur trioxide, wat at 0°, 18°, and 25°. From the above result, it w be seen that in 4·4*N* sulphuric acid, the solubility potassium sulphate is about double that in wat It was decided therefore to investigate fully t data obtained by Stortenbeker and D'Ans, in or to find to what extent the solubility of potassi sulphate could be increased. These results h been recalculated and curves showing the relati ship between the solubility of potassium sulph and the concentration of sulphuric acid, plott As no data concerning the volumes of the liq phases analysed are given, the concentrations of acid could not be expressed in normalities.

From these curves, it will be observed that those uid phases in equilibrium with $3K_2SO_4,H_2SO_4$ ntain the maximum amounts of potassium lphate. By considering the position of the point rresponding to 4·4*N* sulphuric acid which was tained by the author, it will be inferred that these ncentrations are in the region of 5*N*.



Curves at 0° & 25° C:—calc'd from D'Ans' data.
,, ,, 18°C:—Stortenbeker's data.

These considerations show that whereas the solu- ity of the two very soluble salts, aluminium and cinum sulphates, in sulphuric acid of about 5*N* somewhat reduced, that of potassium sulphate is siderably increased. Again, the small solubility alum is slightly decreased. If these conclusions relatively true when all the salts are present in ution, then it appears that a method has been nd by which the potassium sulphate content may enhanced. From the previous experiments, this ms to be the condition necessary to cause a ater separation of alum. This is confirmed by results obtained from the following separation. 100 c.c. of approximately 5*N* sulphuric acid the e quantities as in No. 2 of glucinum sulphate aluminium sulphate were dissolved, but, taking antage of the increased solubility, the amount otassium sulphate dissolved was doubled. Hence initial solution contained the sulphates of cinum, aluminium and potassium in the molecular portion of three to one to four respectively. r allowing it to attain equilibrium in a thermo- at 25° C. for two days, the composition of the id phase was found to be that given in Tables and IV. (No. 1).

TABLE III.

lower temperatures the solubility of alum in r is considerably less, but the range of solutions luminium and potassium sulphate in equilibrium with alum at 0° C. is of the same order as that at 25°. It therefore seemed probable that a better separation would ensue if the solution were allowed to attain equilibrium at a lower temperature. For the purpose of comparison, a separation was carried out by taking the same quantities employed in the previous separation and allowing the solution to attain equilibrium by standing in an ice-chest for two days, the average temperature of the solution being 2° C. The figures obtained are those, No. 2, given in Tables III. and IV. It will be observed that lowering the temperature resulted in an increased separation of alum, the amount of alumina thereby recovered being 92·0% of the amount taken. The solid phase in each case was analysed and found to be alum.

Hence in an actual beryl separation, it is advisable to adjust the concentration of the sulphuric acid in the mother liquor, after the silica has been filtered off, to about 5*N* by the addition of potassium hydroxide. Then saturate the solution with potassium sulphate whilst boiling and set to crystallise at a low temperature preferably at 0° C. Although the solid phases obtained in the experimental separations were always alum, it is important that all the solid phases obtained should be examined. This can be done rapidly by dissolving a suitable quantity, dried between filter papers, in water and titrating a sufficiently dilute solution with *N*/10 sodium hydroxide at 100° using phenolphthalein (*vide* Britton, Trans. Chem. Soc., 1922, 121, 983).

By this method the greater part of the alumina can be separated. It is probable that the process may be repeated several times with advantage, but due attention must be paid to the nature of the solid phases obtained.

The glucina left in the mother liquor may be extracted by the addition in the cold of a concentrated solution of sodium hydroxide such that the last drop just causes the re-solution of the precipitated hydroxides, diluting with sufficient water and boiling for forty minutes. In this way the glucinum hydroxide will be deposited in the so-called crystalline form, which can be filtered and washed easily. There will be little chance of any aluminium hydroxide being deposited as the aluminate solution will have been rendered comparatively stable by the large amount of sodium hydroxide required for the solution of the relatively large amount of glucinum hydroxide. The glucinum hydroxide thus obtained may contain a small quantity of iron oxide. This can be removed by dissolving in a little dilute nitric acid and boiling to oxidise the iron. The solution is then cooled, neutralised, diluted to a suitable volume, and saturated with sodium bicarbonate. By raising to and keeping at boiling point for a half minute, stirring well all the time, it will be found that all the ferric oxide and aluminium hydroxide, if any, will be precipitated, leaving the glucina alone in solution (for details, see the papers in the "Analyst," to which reference has been made). The latter process, of course, may be alone sufficient, *i.e.*, omitting the sodium hydroxide process. Unless special care is taken, however, some glucinum hydroxide will be carried down with the aluminium hydroxide and consequently lost.

The author desires to thank the Chemical Society for a grant from its Research Fund.

VOLUMETRIC DETERMINATION OF PHOSPHATE IN SOLUTION.

BY FRANK W. BURY, M.SC.

It has been shown (Rosin, J. Amer. Chem. Soc., 1911, 33, 1099—1104) that it is possible to determine the amount of sodium phosphate in solution volumetrically by means of silver nitrate if the solution be kept neutral during the addition of the latter:

$$3Na_2HPO_4 + 6AgNO_3 = 2Ag_3PO_4 + 6NaNO_3 + H_3PO_4.$$

Rosin's method consisted in first adding the phosphate solution to an excess of standard silver nitrate, and then rendering the solution neutral by adding a suspension of zinc oxide in water, drop by drop, shaking vigorously for two or three minutes after each addition, and testing for free acid by litmus paper. The precipitate was filtered off and the amount of silver nitrate used found by determining the excess by Volhard's method.

Rosin's method was tested but was found tedious and difficult of execution. Since the zinc oxide suspended in water is barely alkaline, it is almost impossible to attain the neutral point. Excess of zinc oxide vitiates the result.

Copper carbonate was tried instead of zinc oxide, the excess of silver nitrate being determined by titrating the filtrate with potassium ferrocyanide, using the dissolved copper as an indicator. In this case the copper carbonate was added in excess, as it was found to have little effect on the silver nitrate.

When ordinary sodium phosphate, Na_2HPO_4, was used the results obtained by this method were as reliable as those obtained by Rosin's method.

For the acid phosphates, NaH_2PO_4 and KH_2PO_4, the method adopted by Rosin was found to be the better one, although neither method was really good.

Borax was tried as it was thought that the neutral point could then be more readily obtained. The method adopted was to add a measured quantity of the phosphate solution to a measured excess of $N/10$ silver nitrate solution, and run in from a burette $N/10$ borax solution until the liquid was neutral to litmus. The solution was filtered and the excess of silver nitrate determined either (1) by Volhard's method or (2) by adding a measured quantity of $N/10$ potassium chloride and titrating the excess of potassium chloride with $N/10$ silver nitrate, using potassium chromate as an indicator. Of the three methods tried this proved to be the most satisfactory, the results being most reliable. The results of a few titrations with borax are given below.

$N/10AgNO_3$ c.c.	Na_2HPO_4 c.c.	KH_2PO_4 c.c.	NaH_2PO_4 c.c.	$N/10AgNO_3$ used c.c.	Calculated result.

Harter Memorial Lecture.

SOME ACHIEVEMENTS OF CHEMICAL NDUSTRY DURING THE WAR IN THIS COUNTRY AND IN FRANCE.

BY WILLIAM MACNAB, C.B.E., F.I.C.

One effect of the late great war was a demand for an unprecedented amount of various explosives and, later on, for many chemicals of curious and unpleasant properties. As I had the privilege of iding and of being closely associated with the construction and running of many of the factories which were erected in this country and had also the opportunity of visiting most of the similar factories in France from time to time, I propose to give a few particulars of some work which was accomplished in both countries.

At first the demand was met by the existing government and private explosives manufactories and the rapid extension of these works, but it was soon seen that the Government must erect many new factories.

Picric acid was the explosive with which most of our shells were filled on the outbreak of war, for TNT had just been officially adopted and the stock of it and means of manufacture were very limited. America came to our aid by sending over considerable quantities of picric acid and TNT while our new plants were being got ready, and the high prices paid for these commodities induced many private manufacturers to start making picric acid —with woefully wasteful methods in the early days.

The first Government factory for the manufacture of TNT was erected at Oldbury on ground belonging to Messrs. Chance and Hunt. The first sod was cut at the end of February, 1915, and exactly three months after, the first ton of TNT was produced and packed ready for delivery. This factory was designed for an output of 250 tons per week and very soon attained and passed that quantity

It was early seen that the supply of toluene from coal tar would be insignificant, and means were adopted for increasing the quantity by stripping the toluene in the gas supplied for heating and lighting purposes.

Another source, however, was also available, namely petroleum from Borneo. The Asiatic Petroleum Company had large distilleries in Holland, where they separated the benzene, toluene, and xylene in the crude petroleum and concentrated them as far as possible by distillation—for it is impossible by that means to separate these aromatic hydrocarbons entirely from the paraffins with which they are associated—and were thus able to produce a spirit containing about 55% of toluene and the balance of light paraffins or petrol. When this mixture was treated with suitable nitrating acids the toluene was nitrated to mononitrotoluene and, after separating from the acid and washing, the petrol could be distilled off, leaving a very pure mononitrotoluene. This compound had been supplied to German dye manufacturers before the war, but, as the Dutch Government would not permit mononitrotoluene to be shipped to England, arrangements were made for the transference of the entire distillery etc. to Portishead, near Bristol, and the Asiatic Company erected plant at Oldbury for the production of mononitrotoluene from their Borneo spirit. Similar plant was also erected by them on a site adjoining the much larger TNT factory, which was later erected at Queen's Ferry.

The manufacture of explosives demands the use of strong acid mixtures containing often only a small percentage of water, and this requires efficient denitration and concentration plant as well as oleum.

The capacity in this country for the production of oleum was very limited and soon oleum became one of the most precious of chemicals. Large quantities were purchased in America, but there were amazing experiences in the case of some shipments from that country, where the drums either were not strong enough or else, owing to the oleum being of a strength which attacked the steel drums, the oleum got loose in the ship. Those who are familiar with that form of sulphuric acid can imagine the task which confronted those of the staff of the Department of Explosives Supply who were sent to the ship when it arrived in the Thames to get its cargo discharged and the bottom of the ship saved from disappearing as sulphate of iron.

Steps were taken at once to erect plant for concentrating sulphuric acid and also for making oleum. As it was impossible at first to get the blocks of volvic lava which are used in the construction of the Kessler and Gaillard plants, owing to the French having reserved all the available supplies for their own use, recourse was had in the first instance to the various cascade systems formed of silicon-iron or silica vessels. These had to be forced to their utmost capacity, and those who had to work them—and the inhabitants living near some of the factories—had an unpleasant time from the acid fumes in the atmosphere in the early days.

The first oleum plants erected were on the Mannheim system in which the sulphur dioxide and air are passed over heated iron oxide, whereby a conversion of about 40% of the sulphur dioxide into sulphur trioxide is effected. The remaining sulphur dioxide and air are heated again and passed over platinised asbestos to effect the final conversion. The chief source of supply came later from Grillo plants which were erected at Queen's Ferry, Gretna, Avonmouth, and elsewhere.

In addition to a dearth of chemicals, it soon became apparent that there was going to be a dearth of chemists to work the new factories which were being erected, due to the patriotic way in which the greater number of chemists of suitable age had enlisted.

Arrangements were made and a large number were recalled from the colours and sent to the existing explosives works, where they got some training preparatory to beginning in the new works. There was also a great dearth of skilled workmen accustomed to chemical or explosives work, but many of these younger chemists became leading process hands and well and intelligently did they carry out their work, with—I am certain—great benefit to themselves in their subsequent careers if they remained in industrial chemistry. The magnificent part that women played in connexion with the manufacture of war chemicals, undertaking often very disagreeable and dangerous work, and doing it well, cannot be forgotten in a general survey of the chemical industrial activities brought about by the war.

An admirable feature of the nation's time of trial was the whole-hearted way in which different manufacturers offered their information and services to the common cause, and one would fain wish that a means could be discovered in time of peace to get more joint effort and mutual help among chemical manufacturers, as one way of best meeting the competition of other countries.

Our own chemical industry received a great stimulus during the war, but it must not be forgotten that this also occurred in other countries, and—apart from Germany—we must reckon on much more competition from more extended and more intelligently conducted chemical manufacture, especially in France and America. It behoves us to take courage from the great things we undoubtedly accomplished, and utilise to the full the experience gained, not falling asleep nor relapsing into old rule-of-thumb ways.

It might be thought that in Government factories erected under the stress and menace of war, where the steadying influence of dividends and shareholders was not at work, the factories would be run on extravagant lines. A careful study, however, of the Second Cost Report, issued by the Factories Branch of the Department of Explosives Supply, will show that yields and costs compare favourably with those of any of the private factories.

Monthly meetings of the superintendents and heads of departments from the different Government factories were held in London, and the results and conditions of working discussed and criticised, and in this way mutual help was given and a healthy spirit of emulation created between the staffs of the different factories, which bore excellent fruit.

A few statistics of the amounts of some chemical materials produced during the war will show the enormous scale on which explosives were made :—

Picric acid	68,500 tons
TNT	238,000 tons
Ammonium nitrate	378,000 tons
Cordite	139,000 tons

Let us look at these materials a little more in detail.

Picric acid.—The method of manufacture of this substance in the early days was carried out most inefficiently. The phenol was first sulphonated in iron vessels, then transferred to small earthenware jars, into which nitric acid was run at a slow rate. During this nitration process copious brown nitrous fumes were given off and allowed to escape into the air and were lost, besides causing an almost intolerable nuisance. With the view of diminishing the latter, the operations were generally so arranged that the nitration process was started in the evening and the brown fumes escaped under cloak of darkness. These conditions passed muster when the output was comparatively small, but as the demand increased, steps were taken to conduct the nitrous fumes to proper absorption towers, whereby a large percentage of nitric acid was recovered.

Although the manufacture of picric acid was chiefly carried out by private firms, a great deal of work was done by members of the Department of Explosives Supply which resulted in improved working, both as to cost and yield.

Finally a process was perfected whereby the nitration of the phenolsulphonic acid could be carried out in large cast-iron pots by means of strong nitrosulphuric acid, thus avoiding the disadvantage of having to use the small earthen nitrating pots on account of the dilute acid hitherto employed for the nitration.

A most ingenious process for the continuous nitration of the sulphonic acid was devised and successfully worked by Messrs. Brookes Chemicals, Limited, at Lightcliffe, near Halifax. The plant consisted of a long and narrow trough about 80 feet by 2 feet by 19 inches deep, made of acid-proof brick and cement, divided into several compartments. The sulphonation was carried out discontinuously the ordinary way, but with only two molecules of sulphuric acid instead of four. The sulphonic acid after dilution was run together with four molecules of spent acid from the process into the first compartment of the trough (6 ft. long). The mixture was heated with live steam to 100 C., and then overflowed into the nitration compartment (64 ft. long). Four molecules of 65% nitric acid ran in at a number of points along the trough, which was covered in so that the nitrous fumes could be collected and carried to absorption towers. The mixture was kept at 100°—110° C. during nitration, and then passed to the end section of the trough (10 ft. long), where the picric acid in fine crystals and the spent acid were cooled by water coils and stirred by compressed air. Thence it was blown at short intervals by means of an air ejector into earthenware filters.

The home production of picric acid increased to 32,000 tons for the year 1917, but afterwards fell off as the quantity of TNT kept on increasing and the various amatols (TNT and ammonium nitrate) —of which it formed a proportion—were employed in preference to picric acid as filling for shells.

As both the strong acid nitration process and Brookes's continuous process were only developed towards the end of the war, comparatively little picric acid was produced by their means. It is satisfactory to see, however, that the manufacture was greatly improved and carried to a high degree of perfection, both in regard to plant and process, as the result of the careful study and experiment devoted to this manufacture. A large works was laid out and partly completed for the preparation of picric acid by the French process, in which sodium nitrate is used direct instead of nitric acid. I shall refer to this process when discussing the work carried out in France, but this factory never came into action on account of the falling off of the demand for picric acid.

Another method of preparing picric acid was also successfully worked, chiefly by Messrs. L. B. Holliday and Company. It consisted in the conversion of dinitrophenol into picric acid. This dinitrophenol was formed from benzene, which was first converted into dinitrochlorobenzene (a product manufactured by the United Alkali Company before the war). On treating this substance with caustic soda it is converted into sodium dinitrophenolate and—on further treatment with acid—into dinitrophenol, which can be nitrated to picric acid in cast iron vessels by means of strong acids. This process had the advantage of enlarging the output of picric acid, for the supply of phenol from tar, from which to make the picric acid, was limited.

A considerable quantity of synthetic phenol was made in this country also, chiefly by the South Metropolitan Gas Company and by Brunner, Mond and Company, and it was instructive to see how readily an "inorganic" firm like Brunner, Mond and Co. successfully turned themselves into most efficient manufacturers of an organic material by a complicated process. This manufacture, however, never attained anything like the large output reached by the French owing to the gradual disus of picric acid as a charge for shells.

When the war began comparatively little TNT was made here, and the total manufacturing output capacity was only about 20 tons per week. The procedure involved long periods of nitration. Thanks to a visit to France, where a process of nitrating toluene direct to TNT in one operation was seen at work, it was decided—when laying out the works at Oldbury—to aim at much quicker nitration than was being attained here, by providing much more efficient mixing and cooling. Processe had also been carefully worked out at the Research Department, Woolwich, which enabled the Oldbury works to be successfully started right away, and the full estimated output reached in a very shor time.

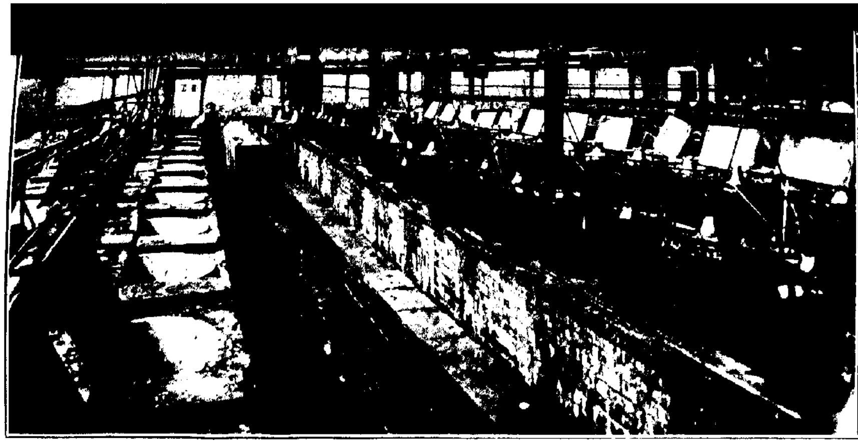

Fig. 1. Pot process. 80 galls.

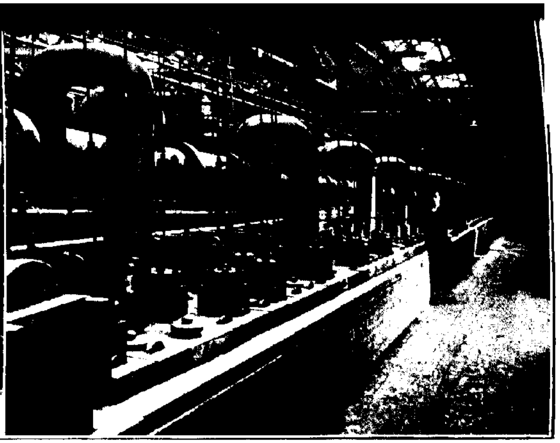

Fig. 2. Nitration plant. Centre view commencing end in background.

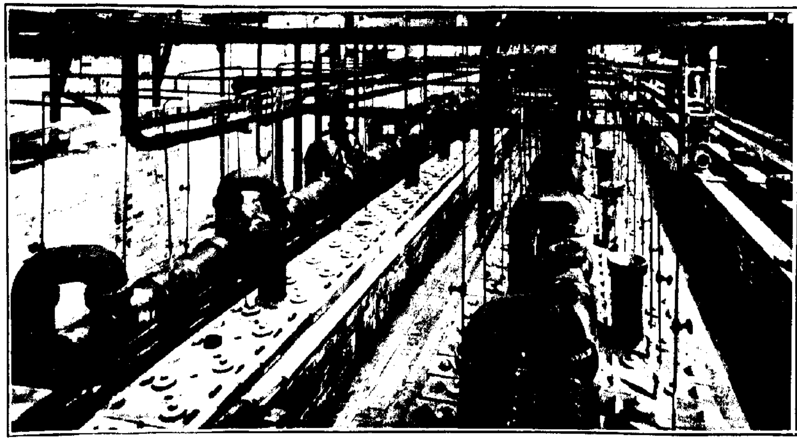

Fig. 3. Nitration plant. Centre view.

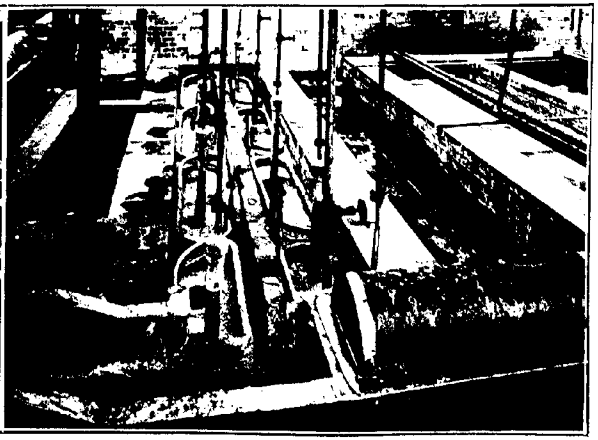

Fig. 4.—Picric coolers, after the nitration.

The largest works for making the TNT were ·ected at Queen's Ferry, near Chester, where the ıtput reached about 100 tons of TNT per day. his large output, however, was only attained by ıe most careful forethought and expeditious modes working and excellent "team" work between l the departments involved. For such an output TNT about 600 tons of fresh mixed acid had to prepared, 600 tons of spent acid had to be enitrated, 400 tons had to be concentrated, and ıen there was the production of 120 tons of nitric cid, both for the TNT and for the nitrocellulose hich was also produced there. There was also a rillo plant which made 250 tons per day of SO_2. he keeping of a proper balance of these enormous uantities of acids in their various stages was work f no mean order, and it may be claimed that the ystem of preparing the mixed acids worked with regularity and accuracy that left nothing to be esired.

The nitric acid and water content of the acid for ıe nitration of cotton had to be within limits of ·2%.

I think that the most outstanding feature of the ıanufacture of TNT, as carried out in the Government factories, was the very great reduction of the ime occupied in nitration. Before the war the ctual time of nitration for the three stages in hich the process was generally carried out was bout 40 hours, whereas afterwards it was reduced) about 10 hours, thus permitting a much greater utput from the plant.

A very ingenious system of continuous countercurrent washing of the TNT was devised at Oldbury y Holley and Mott and adopted elsewhere. he same principle was also applied there to the itration of MNT to TNT, so that there was a continuous output of washed TNT in the one case, and n the other crude TNT from one end of the plant nd spent acid from the other.

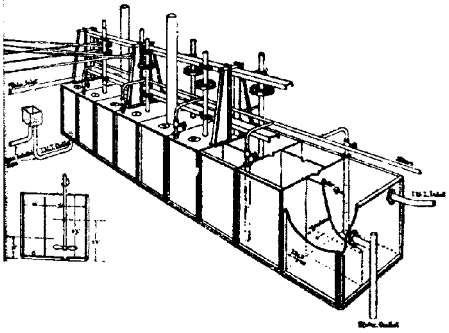

FIG. 5.

The continuous washer consists of a series of large d small compartments communicating with each ıer by specially placed openings (Fig. 5). In the ge compartments stirrers are fixed which keep e contents well mixed. The molten TNT enters e first large compartment, where it is mixed with sh water coming from the small compartment, e emulsion passing through a series of perforations o the small compartment. In this, where there no agitation, the TNT sinks to the bottom and ws forward, through an opening in the bottom the dividing plate, into the next large compartnt, where it is agitated with less acid water. e water flows from the small settling compartnt through an opening, at a higher level, in the e of the end compartment to waste, or from the ıer small compartments counter current to the T to the next large mixing compartment. Clean water enters the large compartment at the other end of the plant, meeting the well-washed TNT, which has travelled counter current to the water through the compartments where the TNT and water are successively mixed and allowed to separate.

The nitrating plant is constructed on the same principle, the compartments, however, consisting of separate cylinders connected at suitable levels as indicated on Fig. 6.

Diagram showing Counter Current Flow in Continuous Nitration Plant.

(Plan)

m-Connection half-way up. b-Connection near bottom.

FIG. 6.

A system of purification of TNT by means of sodium sulphite, for which we are indebted to the French, was put into successful operation. It depended on the fact that, when crude TNT is allowed to crystallise, the crystals are very nearly pure TNT, the impurities being concentrated on the surface of the crystals. As first devised in France, the molten TNT was allowed to cool slowly in shallow pans and this toffee-like material was broken up and then washed with sulphite solution. It was subsequently found that, if molten TNT and water were allowed to cool while being constantly stirred —the TNT separated out in fine crystals—on adding sulphite solution to this magma, the impurities were dissolved and small crystals of TNT of great purity could be separated by filtration and washing with water.

At first TNT was not considered by the Home Office to be an explosive within the meaning of the Act and could be used without the usual restrictions of the Explosives Act. This belief undoubtedly resulted in greater expedition in the production of the explosive when it was so greatly needed in the early days and possibly was an advantage. It was not long, however, before there were unpleasant indications that it was not the well-behaved substance it was formerly considered to be.

There is still much to be learned about TNT. Generally speaking, it is a very stable substance, not easily brought to explosion. It has been chipped by hammer and chisel out of tanks and vessels in which it had solidified without accident, and yet a violent explosion has occurred during the removal of the plug of an old cock, which had stuck, through which molten TNT had passed, although it had been steamed to free it from TNT.

Large quantities have been known to burn without exploding, but, unfortunately, several instances occurred in which fire led to most disastrous explosions of TNT.

The freedom from serious explosions at the Government factories was matter for much thankfulness.

In addition to explosion risks, considerable trouble was caused at first to the health of the workers from the injurious action of the TNT. Some individuals were much more easily and adversely affected than others, indeed some were quite immune to the action of the nitro-compounds. By careful selection of the workers and attention to health and cleanliness, their health was soon kept in excellent condition. It is not easy to get workers, male or female, to take simple precautions and avail themselves of the means provided for protection against noxious fumes or dusts; however, patience, sympathy, and explanatory information, do much in leading them into good and healthful ways of working.

The manufacture of sulphuric and nitric acids developed rapidly as the demand for more and more explosives increased. At first the disposal of the nitre cake was effected at Gretna, by mixing it with water and running it into the sea. At Queen's Ferry, it was sent in trucks and dumped into the sea on the Welsh coast. Soon, however, the necessity of conserving the sulphuric acid arose and nitre cake was utilised in many industries instead of sulphuric acid. Two methods were adopted of producing the bisulphate in more convenient form than broken cake. One consisted in running the molten bisulphate from the retort into large, shallow, circular pans, in which ploughs, attached to radial arms, revolved. As the bisulphate cooled and began to crystallise, it was kept from solidifying in one mass and the friction of the crystals on each other resulted in a fine, dry powder being produced, which was easy to pack and convenient to use. The other method consisted in allowing the bisulphate to flow from a pipe, subjecting the molten stream to a strong blast of air, which atomised and chilled it, producing a fine powder.

The production of sulphuric acid and oleum was carried out on a great scale. At Queen's Ferry, 250 tons a day of SO_3 was made by the Grillo process, a portion being dispatched to other factories.

The average monthly production of sulphuric acid (as 100% H_2SO_4) for the three months Dec., 1916—Feb., 1917 was 114,700 tons. Of this 17,000 tons came from contact plants. Explosives absorbed 50,600 tons, sulphate of ammonia 21,200 tons, and superphosphates 14,500 tons.

Oleum was also produced by the Tentelew and Mannheim plants, but by far the largest amount came from the Grillo plants at Queen's Ferry, Gretna, Avonmouth, and Greenwich, also the most economical working.

An interesting development of the demand for lead burners was the rapid supply of competent operatives. Lead burning had been a somewhat close craft, and comparatively few were initiated into its inner mysteries.

One of the best and most experienced burners undertook the teaching of candidates, and before long there were sufficient capable lead burners for all requirements. Advantage was also taken of experienced men in Australia, and several of the complicated leaden nitrators for nitroglycerin, all complete for use at Gretna, were sent from Melbourne.

Many chemists and engineers came from Australia and other colonies and played important parts in the factories, and have now returned with much useful knowledge and experience which should bear good fruit in their home lands. Let us hope they have also carried back the conviction that the old country is not so effete as it may have sometimes appeared when viewed from afar through the telescope of ignorance or imperfect knowledge.

The manufacture of M.D. cordite, the regulation propellant explosive, involved the use of acetone. The stock of this essential solvent was small, and supplies had to come from overseas and were uncertain and inadequate. R.D.B. cordite was accordingly evolved at the Research Department, Woolwich, and made at Gretna and elsewhere. It was necessary to produce a propellant which would give the same ballistics as M.D. cordite for the same size and weight of charge, so that existing cartridge cases, rifles, and guns could be used without alteration.

To those acquainted with the interdependence of chemical composition and physical state and form of a propellant and its ballistic results, it will be recognised that it was no mean achievement during the rush and stress of war to produce an explosive which did its work so admirably.

R.D.B. cordite was composed of nitroglycerin, "soluble" nitrocellulose, and mineral jelly, whereas M.D. cordite contained "insoluble" nitrocellulose or guncotton. This enabled ether-alcohol instead of the scarce acetone, to be used as the promoting solvent or gelatiniser. Alcohol from the home distilleries and the colonies was used and much whisky was held by the Government in case it might be necessary to resort to it for the alcohol it contained.

A large plant, which made 75 tons a day of ether, was erected at Gretna on the design of Barbet, of Paris, which worked excellently.

A striking instance of the pluck and presence of mind of a girl worker occurred in the ether factory. She was filling a can with ether from a large tank, when it burst into flame; before running away, she managed to shut off the cock delivering the ether, and thus prevented the development of a serious fire.

The manufacture of a satisfactory nitrocellulose for R.D.B. is much more difficult than the production of guncotton for M.D. cordite; not only must the percentage of nitrogen be kept within the limits of ±0·1%, but it must be perfectly soluble in ether-alcohol, and the solution must have a certain viscosity. The first two conditions are mainly dependent on the composition and temperature of the nitrating acids, and can be steadily maintained. This involves great accuracy in preparing the mixed acids. When it is remembered that the content of nitric acid and water must not vary more than ±0·2%, it will be realised that the greatest credit is due to the chemists who devised and controlled the excellent system of acid mixing and maintaining the balance of the huge quantities of acid being made, mixed, denitrated and concentrated.

The third condition, the viscosity, however, is greatly influenced by the character of the cotton. This led to much investigation and experimentation, and it was only after the effects of the preliminary treatment of the cotton waste at the mills had been carefully studied and standardised that uniformly satisfactory nitrocellulose and R.D.B. could be regularly produced. Thus the introduction of R.D.B. led to a much better knowledge of the properties and preliminary treatment of cotton.

A large plant for refining 40 tons per day of crude glycerin was erected at Gretna under the supervision of Mr. van Ruymbeke, and worked excellently.

Before America came into the war, and when it was being realised that the supply of glycerin might not be sufficient to meet the demand, the erection of a large factory to produce a nitrocellulose propellant was begun at Henbury. On America definitely joining the Allies, the work on this factory was discontinued—a wise decision, seeing that finished powder could be imported from America in about one-fourth of the tonnage required for the importation of the equivalent raw materials, nitre, sulphur, pyrites, and cotton, and the destructive activities of the U-boats were still a serious menace.

For the concentration of sulphuric acid, the chief feature was the extensive use made of the Gaillard tower. As the volvic stone use by Gaillard could not be procured at first, many of these towers were constructed of acid-proof tiles, which withstood the heat and acid fumes excellently. At Queen's Ferry there were 16 towers 9 ft. diam. × 50 ft. in height, and when the maximum output was obtaining, even the few grains of SO_3 per cub. ft. of gas discharged to atmosphere, permitted by the Alkali Act, became a serious nuisance to the workers in the factory, and also to the neighbourhood. After some time, Cottrell's electrical precipitator was installed and completely stopped the nuisance, besides recovering about 25 tons per day of 50% acid.

There was a curious evidence of the comparative stability of DNT. The spent acid from the TNT manufacture always contained some DNT in solution. A portion separated out during denitration and was recovered, but the acid sent forward for concentration still contained some DNT. It was undoubtedly chased out of the sulphuric acid in the Gaillard towers, but turned up unharmed in spite of the electric strain of 80,000 volts, in the Cottrell precipitator where some was recovered, and finally it formed an incrustation on the exit stack and fell down inside from time to time and was collected.

Another important manufacture which attained large proportions was that of ammonium nitrate.

At the beginning of the war the high explosive shells were filled either with picric acid or with TNT. To those of us who were acquainted with the strength and merits of the ammonium nitrate class of explosives, the employment of a large percentage of ammonium nitrate, along with TNT, seemed the obvious way of producing more explosive from the limited amount of TNT available. The War Office, and especially the Admiralty, were very conservative, and did not approve of an explosive containing a hygroscopic ingredient. Had there been a less strong man than Lord Moulton at the head of the Department of Explosives Supply, the merits of ammonium nitrate explosives would not have been so quickly ascertained and utilised. He insisted that they should be studied as the only means of ensuring an adequate supply of explosives, and thanks to the diligent work of the Research Department we soon had the various amatols (mixtures of ammonium nitrate and TNT). Large quantities of ammonium nitrate were procured from Norway. Brunner Mond and Co. soon entered the lists, and before long were turning out large quantities of ammonium nitrate by three different processes at their own factories and at others which they erected for the Government. The first was a modified ammonia soda process in which sodium nitrate replaced the chloride. Then calcium nitrate, at first obtained from Norway, was treated with ammonium carbonate, the reaction being quantitative. Afterwards, the calcium nitrate was produced by the Ammonia Soda Co. and by Brunner Mond and Co. from calcium chloride and sodium nitrate. The largest quantities were, however, ultimately produced by the double decomposition of ammonium sulphate and sodium nitrate.

It is so easy to write the equations for these reactions and so difficult to carry them out. There was ample scope for the phase rule, and fortunately one of its brilliant exponents was on the spot in the person of Captain F. A. Freeth, who, by the aid of an elaborate series of curves and diagrams, was able to get in full sympathy with all the phases of the different substances and bring them completely under control.

A large factory was erected at Swindon by the Government for making ammonium nitrate from sodium nitrate and ammonium sulphate, and it turned out about 2000 tons per week.

Many other chemical manufactures were started for the first time, or existing ones increased and modified, but it is not possible to deal with them here. I wish, however, to say a word about the skill and real heroism of those who were engaged in devising and working the processes for making poison gases. Some were killed, some permanently injured, and nearly all suffered abominably, yet they carried on in the most self-sacrificing manner. Truly the chemists did not fail the nation in its time of need!

France.

Now, as to some of the achievements of chemical industry in France. Towards the end of 1914 I had occasion to visit France when the seat of the Government had been transferred from Paris to Bordeaux. There I found heads of departments carrying on the administrative work of the country and a great war under most trying conditions. Some in hotels, in the University, schools, barracks, and other public buildings. Think what it must have meant, to transfer hurriedly all the working papers and documents for carrying on the affairs of a great country and restart the machine again. I shall never forget the impression I got of the grim determination to hold on, the same spirit that inspired later the immortal words at Verdun: "Ils ne passeront pas."

The most cordial relations developed between the Ministère des Munitions and our own Department of Explosives Supply, and members of the staffs exchanged visits and inspected the different factories from time to time. They communicated information freely, and helped us in many ways, and we reciprocated to the best of our ability. I paid many visits and followed the growth and operating of many factories with the greatest interest. We were justly proud of what we were accomplishing here, but I always returned from France somewhat chastened and full of admiration and astonishment at what they were accomplishing. Here we had our difficulties with "priorities" and other hindrances to rapid constructive work, but we had not, like the French, many of our largest engineering and constructional works in the hands of the enemy; and yet—in spite of such embarrassing difficulties—they made magnificent efforts and achievements.

In 1914, I visited the large Arsenal near Lyons and saw shells being filled with picric acid in a way which would have made our officials' hair stand on end!

In a very extensive building, there were erected a large number of glycerine baths in which cans of picric acid were stood until the acid was melted ready for pouring into the shells. The baths were heated by open coke fires and the building was thronged with workmen. As the officer in charge truly said: "With the enemy on our doorstep and our soldiers crying out for ammunition, risks must be taken in factories which would not be thought of in peace time." It is satisfactory to be able to record that no disaster occurred in that particular department.

Immediately after returning from this visit I went to Woolwich Arsenal and was much impressed, possibly dismayed, with the leisurely manner in which shells were being filled with picric acid there. The fact of a large and important part of one's country having been invaded and occupied by the enemy accounts for many apparent anomalies in the way in which French and English regarded many things during the early days of the war. Perhaps it took us a little longer to get into our stride, but we soon had no occasion to be dissatisfied with our output.

In France, the manufacture of explosives—both for military and civil purposes—was practically a monopoly of the State. It was conducted by the "Service des Pourdes et Salpêtres," which was established on 13 Fructidor in the year V., otherwise August 30, 1797. This Department had at the beginning of the war 10 factories, two for nitrocellulose at Angoulême and Moulin Blanc, five for propellant Poudre B, at Le Pont du Buis, Ripault, St. Médard, Toulouse and Sevran-Livry; and three for disruptive explosives at Esquerdes, Vonges and St. Chamas. About 6000 persons were employed in these factories at first and this number rose to 120,000 in 1917.

Workers employed in explosives factories from 1914 *to* 1918.

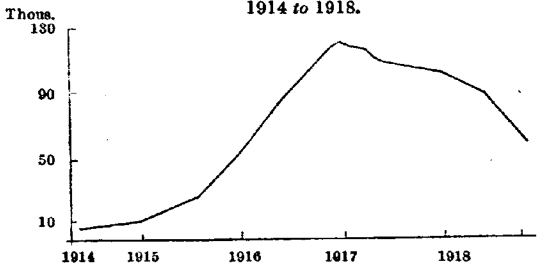

FIG. 7.

The French were not unprepared in regard to explosives for a great war. The general staff had elaborated a plan during peace in which it was provided that there should be capacity for producing 24 tons of propellant powder per day. The actual capacity of the Government factories on the outbreak of war was about 22 tons a day, and there was a stock of 750 tons in the country, so that the anticipated requirements of 24 tons per day could be easily supplied until the factories could bring up their outputs sufficiently. The facilities for making high explosives were very limited, but sufficient stocks had been accumulated to serve for the few months during which it was believed a great war could last, and it was not considered necessary to have available factories for these explosives.

Almost from the first, however, it was seen that the consumption of all kinds of explosives was going to exceed anticipations, and the Battle of the Marne led to greatly increased demands.

Even the greatest difficulty was experienced in keeping up the supply of powder for the Army. The Navy assisted by giving up many guncotton torpedo charges, which were sent to the factories to be broken down and worked up into powder. During the scare which followed the explosion on the "Liberté," large quantities of powder had been sunk in Toulon Harbour. This powder was dredged up, found to be stable enough, and was re-worked, and —in one way and another during the trying first months of storm and stress—the troops were kept supplied.

In addition to enlarging existing factories, two entirely new works were erected at Bracqueville, near Toulouse, and at Bergerac to produce 100 tons and 60 tons per day respectively of Poudre B. These works were finely laid out and constructed, reinforced concrete playing a leading part in the building, and also in the chimney stacks.

Large numbers of orientals from Annam and Cochin China, and natives from Algeria and Senegambia, were employed in the explosives works. Special arrangements for their housing and oversight had to be made, thus causing additional work. The provision of a competent staff for the different factories was no easy matter, for there was no large and well-developed organic chemical industry in France, from which experienced men could be obtained; however, professors, teachers, and many others were enlisted, and the factories were successfully brought to the desired output.

During repeated visits it was intensely interesting to see the rapid growth of these factories and often to learn, on a succeeding visit, that what had previously seemed a very large output was then being doubled.

Angoulême is the largest nitrocellulose factory, and was equipped with the Selwig nitrating centrifugals and the Thomson displacement nitration process. Pending the arrival of new plant for these excellent processes, recourse was had to the old Abel small pot process, which could be easily and quickly installed, with all its inconvenience of much labour and noxious fumes.

Nitrocellulose.

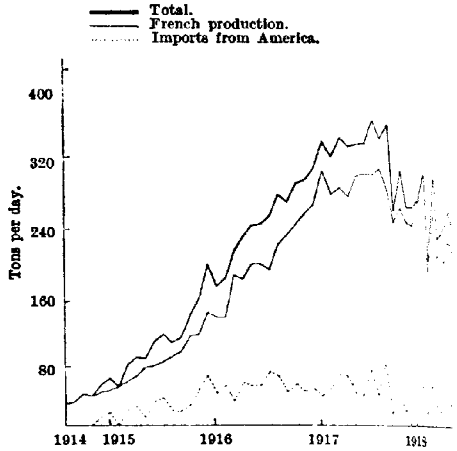

FIG. 8.

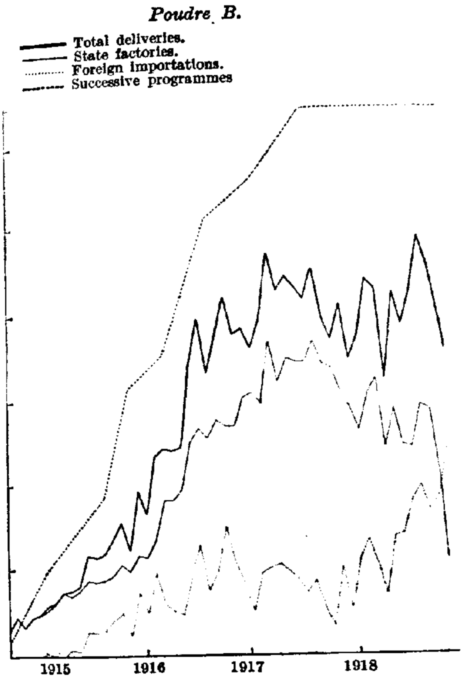
The manufacture of the French Poudre B requires a large amount of alcohol as such and after conversion into ether. Here, again, many ingenious methods were adopted for eking out the precious liquid. Many of the large distilleries were in the occupied territory, and this added much to the difficulties of supply. A useful source of alcohol was found in the quantities of alcoholic extracts of absinthe, which had been impounded owing to its consumption having been prohibited recently. Attempts were made to produce alcohol from the large quantities of cider fruit available, but were unsuccessful until it was discovered that by mixing a certain proportion of beetroot with the apples fermentation could be carried out satisfactorily.

In making the French powder a mixture of "insoluble" and "soluble" nitrocellulose is gelatinised by means of ether-alcohol and then pressed out in the form of ribbon which is subsequently cut into suitable lengths or strips or small squares. The ribbon had to be dried to get rid of the solvent and at first a considerable quantity of ether-alcohol was recovered by drawing the air, laden with the solvent, from the drying chambers through a carbonic acid refrigerating system. Later on a greatly improved recovery was obtained by absorbing the ether-alcohol in the air in cresol in suitable scrubbers according to Bregeat's patent.

The output of Poudre B. reached as much as 370 tons per day, and the total production of this powder in France, during the war, was 306,700 tons, whilst 117,000 tons was imported from America.

Picric acid.—The production of picric acid became one of the chief necessities and numerous proposals were put forward to procure an adequate supply.

In Germany before the war, nearly all the picric acid was made from chlorobenzene, as they had plenty of chlorine from their electrolytic processes. No chlorine was available in France, but—not to ave out any possible means of increasing their ipplies—1000 tons of chlorine was ordered from merica. It was never used for picric acid, as the rst gas attacks in April, 1915, had occurred, and is chlorine was handed over to the Service du latériel Chimique de Guerre for experiment and ibsequent use in counter gas attacks.



Poudre B.

FIG. 9.

The chief source of the raw material for picric acid was the synthetic phenol made from benzene. The amount of phenol available from coal tar was small, and the French had obtained most of the phenol they required from Germany. One firm, however—the Société Chimique des Usines du Rhône—was making about 1 ton of synthetic phenol per day before the war at St. Fons, near Lyons. Arrangements were made successively for increasing the output to 10, 15, and 30 tons per day, and finally the company erected for the Government a new factory at Peage de Roussillon, further down the Rhône, which produced 75 tons per day in 1917. This was a magnificent factory, and we in England benefited much in carrying out our processes for making synthetic phenol from the greater experience of the French, who freely gave information.

The process consisted in the sulphonation of benzene with strong sulphuric acid in the usual way. Later on Guyot improved this stage greatly by passing the benzene in vapour form into acid, heated to 100° C., and condensing any unabsorbed benzene and the water which had been formed by the reaction. After drying, the unabsorbed benzene re-entered the cycle. By this method nearly all the sulphuric acid was utilised, thereby effecting considerable economy in acid, lime for neutralisation, and attendance.

The product of sulphonation was diluted with water and neutralised with lime, then treated with sodium sulphate or carbonate to convert the calcium benzenesulphonate into the sodium salt. The sodium benzenesulphonate solution was separated by filtration from the calcium sulphate or carbonate, and then concentrated *in vacuo* to crystallising point. The crystals were then heated until the water of crystallisation was driven off.

A great improvement in this stage was ultimately introduced. To the product of sulphonation, which contained a considerable amount of free sulphuric acid, sufficient normal sodium sulphate was added to form sodium benzenesulphonate, which, under certain conditions of concentration and temperature, crystallised out almost completely from the solution. This method avoided the neutralisation with lime and expensive evaporation of the sodium benzenesulphonate solution. The yield was not quite so high as by the old method, but this was much more than counterbalanced by economy in lime, fuel, time, and labour. This method, along with the process of sulphonation of benzene in the state of vapour, marked distinct progress in the manufacture of phenol.

The sodium benzenesulphonate, after fusion with caustic soda and extraction with water, gave a solution of alkaline phenate and sodium sulphite which was precipitated. The sodium phenate solution was decomposed by sulphuric acid, which set free the phenol, which was decanted and distilled under vacuum, while the sodium sulphate in solution was recovered after concentration and crystallisation, and used again in the earlier stage of the cycle. Altogether, from Government and private factories, 200 tons per day of synthetic phenol was obtained.

The manufacture of picric acid attained large proportions. Private factories ultimately turned out about 100 tons per day. New Government factories for making picric acid were erected at Sorgues near Avignon, Bassens near Bordeaux, and Oisel near Rouen, their joint output being about 180 tons per day. The works at St. Chamas, near Marseille, were also greatly extended and produced a large amount of picric acid and other explosives.

The process almost invariably followed in France consisted in first sulphonating the phenol, then running the acid sulphonate into a mixture of sodium nitrate and dilute nitric acid contained either in small earthenware nitrating pots—each mounted on a small trolley—or else into large cast iron pots lined with acidproof bricks and cement. The large cast iron pots were connected permanently to condensing and absorbing towers and the small pots, when charged with nitre and dilute nitric acid, were moved to stations and connected to absorbing towers. The sulphonic acid was run in, and a current of air blown through the contents served to control the reaction, remove the fumes and promote the formation of the picric acid in fine crystals. When the evolution of fumes ceased, after about 3 hours, the pots were removed to a distance and allowed to stand for 14 hours, when the nitration was complete. The crystals of picric acid were separated by filtration, washed and dried.

This process has the advantage of not requiring plant for the manufacture of nitric acid, the dilute nitric acid above referred to coming from the condensation and oxidation of the nitrous fumes evolved. On account of being directly associated with the sodium nitrate in the nitrating pot, the picric acid has always a higher ash content than when made with nitric acid. This was looked on with disfavour by our authorities, although the French found it unobjectionable. Special relaxation in the specification was contemplated had the factory erected in England for making picric acid according to the French practice come into operation.

TNT was also made in France in considerable quantities, but this manufacture never attained the proportions reached in England. At first the toluene was nitrated direct to TNT in one operation, requiring about 10 hours in the nitrating vessels; this enabled a larger output to be obtained from the plant, which was a great advantage in the early days, but this process involved a larger consumption of acid and was abandoned when more plant could be procured. A three-stage process was generally followed afterwards.

In order to increase still further the supply of explosives endeavour was made to nitrate the mixtures of *o*-, *m*-, and *p*-xylenes contained in the Borneo spirit, but this gave a most unsatisfactory product, both from the manufacturing and usage points of view. The French, however, studied the problem and finally evolved a good process which produced an excellent explosive substance very similar in explosive character to TNT.

The xylenes in the spirit existed in three isomeric forms, *m*-xylene being the only one which gave a suitable trinitroxylene. As it was impossible to separate these xylenes by physical methods, the separation was effected by treating the Borneo xylene spirit with 94% sulphuric acid. Under suitable conditions of time and temperature, only the *o*- and *m*-xylene are sulphonated. After washing, the *p*-xylene and the aliphatic hydrocarbons are distilled off and the remaining *o*- and *m*-xylenesulphonic acids are heated to 130° C. with dilute sulphuric acid, when the *m*-xylenesulphonic acid is decomposed and the *m*-xylene driven off, the sulphonic acid of *o*-xylene not being split up until 160°. This reaction with hot dilute sulphuric acid involved the use of silicon-iron vessels or other acid-resisting materials. Considerable success was obtained by painting ordinary cast-iron vessels with a special acid-resisting composition.

Nitro and nitrated explosives.

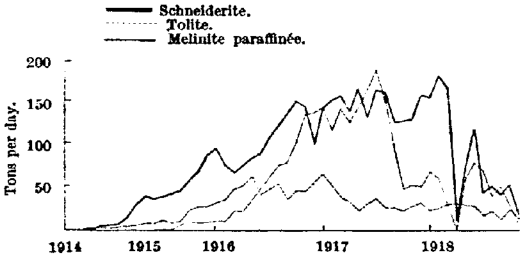


FIG. 10.

Arrangements had been made in England for making *m*-xylene in this way, but were not carried out as the supply of toluene proved sufficient for our needs.

Chlorate and perchlorate explosives.

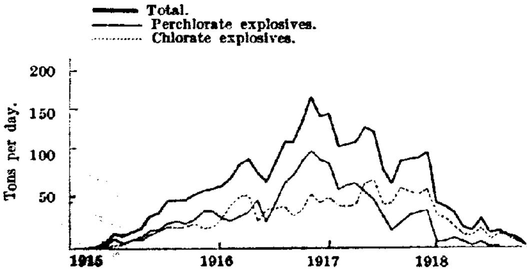

FIG. 11.

The manufacture of chlorates and perchlorates was carried out on a considerable scale at Chedde and elsewhere to the extent of 80 tons of sodium chlorate and 73 tons of ammonium perchlorate per day. Explosives made from these compounds as base, being too sensitive for use in high-velocity shells, were chiefly used in hand grenades and trench mortars, also for aeroplane bombs.

At Angoulême "Yperite" or mustard gas was made according to a process devised by the Société Chimique des Usines du Rhône. The output contemplated was 24 tons per day; at the Armistice 6 tons per day was being made from 2 units, two others were ready to start and the full output would have been reached by the end of the year. Angoulême also turned out 70 to 80 and Bassens 25 to 30 tons per day of nitrogen peroxide, which formed the base of the explosive "anilithe" used for filling aeroplane bombs. Like us, the French found themselves embarrassed by large quantities of mustard gas after the armistice, and much was taken to sea and drowned.

The supply of oleum soon proved insufficient, and large quantities were imported from America until new plants were erected and brought into operation. One oleum plant at Thann, in Alsace, was dismantled while under fire and successfully removed during the night and erected and re-started at St. Denis.

Consumption of 66° *sulphuric acid and oleum, January* 1915 *to October* 1918.

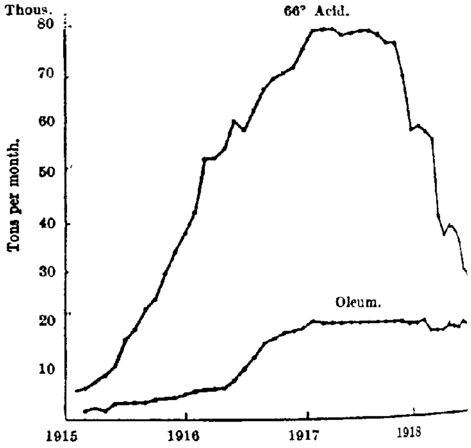

FIG. 12.

The manufacture of nitric acid from saltpetre was nearly always carried out according to the Valentiner process. The French seemed to be able to procure much larger and better earthenware plant than we could make. It is interesting in this connexion to recall a visit to the celebrated porcelain works at Sèvres, where were seen many of the most skilled makers of the delicate porcelain articles busily moulding large vessels for different kinds of chemical work.

The French, however, did not consider it safe to rely entirely on Chile saltpetre for their nitric acid requirements. There was a small factory at Rôche-de-Rame working the Pauling process and producing 2 tons per day of 50% nitric acid. This was taken over by the Government; later, plant was erected by the Norwegian Company to work the Birkeland and Eyde process at Soulom in the Pyrenees, where the Midi Railway Co. had erected a large hydroelectric power station and could offer 12,000 kw.-h. for this purpose. About 300 tons, calculated as strong nitric acid, was delivered per month from this works, either as nitric acid or ammonium or sodium nitrates, as required.

A large plant was also erected at Angoulême for the oxidation of ammonia, derived from cyanamide, by the Kuhlmann-Ostwald process.* Arrangements were made for the supply of 3500 tons of cyanamide per month and the plant was in full work in 1917.

The submarine menace becoming still more serious, it was decided to create new works capable of producing 500 tons of nitric acid and 150 tons of ammonium nitrate per day. This involved a supply of 1000 tons of cyanamide and electric energy of 125,000 kw.-h. This power was found in the Pyrenees, the Alps, and centre of France, and provision was also made for supplying a reserve amount from steam.

At the time of the armistice two of the new works had begun to manufacture and the others were nearly completed.

With all the plant in operation, France would have been independent of outside supplies of nitre. In this branch of chemical industry they got much ahead, and still remain far in advance of us.

And here I wish to express my thanks to my friend, Professor Haller, of Paris, for permission to draw on the information contained in his two papers published in the Bulletin de la Société d'Encouragement pour l'Industrie Nationale, November/December, 1920, and for the loan of his slides, and to members of the Service des Poudres et Salpêtres, who have kindly helped me from time to time.

In this sketch I have endeavoured to indicate the really magnificent efforts that were made in this country and in France in chemical industry during the war, and the enormous outputs of many and varied chemical products. As achievements of chemical industry, all concerned may regard them with pride.

And yet it is a bitter thought that all this intensive effort and expenditure of brains and intelligence resulted literally in smoke and destruction of life and property that is truly appalling. As chemists, we know better than most people the awful possibilities of suffering and destruction another great war would entail, unrestricted as it would be in every sense.

It seems to me that it is especially laid on us to bear this in mind and combat every tendency which might lead to war, and endeavour to prevent mankind from entering on such a suicidal course.

Fortunately there is a more cheerful and hopeful way of looking at these chemical activities. Chemical industry, in nearly all its branches, received a great stimulus from the war. A very large number of chemists were brought into close contact with industrial work, and have gained a valuable experience in factories, and have become practically acquainted with the construction of plant and running of chemical processes, and—in many instances—the *coup de grâce* has been given to rule-of-thumb methods.

We were fortunate too in having at the head of the Factories Branch of the Department of Explosives Supply K. B. Quinan, whose good influence on our chemical industry is being widely felt, especially through the work of the younger men who have assimilated—and practise—his excellent methods of studying and handling technical problems. Quinan was an inspiration to all of us who had the privilege of working with him. He had much in common with the distinguished chemist in whose memory these lectures have been established, and was very desirous that the country should derive as much benefit as possible from the knowledge and experience gained during the war.

We may look forward with hope to holding our own and competing successfully in all branches of chemical industry if we seek for, and apply, the highest scientific knowledge available.

The Universities and Colleges I am sure wish to help industry as much as possible, whether by pure research or by imparting more technical teaching to those chemists intending to enter on an industrial career. Many of the professors and teachers did splendid work during the war, and were brought into close contact with many works and those controlling them. This experience, as well as the broadened sympathy which must have resulted between professors and manufacturers, should also be very helpful in developing technical education on sound lines.

In looking over the long list of Hurter's activities and accomplishments one cannot help regretting that we had not the advantage of his great abilities when faced with so many difficult and important industrial problems which he would have delighted in attempting to solve, and yet one has to recognise the pain it would have been to one so closely allied to two nations caught in the horrid cataclysm of war and feel glad that he was spared that experience. The war showed us our lack of men of Hurter's stamp, men of high scientific attainments coupled with the knowledge and practice of technical working. Undoubtedly we had some splendid ones, but not nearly enough. Hurter has left us a great legacy in showing us the way in which technical problems should be handled, which is often of more general use than the solving of particular ones. Let us hope these Hurter memorial lectures will help effectively to keep his name and influence before us and induce us to pay closer attention to what he can teach us.

In passing, I would like to refer to a subject I have much at heart and which seems to me not unsuited to be mentioned in a Hurter memorial lecture.

The Institution of Chemical Engineers has just come into actual being. There has been much talk and discussion from time to time as to the definition of a chemical engineer, but whatever our individual opinions may be as to his education and his scope, I am certain we are one and all desirous of seeing British chemical industry in a flourishing condition. Some one in a works must have a good knowledge of both chemistry and engineering if the work is to be wisely co-ordinated and the best results obtained.

It is not easy to prescribe the best means of educating and developing men of this class, but I am convinced that it should be attempted. I would earnestly ask those who are actively connected with the technical side of chemical industry, as well as professors and teachers, to give this new Institution their whole-hearted support, sympathy, and advice, so that its activities may be wisely directed and prove a real force.

There can be no difference of opinion as to the immense value of Hurter's contribution to the technology of chemistry, whether we consider his studies of the means of promoting action between gases and liquids which were conducted in such a scientifically systematic manner, or his work in connexion with the manufacture of chlorine, or indeed any of his many activities. He seems to me to represent the highest type of industrial chemist or chemical engineer, whose example should be an inspiration to all of us.

I cannot but think that he would have approved of this new Institution, and if it takes him as an ideal after which to strive to fashion its members, chemical industry will benefit and Hurter's memory be kept greener than ever.

---

* Professor Haller has pointed out that, although the ammonia-oxidation process bears the name of Ostwald, the principle was established by Kuhlmann, of Lille, in the first half of last century.

Communication.

THE NITROMETER METHOD FOR THE DETERMINATION OF NITROGEN IN NITRATES AND NITRIC ACID.

BY H. W. WEBB, M.SC., F.I.C., AND M. TAYLOR, D.SC.

The following investigation was undertaken to determine the cause of repeated discrepancies observed in practice between the percentage of nitric acid in samples of commercial acid, as determined by means of the nitrometer on the one hand and by titration with alkali on the other. The total acidity by titration with alkali was found to give values agreeing with the total obtained by determining the nitrous acid with permanganate and the nitric acid by the ferrous sulphate method of Bowman and Scott.

The experiments here described were hence carried out with the object of deciding whether the discrepancy was due to inherent errors in the method, or to faulty manipulation.

The materials employed consisted of (1) potassium nitrate recrystallised until free from chloride and sulphate, and dried at 120° C.; (2) concentrated nitric acid freed from chlorine and sulphuric acid by distillation, and from oxides of nitrogen by bleaching.

In the case of potassium nitrate the accuracy of the method was checked by direct weighing, while in the second case the acid was titrated against standard sodium hydroxide solution. *N*/1 Hydrochloric acid was prepared by distillation under known pressure, according to the method of Hulett and Bonner (J. Amer. Chem. Soc., 1909, **31**, 390), and was used as the standard in alkali titrations.

The sodium hydroxide solution was free from carbon dioxide and was prepared by allowing clean sodium, supported by a nickel gauze, to deliquesce into a nickel crucible in an atmosphere free from carbon dioxide (Ostwald-Luther, "Phys. Chem. Messungen," 3rd German Edn., 1910, 491).

All the instruments employed were calibrated, the nitrometer by means of mercury, and burettes by means of water. An Ostwald-Luther calibration pipette was used in the case of the burettes. Standardised weights were used.

The sulphuric acid used in the nitrometer was tested for freedom from nitrogen (1) by shaking with mercury in the nitrometer, (2) by the ferrous sulphate test, (3) by diphenylamine, which gave only a faint blue coloration on warming and standing.

The pure 97% acid was diluted to 91—92% before use in the nitrometer.

Manipulation.—The quantity of sulphuric acid was kept as low as was compatible with complete washing in of the nitrate.

According to Marqueyrol and Florentin (Bull. Soc. Chim., 1911, **9**, 201) long shaking with strong sulphuric acid and mercury causes reduction of nitric oxide to nitrous oxide and nitrogen, therefore unnecessarily long shaking was avoided. After introduction of the materials the nitrometer was given one shaking consisting of 30 to 40 separate shakes. It was then allowed to stand for about twenty minutes and the process repeated until no more gas was liberated. Usually a slight increase in volume was observed after the second shaking, and further shaking produced no further increase. In no case was a decrease in volume observed as a result of repetition of the shaking. The level of the open limb of the nitrometer was adjusted until there was practically no influx of acid from the cup on opening the tap.

It was observed that the thermometer attached to the outside of the nitrometer responded more rapidly to change in temperature than the gas. During a reading the thermometer would rise from 0·5° to 1·5° C., while, with rapid reading, the gas showed no change in volume. Consequently the temperature was always read before the final adjustment and reading of the volume of the gas. For the same reason the readings should be taken in a room free from fluctuations of temperature such as are caused by draughts or direct sunlight. The barometer readings were corrected for temperature and the pressure was corrected for the column of sulphuric acid in the cup, the density of the acid being taken as one-seventh that of the mercury. The volume of the sulphuric acid in the nitrometer was read to allow of correction for the solubility of nitric oxide in the acid.

In the calculations 1917 atomic weights were used, and Gray's value 1·3402 g. was taken as the weight of 1 litre of nitric oxide at 0° C. and under 760 mm. pressure. Using these values, 1 c.c. of nitric oxide is equivalent to 4·5154 mg. of potassium nitrate and to 2·8144 mg. of nitric acid.

Results with potassium nitrate.

(1) 0·3106 g. KNO_3 yielded 74·5 c.c. NO at 22·7° C. under 755·7 mm.

Volume of 91—92% H_2SO_4 in nitrometer = 20·5 c.c.

Percentage of KNO_3 in purified potassium nitrate (not corrected for solubility of NO) = 74·5 × 755·7 × 4·5154 ÷ 760(1 + 22·7 × 0·003665)3·106 = 99·42.

(2) 0·3152 g. KNO_3 yielded 75·5 c.c. NO at 25° C. under 757·7 mm.

Volume of H_2SO_4 in nitrometer = 20·5 c.c.

Percentage of KNO_3 (uncorrected) = 99·45.

(3) 0·2836 g. KNO_3 yielded 67·75 c.c. NO at 22° C. under 757·55 mm.

Volume of H_2SO_4 in nitrometer = 12·5 c.c.

Percentage of KNO_3 (uncorrected) = 99·55.

(4) 0·3010 g. KNO_3 yielded 71·6 c.c. NO at 20·8° C. under 760·1 mm.

Volume of H_2SO_4 in nitrometer = 11 c.c.

Percentage of KNO_3 (uncorrected) = 99·64.

The above experiments show that the larger the volume of sulphuric acid in the nitrometer the greater the error in the determination of the percentage of potassium nitrate. Therefore before reducing to standard conditions a correction for the solubility of nitric oxide in the acid must be applied to the volume actually read.

According to Lunge (J., 1885, **4**, 448) 10 c.c. of 96% sulphuric acid dissolves 0·35 c.c. of nitric oxide at 18° C. and under 760 mm., while according to Tower (Z. anorg. Chem., 1906, **50**, 382) 10 c.c. of 90% acid dissolve only 0·193 c.c. of nitric oxide at 18° C.

Table I. affords a comparison of the effect of these two different corrections.

TABLE I.

1. No. of expt.	2. Wt. of KNO_3 g.	3. Vol. uncorrected c.c	4. % of KNO_3 calc. from vol.	5. Vol. of acid in nitrometer c.c.	6. Lunge's corr. vol. c.c.	7. Tower's corr. vol. c.c.	8. % of KNO_3 corrected for solubility of NO, according to	9.
							Lunge.	Tower.
1	0·3106	68·39	99·42	20·5	69·04	68·77	100·3	99·97
2	0·3152	69·42	99·45	20·5	70·08	69·79	100·4	99·99
3	0·2836	62·49	99·55	12·5	62·89	62·72	100·1	99·92
4	0·3010	66·39	99·64	11·0	66·75	66·59	100·1	99·94
Mean							100·2	99·96

The numbers in columns 6 and 7 were obtained by adding the number of cubic centimetres, presumed to be dissolved, to the actual number read and subsequently reduced to standard conditions. The percentages obtained by applying Tower's correction differ inappreciably from 100%, while Lunge's correction gives a value slightly too high. It is hence evident that the nitrogen in potassium nitrate can correctly estimated by means of the nitrometer ien 91—92% sulphuric acid is employed, and the lubility of nitric oxide in this acid is assumed to 0·2 c.c. in 10 c.c. of acid.

Experiments with nitric acid.

The acid purified by distillation was titrated ainst pure sodium hydroxide solution free from rbon dioxide. To avoid loss of fume it was ighed directly into a deep flask containing nearly ough sodium hydroxide to neutralise it, and lium hydroxide was then added to exact utrality.

(1) 1·7715 g. nitric acid required 48·02 c.c. 0·5530*N* NaOH solution. HNO_3 = 94·47%.

(2) 1·8381 g. nitric acid required 49·82 c.c. 0·5530*N* NaOH solution. HNO_3 = 94·46%.

Nitrometer estimations gave the following sults:—

(1) 0·2664 g. nitric acid yielded 94·9 c.c. NO at 21·2° C. under 763·9 mm.
Volume of acid in nitrometer = 21 c.c.
Percentage of nitric acid (uncorrected) = 93·55.
Corrected for solubility of NO according to—
Lunge = 94·28.
Tower = 93·97.

(2) 0·2183 g. nitric acid yielded 78·8 c.c. NO at 18° C. under 740·2 mm.
Volume of acid in nitrometer = 25 c.c.
Percentage of nitric acid (uncorrected) = 92·82.
Corrected for solubility of NO according to—
Lunge = 92·91.
Tower = 93·44.

(3) 0·2137 g. nitric acid yielded 71·0 c.c. NO at 21·7° C. under 763·2 mm.
Volume of acid in nitrometer = 18 c.c.
Percentage of nitric acid (uncorrected) = 94·31.
Corrected for solubility of NO according to—
Lunge = 95·11.
Tower = 94·78.

(4) 0·2128 g. nitric acid yielded 75·0 c.c. NO at 17·8° C. under 751·4 mm.
Volume of acid in nitrometer = 32 c.c.
Percentage of nitric acid (uncorrected) = 92·04.
Corrected for solubility of NO according to—
Lunge = 93·42.
Tower = 92·81.

The cause of the discordance shown by these lues was detected by weighing the acid from an um bulb into a weighing tube containing strong phuric acid. In one experiment the weight of d removed from the oleum bulb was 0·2079 g. and weight of acid transferred to the weighing tube s 0·2066 g.—a loss of 0·6%.

Calculated from the weight of acid in the weigh- tube, 0·2066 g. nitric acid yielded 74·2 c.c. NO 18° C. and under 748·2 mm.
Volume of acid in nitrometer = 25 c.c.
Percentage of nitric acid (uncorrected) = 93·35.
Corrected for solubility of NO according to—
Lunge = 94·41.
Tower = 93·96.

second experiment:
eight of acid taken from oleum bulb = 0·2194 g.
eight of acid transferred to nitrometer = 0·2138 g., indicating a loss of nearly 3%.
2138 g. of acid yielded 76·5 c.c. of NO at 16·6° C. under 746·1 mm.
olume of acid in nitrometer = 20 c.c.
ercentage of nitric acid (uncorrected) = 93·19.
orrected for solubility of NO according to—
Lunge = 94·04.
Tower = 93·67.

will be noticed that the greater loss of fume he second experiment has caused a further drop he percentage of nitric acid, in the acid which hes the nitrometer.

In an attempt to weigh the acid in a sealed bulb loss of fume was observed on sealing, and the percentage of nitric acid after applying Tower's correction was only 92·22.

At this stage the nitric acid was re-titrated against sodium hydroxide solution by weighing into standard soda solution.

1·5054 g. nitric acid required 40·79 c.c. 0·5530 *N*NaOH solution. HNO_3 = 94·43%.

TABLE II.

Percentage of HNO_3 in redistilled nitric acid.

Determined by the nitrometer.			
Uncorrected for solubility of NO.	Corrected for solubility of NO according to Lunge.	Tower.	Determined by titration with alkali.
93·55	94·28	93·97	94·47
92·82	93·91	93·44	94·46
94·31	95·11	94·78	94·43
92·04	93·42	92·81	—

From the values recorded in Table II. it is evident that the method of weighing the acid into sodium hydroxide solution, instead of into water, for the alkali titration, gives concordant results. On the other hand, fuming nitric acid cannot be weighed without loss into sulphuric acid, in the small quantities required for a nitrometer estimation.

In the following experiments this loss was minimised by weighing a large quantity of nitric acid into a deep bottle of about 150 c.c. capacity containing a known weight of 97% sulphuric acid. The mixed acid of known composition can then be weighed from the oleum bulb into the cup of the nitrometer.

The following figures show the extent to which loss of fume was eliminated by this method.

Weight of nitric acid determined by difference in weight of oleum bulb content 4·2740 g.
Weight of nitric acid determined by increase in weight of bottle containing sulphuric acid 4·2726 g.
Therefore the loss of fume is now less than 0·04%.
Weight of 97% sulphuric acid 53·8264 g.
Weight of nitric acid added 4·2726 g.
Percentage of fuming nitric acid in the mixed acid 7·354.

In the first experiment the weight of mixed acid employed was determined by difference in weight of the oleum bulb and checked by re-weighing in a stoppered tube.

Weight of mixed acid taken from oleum bulb = 2·6456 g.
Weight of mixed acid in stoppered tube = 2·6458 g.

These weights showed that the mixed acid could safely be weighed into the cup of the nitrometer, and its weight taken as the difference between the weights of the oleum bulb contents. Therefore in the second experiment the double weighing was dispensed with.

(1) 2·6458 g. of mixed acid containing 0·1946 g. of nitric acid yielded 72·4 c.c. NO at 19·0° C. under 728·8 mm.
Volume of acid in nitrometer = 17 c.c.
Percentage of HNO_3 in fuming acid (uncorrected) = 93·91.
Corrected for solubility of NO according to—
Lunge = 94·69.
Tower = 94·34.

(2) 2·1410 g. of mixed acid containing 0·1575 g. of nitric acid yielded 58·6 c.c. NO at 19·0° C. under 729·4 mm.
Volume of acid in nitrometer = 12 c.c.
Percentage of HNO_3 in fuming acid (uncorrected) = 93·99.
Corrected for solubility of NO according to—
Lunge = 94·64.
Tower = 94·39.

It was thought possible that the nitric acid might contain enough carbon dioxide to have appreciable effect in the titration of the acid with soda solution.

A large quantity (3—4 g.) of the acid was therefore weighed into a known volume, in excess, of standard sodium hydroxide solution, and the excess titrated with $N/10$ hydrochloric acid solution. The sodium hydroxide had been previously standardised against hydrochloric acid using the same two indicators.

Strength of caustic soda solution using methyl orange indicator = 1·1803N.
Strength of caustic soda solution using phenolphthalein indicator = 1·1785N.
(1) 55·165 c.c. of sodium hydroxide mixed with 4·3396 g. HNO_3 required:
(a) For neutrality to methyl orange 0·66 c.c. 0·1013N HCl solution.
(b) For neutrality to phenolphthalein 0·63 c.c. 0·1013N HCl solution.
(a) Using methyl orange, HNO_3 = 94·45%.
(b) Using phenolphthalein, HNO_3 = 94·40%.
(2) 50·18 c.c. of sodium hydroxide solution mixed with 3·9038 g. HNO_3 required:
(a) For neutrality to methyl orange 7·84 c.c. 0·1013N HCl solution.
(b) For neutrality to phenolphthalein 7·11 c.c. 0·1013N HCl solution.
(a) Using methyl orange, HNO_3 = 94·34%.
(b) Using phenolphthalein, HNO_3 = 94·31%.

These values show that the percentage of carbon dioxide present is so small that it can be neglected in considering the results.

Table III. compares the results obtained by weighing the nitric acid as mixed with those obtained by alkali titration of the nitric acid.

It is hence evident that when fuming nitric acid is weighed out in such a manner that loss of fume is avoided the use of the nitrometer gives values for the percentage of nitrogen, calculated as nitric acid, which agree within 0·15% with the values obtained by titration with alkali.

TABLE III.

			94·47	
			94·46	
93·99	94·64	94·39		
			94·43	
			94·40	94·45
			94·31	94·34
Mean		94·37	94·41	94·40

Conclusions.

1. The nitrogen in potassium nitrate can be correctly determined by means of the nitrometer when 91—92% sulphuric acid is employed, and the solubility of the nitric oxide in this acid is assumed to be 0·2 c.c. in 10 c.c. of the acid.

2. When nitric acid is weighed out in such a way that loss of fume is avoided the nitrometer determination gives values for the percentage of nitrogen, calculated as nitric acid, which agree within 0·15% with the values obtained by titration with alkali.

3. The correction for the solubility of nitric oxide in sulphuric acid (0·35 c.c. of nitric oxide in 10 c.c. of sulphuric acid) given by Lunge (*loc. cit.*) is too high when 91—92% sulphuric acid is used.

4. The nitrometer should be used in a room free from rapid fluctuations in temperature, and the temperature should be read before the volume of gas, in each case.

5. A large quantity of the nitric acid for analysis should be weighed with a known weight of strong sulphuric acid contained in a deep vessel and the necessary amount of the mixed acid weighed into the nitrometer.

Technical College, Cardiff.

Chemical Engineering Group.

Meeting held at the Chemical Industry Club on November 10, 1922.

THE DE-WATERING OF PEAT BY PRESSURE.

BY PROF. J. W. HINCHLEY, WH.SC., A.R.S.M., F.I.C.

(Abridged.)

Peat is a material which occurs in extraordinarily large areas all over the world, and is formed by the decomposition of plants in the absence of air.

The quality of the peat is determined by the character of the plants which led to its formation, the latitude of the place and the geological formation of the country.

Since water forms the medium by which contact with air is prevented, the country where the peat accumulates is shaped like a basin and the subsoil consists of an impermeable layer of clay or similar material.

It will be realised that there is enormous variation, both chemically and physically, in the quality of peat from different bogs, and any discussion on the treatment of peat cannot be exact in a general way, since the behaviour of the peat from different districts must vary considerably. Peaty matter contains on an average, when free from moisture, about 58% of carbon, the remainder being mainly hydrogen and oxygen, and according to the conditions under which the deposit is formed, associated ash may vary from 0·5 to 20 or 30%. It s obvious that peat will contain such chemical substances (or their decomposition products) which characterise the plants from which it is produced, and it is found that while some peats contain as much as 10% of waxes, resins, etc., others may contain less than 1% of these substances. As a general rule peat contains less sulphur than the plants from which it is derived, and it is interesting to note that this elimination of sulphur may often be observed in peat bogs. In the Doncaster Bog, or example, the light-coloured peat which is found near the surface of the bog is continually giving off ulphurous gases, while the black peat immediately under it is absolutely free from smell.

On account of its comparative freedom from ulphur, and its well-divided condition, dry peat urns with higher efficiency in furnaces than coal nd does not seriously attack the metal parts of he plant. On this account peat-fired plant has a ower rate of depreciation than coal-fired apparatus. Peat carbon is a valuable raw material in industry, nd it is possible to obtain from it an almost hemically pure carbon. Its finely-divided condition makes it most convenient also for the manufacture of decolorising and activated carbons. Raw eat in fairly-drained bogs usually contain from 85 o 90% water, *i.e.*, each part of the dry substance s associated with from 6 to 9 parts of water. The eat also contains a quantity of colloidal material hich is useful in some processes for the utilisation f peat, whilst in other processes steps are taken o destroy it. The shrinkage of air-dried peat as ut from the bog, on account of the presence of this olloidal material, is generally about 70%.

Up to the present, the only methods of utilising eat which have persisted have depended upon airrying. The simplest process consists of exposing ods cut from the peat bog to the air for a sufficient ngth of time. Variations of this process consist n "kneading" or "masticating" the peat in such way that the plasticity is increased; so that, on rying, the contraction is greater and the density f the final product is raised.

As peat occurs in the bog, it may be taken roughly, that one cubic metre of peat weighs 1000 kg. (say one ton), and as in the course of drying, contraction takes place, the density of the final peat may vary from 0·2 to 1. It is obvious that the quality of the peat will vary with its depth from the surface of the bog, the upper layers or youngest peat being most fibrous and the oldest peat, that at the bottom of the bog, being most decomposed. At the same time, owing to the water-logged condition of the bog, the lower layer will not only be more decomposed, but may contain colloidal material washed from the other layers. The density of the dried peat from the lower layers on account of pressure will be much greater than that from the upper layers, while the content of water is usually less. Peat from the upper layers of many bogs is of a fibrous character, and, after drying, makes a most useful "litter" for animals, and the dust gives a packing for fruit and similar goods. The products of the decomposition of the vegetable matter have disinfectant properties, which render the material of extremely great value for these purposes, whilst, after use, it is available as a manure.

The efficiency of methods of obtaining peat by air-drying is limited by the character of the climate, and in few cases can more than two "crops" per year be obtained. It is obvious, therefore, that the commercial utilisation of peat can only be small, since the rate of working from a bog is so slow. Attempts have been made and very large sums of money have been lost in machine-devices for drying peat at a sufficiently rapid rate to produce commercially an industrial fuel or other industrial products.

Now the calorific value of ashless, dried peat is at the most, 6000 calories per kg. The best British peats have a calorific value of about 5500 calories per kg. The calorific value of peat as burnt in furnaces is somewhat lower than this, on account of the "equilibrium-moisture" associated with it, and may generally be taken at about 3500 calories per kg. Of all the processes for the rapid drying of peat, it will be clear without much consideration that a direct drying operation could not be a commercial success. In the best drying plants at least 600 calories is required for the evaporation of one kg. of water, so that the association of one kg. of peat with 6 kg. of water would mean that the whole of the heat energy available from the peat on combustion would be required for its drying. Recently, the problem of drying by direct heat has been resuscitated through the development of the "heat pump evaporator." Heat pump evaporators are now made which may be depended upon to evaporate at a rate such that 1 kg. of steam will evaporate 4 kg. of water. Whether this process can be applied to such a material as peat is extremely doubtful, since the difficulties associated with evaporating liquids in such apparatus are enormously increased with a material like peat.

The author has been engaged for several years past on methods of de-watering peat by pressure and is convinced that such methods offer an attractive commercial solution of the problem.

In drying peat by heat or by air-drying processes, the presence of the colloidal matter may be a distinct advantage, but in getting rid of the water by pressure, the presence of this material is a most serious objection, and methods have to be adopted by which it is completely or largely destroyed. Both extreme cold and heat are capable of bringing about this result, and the problem of getting rid of the water is reduced to devising a mechanical process which shall not only be practical but will pay.

It has been stated that the percentage of water in peat as it occurs in a drained bog is usually from 85 to 90%. By a simple pressing operation in the cold, which can be carried out by means of a "squeezing-conveyer" at the bog itself, this percentage of water may be reduced to from 80 to 81%, or four parts of water to one part of peat. A pressure of 50 lb. per sq. in. is necessary and the time of application will depend on the thickness of the layer.

Curves showing change in pressure, thickness of cake, flow of water.

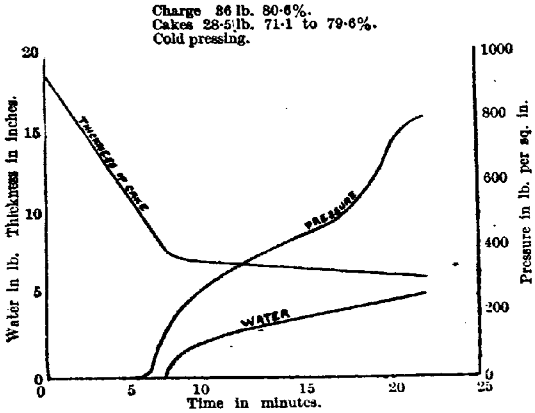

FIG. 1.

Practical experiment by the author has shown that in suitable apparatus it is not necessary to destroy entirely the colloidal matter present in the peat to remove the water successfully by pressure down to approximately 50%. Ekenberg has stated that a temperature of over 150° C. is required for this purpose. The author has found, however, that temperatures approaching the boiling point of water are sufficient provided that suitable apparatus is used.

The work of the author has been carried out in a press, which, from a mechanical point of view, may be seriously criticised, but from a practical point of view is extremely effective and efficient. Experiments on this small press showed that after warming to the boiling point of water, suitably applied pressure rising slowly to half a ton per sq. in. reduced the water-content of Norfolk peat below 50%. In some of the experiments with certain Norfolk peats a figure of 35% was obtained, but generally the figure was 42 to 45%. It will be obvious that the final percentage of water will depend upon many factors, but mainly upon the original vegetation from which the peat was formed and its age.

With peat from the Doncaster district a final moisture content of 55% was found to be the limit, and in experiments with peat from other districts in this country it is found that the lower limit for practical purposes varies from about 40 to 55% of moisture.

With regard to the cold pressing of peat, it is desirable to know to what extent cold pressing can be applied, and Fig. 1 is a curve obtained in experiments on Somerset peat, from which it will be seen that at a pressure of nearly 800 lb. per sq. in. and pressing under the very best conditions the percentage of water was only reduced to an average of about 75%. The press used is shown in Fig. 2 mounted at the works of Armstrong, Whitworth and Co. The stroke of this press was 18 in. and the area of the pistons 120 sq. in., the width of the cake

FIG. 2.

being 5 in.; the head and piston of the press were solid, and the sides of the press were formed of filtering surfaces consisting of tinned steel wire gauze.

It will be noticed from the curve that the particular peat used on that occasion did not part with any water until a pressure of 150lb. per sq. in. had been reached. On examination of the press after the cold pressing was concluded, it was found that the filtering surface was completely choked, and that a considerable amount of work in cleaning was necessary before the press could be used again.

As already stated, the sides of the chambers were provided with filtering material, and the mechanical construction of this part of the press calls for a great deal of ingenuity in order that the filtering surfaces of large presses can be renewed without much loss of time. The pistons slide on strips of metal which are used to hold the filtering surfaces in position, and at the same time protect the filtering surface from wear from the piston itself. Now it will be noticed that in this method of working the direct pressure of the press does not come upon the filtering surface. During no part of the process of pressing does the peat behave as a fluid, and only to some extent does it behave as a semi-fluid. There is little doubt, however, that near the end of the stroke of the press the lateral pressure is not more than one-third of the vertical pressure, whilst at the beginning of the pressing the lateral pressure near the piston is about four-fifths. Arrangement are made in the press so that steam may pass through one filtering surface and discharge through the opposite filtering surface and *vice versa*. At the same time when the press is full of peat the admission of steam may be used to blow out any accumulation of deposit at the back of the filtering surfaces. It will be realised, therefore, that the surface of the peat nearest the filtering surface is submitted to the highest temperature conditions, and that normally in a pressing operation the colloidal matter in the centre of the cake is only partially destroyed, while that nearest the filtering surface is wholly destroyed.

The operation of pressing in this little press may be completed in from 20 mins. to half an hour, and in the first two minutes of this operation the steaming may take place. Visible steam is not produced.

Curves showing change in pressure, thickness of cake, flow of water.

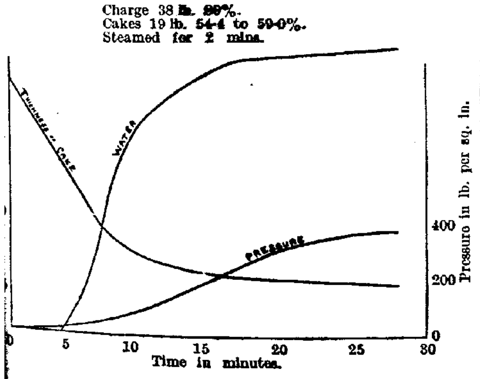

FIG. 3.

he curves (Fig. 3) show a typical hot pressing of omerset peat by which the percentage of water was educed from 80% to about 57%. On comparing the curves of Fig. 3 with Fig. 1 it will be noticed how the water curve lies much above the pressure curve in the latter case, and it will also be realised that the pressure necessary is now less than 500 lb. per sq. in. Now the reduction of water content from 80 to 60% means that one part of peat associated with four parts of water has become one part of peat associated with one and a half parts of water, that is by this process of pressing, two and a half parts of water associated with the peat have been eliminated. The cost of a press and its wear and tear are not such serious matters with pressures up to 500 lb. per sq. in. as with pressures formerly considered necessary. The reduction of the water content from 55 or 60% to 25 or 30% is not a very serious problem, although at first sight it would appear so. To begin with, the peat cakes are discharged from the press at a temperature of about 95° C., and in cooling down to the ordinary temperature while exposed in a suitable way to the air, the actual water content is reduced nearly to 50%. The further drying to 30% (the usual air-dried peat figure) may be carried out in the course of 4 or 5 hours by passage through a long tunnel dryer the air of which is heated by the waste heat from the power plant.

A simple estimation of the amount of energy required to carry out this pressing operation is desirable. In the first instance, at the factory one part of peat is associated with four parts of water, and it may be taken that to heat this material to 100° C. about 320 calories per kg. of dry peat present would be required. Assuming that the dried peat had a calorific value of 5000 calories per kg., this means that between 6 and 7% of the energy of the peat is required for this process. If, however, air-dried peat with a calorific value of, say, 3500 calories is being burnt in the power plant, this would be equivalent to 9% of the heat energy available from that peat. Assuming that the power plant has an efficiency of 50%, which ought to be a sufficiently conservative value, this would mean that 20% of the energy of the peat would be required for the steaming process.

The cost of the pressing processes in heat energy is readily reckoned, and will be found to be approximately 0·7% of the heat energy contained in the peat. Since, however, hydraulic plant is notoriously inefficient, 7 times this value may be taken as a figure certain to be realised, and it may be assumed that not more than 5% of the energy of the peat will be needed for the pressing operations. These considerations show that one quarter (20% + 5%) of the peat produced must be burnt in the power plant to produce the energy necessary for the process, three-quarters of the production being available for the market or other purposes.

The little press illustrated has been worked for six weeks continuously without any difficulty with the filtering surfaces and with practically no variation in its performance. It was designed after several years of experiment as a small portion of a larger commercial press of six chambers to take a charge of 1½ tons per operation. Such a press with accessories would cost about £2000, and would treat about 60 tons of 80% peat per day of 24 hours, yielding 30 tons of peat cake and about 20 tons of dried peat per day, of which 5 tons would be burned in the power plant, giving a net yield of 15 tons per day.

The commercial efficiency of this process is bound up with that of the method of obtaining peat from the bog.

This subject is an extremely wide one, but it may be assumed that with a project of reasonable size, the modern excavator or a modification of the dredger would give that low cost of winning from the bog that is necessary.

entirely from straw is found to be much weaker than that made from esparto. Straw, however, is a cheap material, and is capable of producing a very white pulp, which also has the property of hydrating and partially gelatinising during the "beating" process. This gives a "hardness" and "rattle" to the finished paper which is considered desirable for many purposes. Straw pulp is, therefore, useful when mixed with other pulps, such as those from esparto, cotton, or flax, to produce fine qualities of paper.

It is possible that since the introduction of liquid chlorine in cylinders this "gas bleach" will come into favour once more. The production, handling, and control of chlorine at a mill were difficult and expensive undertakings, whilst hypochlorites were simple and convenient to use, with the result that hypochlorites came into general use in place of elementary chlorine. This position may easily be reversed now that the supply of chlorine on a commercial scale in a convenient and easily used form is possible.

In America liquid chlorine has already been extensively used in some paper mills for the production of bleach liquor from milk of lime. In America, as in Europe, large plants had been installed for the production of liquid chlorine for war purposes, and even during the war attempts were made to apply this liquid chlorine to paper making. It was believed that its use would improve the whole practice of bleach liquor production and would eliminate an unpleasant portion of the mill—that is, the bleach-mixing plant. It was these motives, rather than the hope of effecting economies, which inspired the earlier work. The war and the increase in production and increase in efficiency of liquid chlorine plants put the whole matter on a different footing and definite economies were effected.

The process used is as follows:—Suitable quantities of lime of high calcium content and of water are placed in a tank and kept constantly agitated. Quicklime may be used if necessary, but it is preferable to use slaked lime and so avoid delays for cooling. Milk of lime is pumped from this tank to the top of an absorption tower, which is usually built of, or lined with, stoneware. The tower is packed with small cylindrical stoneware rings so as to give a large absorption surface. The milk of lime flows down this tower and returns to the original tank. When sufficient time has elapsed to ensure a good circulation being established, chlorine gas is introduced at the base of the tower and absorbed in the descending stream of lime. Circulation of the liquor through the tower is maintained until the solution has reached any desired strength up to about 50 grams of available chlorine per litre. The chlorine supply is then cut off and the agitator and circulating pump stopped. The liquor is allowed to settle and the clear bleach solution run off to stock tanks. The small amount of sludge remaining is allowed to accumulate during several repetitions of the above proceeding. When this accumulation of sludge has become too large for convenience it is pumped to a sludge tank and washed by agitating it with water. After settling the wash water is run off to the original mixing tank as make-up liquor for another batch of lime. Usually it is sufficient to wash the sludge twice before disposing of it as refuse. In some cases the use of a sludge tank has been found to be unnecessary as the washing can be carried out in the lime mixing tank.

The chlorine is supplied from cylinders or, in the case of a large plant, from tank wagons. In America liquid chlorine is drawn off from a tank wagon into an evaporator consisting essentially of an iron still surrounded by a water tank which is maintained at a temperature of about 70° C. by injecting a suitable quantity of steam into i Liquid chlorine is dripped into the evaporator an gas drawn off to the absorption towers.

In 1921 an efficiency test was made by th Electro Bleaching Gas Company of New York on plant installed by them at a large paper mill i Canada. This plant consists of a hydrating tan for slaking quicklime, three agitating tanks used a mixers for the batches of milk of lime, an absorptio tower, a sludge tank, and three stock tanks fo finished liquor. Each batch of milk of lime con tained about ten to twelve thousand gallons an the chlorine was absorbed at a rate betwee 400 and 500 lb. per hour. When the availabl chlorine content reached 35—40 grams per litre depending upon the amount of excess lime present the process was stopped and the liquor allowe to settle. A fresh batch from another slaked lim tank was then started.

Ten batches of bleach liquor were made, and th entire contents of a tank wagon were consume in the test. The wagon was weighed at the begin ning and end of the run. Analyses of the mil of lime, the finished bleach liquor, and the refus sludge were made. The total chlorine (i.e. available Cl, chloride and chlorate) present in th original milk of lime was 2602 lb. The tota chlorine in the finished liquors was 32,642 lb. Thu a total of 30,040 lb. of chlorine had been absorbed The weighings of the tank wagon showed it to con tain 30,000 ± 100 lb. Thus the efficiency of absorp tion must have been practically 100%. Of th 30,040 lb. of chlorine absorbed, 29,790 lb. wa present as available chlorine. This means th efficiency of absorption from a bleach-making poin of view was 99·17%. There had been practicall no formation of chlorate. Analysis of the sludg as it was run to waste showed it to contain a tota of 92 lb. of available chlorine, *i.e.*, 0·31% of th available chlorine absorbed. The amount of lim used was 1·052 lb. of quicklime per lb. of chlorin absorbed.

The whole test shows the plant to be very efficient and it has decided advantage over the usual metho of producing bleach liquor from dry bleachin powder. The liquor contains less lime sludge, an therefore settles more quickly. Strong bleac liquors can be prepared and diluted as required fo use. Thus a comparatively small plant has a larg output. The reduced quantity of sludge to be dis posed of naturally means more efficient washin and therefore less available chlorine goes to th refuse tip. Also the cost of sludge disposal i reduced in proportion as the sludge is reduced.

In this country, as yet, liquid chlorine has no effected any such enormous changes. Howeve with apparatus such as exists in present-day Britis paper mills and bleach fields it is possible t chlorinate milk of lime and produce bleach liquor direct. A rapid agitation is necessary and a fairl deep mixing tank is desirable.

Details of such a run are as follows:—The mi at which the trial was made uses bleach liquo at 5½° Tw., that is about 17·1 g. per l. o available Cl. 264 lb. of poor lime (85·6% CaO and 237 lb. of liquid chlorine were used. Th total quantity of bleach liquor at 5½° Tw. ob tained was 211·5 cubic feet, and it containe 231·0 lb. of available chlorine. The yield o available chlorine on the total chlorine absorbed i therefore 97·4%. This compares very favourabl with the efficiency of most bleaching mixing plants Using bleaching powder it is somewhat difficult t get even a 95% efficiency of extraction; in fact, s high a figure is probably rare.

There is one other method of using liquid chlorin to advantage in the production of bleach liquor and it is this last method which at the moment wil probably find most favour in the eyes of pape iakers and bleachers. It consists simply in hlorinating the free lime present in all bleaching owders, during the agitation of the bleaching owder with water to make bleach liquor. This rocess can be undertaken with ease in the usual ype of bleach mixer. All the extra apparatus equired consists of one or two dip pipes leading own to the bottom of the mixer, to which the hlorine cylinders can be connected. If the agitation of the mixer is very rapid, having a peripheral eed of 500 feet per minute or thereabouts, the lorine can be introduced into the bleach batch as quid and allowed to vaporise in the mixing tank. his allows the cylinders to be emptied rapidly, and t is possible, given a suitably deep tank and rapid gitation, to introduce the necessary quantity of hlorine in 20—25 minutes. When agitation is slow t is advisable to bubble chlorine gas into the liquor. his is done by using cylinders having no internal iphon pipe, which, therefore, deliver gas. This lows the process down somewhat, but is not a erious obstacle to success. It has been found by xperiment that average bleaching powder, containing 35—37% of available chlorine, can absorb by his process about one ninth of its weight of extra hlorine. The residual sludge is, of course, considerably reduced, sometimes to as little as one ourth of its normal bulk. The original sludge onsists chiefly of free lime, and this has gone into olution to form hypochlorite.

Bleaching powder casks contain about 6 cwt. of he powder. A cylinder of liquid chlorine contains 0 lb. of chlorine. Thus a cask of bleaching powder eighs a little more than 9 times as much as the ontents of one cylinder of chlorine. It will be een that one cask—one cylinder is a convenient ractical arrangement.

Details of a typical run are as follows:—

Weight of 35% bleaching powder used	= 4432	lb.
Available chlorine content of this quantity	= 1551·2	lb.
Chlorine added as liquid	= 360	lb.
Theoretically possible quantity of available chlorine in finished bleach liquor	= 1911·2	lb.

Actually 10,737 gallons of 6° Tw. bleach liquor was produced, containing 1863·9 lb. of available chlorine. The loss of available chlorine is therefore 47·3 lb. or 2·47%. This proved to be a more economical working than the usual mill practice, and in addition the process has all the advantages claimed for the American practice of chlorinating milk of lime in towers.

1. Stronger bleach liquors can be obtained if desired. In other words, the output of any given plant can be considerably increased without any other alteration than the provision of chlorine inlet pipes. In one case as much bleach liquor is being produced in three mixers as was originally made in five.

2. The quantity of sludge is considerably reduced. Instead of sludging out after each mixing, two or even three batches can be mixed in succession before the sludge need be washed and rejected..

3. The liquor settles faster. There is less solid to settle.

4. Economy of bleaching powder is effected The extraction of the available chlorine is more complete, chiefly because the reduced amount of sludge can be more efficiently washed.

5. There is less bleaching powder dust floating about the bleach house because less bleaching powder is used. This is a point to be considered, as bleaching powder dust is very irritating to the eyes, nose, and lungs.

This process of chlorinating bleaching powder during mixing has been in use in Germany for many years. It was seen by a Scottish papermaker at the Zanders Mill before the war, and shortly after the armistice a member of the United Alkali Company's chemical staff visited this mill and saw the process being operated. Practical trials were then made at an English paper mill in the summer of 1919, but at that time the cost of liquid chlorine did not permit of economical working. This cost factor has since changed, and the process now offers financial advantages.

Summing up the developments in the use of bleaching agents, it would appear that the advent of liquid chlorine as an everyday article of commerce will mark a new era in bleaching practice. Liquid chlorine is a comparatively new product in this country, and is only beginning to make its presence felt. It would be a bold statement to say that it is going to place bleaching powder among the obsolete chemicals either here or in America, but there can be no doubt that it is going to find extensive application either as an adjunct to bleaching powder or in special cases as a substitute for it. Bleach liquors will be made by the consumer. We are reverting to the position of over 100 years ago—with one difference, viz., liquid chlorine instead of chlorine gas.

DISCUSSION.

Mr. R. EASTON had observed that during the war dandy rolls were more liable to break down than previously. He asked whether the breakdown was due to chlorine in the pulp or whether other factors were responsible.

Mr. INMAN thought that it was very unlikely that surplus bleach liquor would survive the various paper-making operations which followed the bleaching process and pass along the machine to the dandy rolls unless an enormous excess had been used.

Dr. A. HOLT asked whether data were available as to the stability of strong solutions of hypochlorites in stock tanks.

Mr. INMAN said that the practice was to run the solutions into tanks where the sludge settled fairly quickly, and to use the hypochlorites practically as soon as they were made—actually they were not kept for more than two or three days. Some bleachers preferred fresh solutions which contained excess of alkali and acted slowly, while others preferred older solutions where the free alkali had been partly neutralised by carbon dioxide, and which bleached more quickly.

Mr. ARTHUR CAREY remarked that the greater speed with which sludge settled in the newer process was explained by the fact that calcium carbonate settled quickly, lime slowly, and chlorination of the hydroxide caused its removal, leaving only the material which gave a clean solution readily.

Mr. A. T. SMITH said that the American practice was very interesting as showing the trend of affairs when large-scale production was required. Variations in technique with scale of production did not explain why the use of towers was preferred to the direct way of passing the gas direct into milk of lime. There was no doubt about the convenience of making bleach liquors where they were to be used; further, the new process evaded the difficulty of sludge disposal, which was a serious matter in older works—it did not produce sludge in quantity. One main reason why liquid chlorine had not been used as widely here as abroad was the policy of the railway companies, who refused to grant facilities for transporting liquid chlorine.

The CHAIRMAN said that the question of transfer of liquid chlorine by rail was of great importance if it was to be used in paper manufacture.

Meeting held at Sydney on October 11, 1922.

MR. F. A. COOMBS IN THE CHAIR.

NOTE ON THE WAX COATING THE STEMS OF THE AUSTRALIAN "CANE GRASS," *GLYCERIA RAMIGERA*, F.v.M.

BY HENRY G. SMITH.

In addition to the name "Cane grass" this Australian plant is also known as "Bamboo grass." It is perennial and occurs plentifully in certain localities in New South Wales, Victoria, and South Australia. It is a coarse, cane-like species, has a hard stem, and grows in what are known as "cane swamps." It has considerable weather-resisting properties, and being quite suitable for thatching is employed for that purpose in localities where it grows abundantly. The sample from which the wax was prepared was forwarded to the Sydney Technological Museum by Mr. J. P. Butler, who procured it from the neighbourhood of Warren, New South Wales. The entire stem is coated with an almost colourless wax, which separates in flakes when the stem is sharply bent. The wax as thus separated melted at 82° C., and in appearance, melting point, and hardness, much resembles carnäuba wax, and might be equally well employed for industrial purposes. It is sufficiently hard and brittle to be powdered, and although but little soluble in ether, yet the ether has the property of separating the wax entirely from the stem, the greater portion falling to the bottom of the containing vessel as a whitish powder.

The peculiarity of *Glyceria* wax is its high acid value, thus indicating a large proportion of the wax to consist of one or more of the higher acids. The melting point of the separated acid was 82°, a figure suggesting it to consist largely of cerotic acid.

For the preparation of the wax in larger quantity the stems were cut to a convenient size, treated with cold ether, and the process repeated. 5¼ lb. of material—containing 10·6% of moisture—gave 55 grams of wax insoluble in ether, equal to 2·2%, and 10 grams soluble in ether, equal to 0·4%, or a total of 2·6%.

The portion soluble in ether was somewhat dark coloured, caused by the chlorophyll extracted at the same time, but the larger insoluble portion was quite light coloured. The ether-soluble portion melted at 73° C. by the capillary tube method in water, and the larger insoluble portion at 83°. *Glyceria* wax is insoluble in water, and but slightly soluble in alcohol, benzene, acetone, and chloroform in the cold, but mostly dissolves in any of those solvents when boiled, separating out again as the solution cools. The portion insoluble in cold ether was also insoluble in boiling ether.

The ether-soluble portion had sp. gr. 0·975 at 18° C., and the insoluble portion 0·9819 at 19° C.

The acid value was 54·26—54·33, and the separated acid constituents had m.p. 82° C.

The saponification value of the portion of the wax insoluble in ether was 89·4, and of the esters 35·1.

The portion of the wax soluble in boiling alcohol, and separated from the insoluble portion, had m.p. 84°—85° C.

PROF. J. W. COBB IN THE CHAIR.

NOTE ON THE DETERMINATION OF VOLATILE MATTER IN FUELS.

BY P. WEDGWOOD, B.SC., AND H. J. HODSMAN, M.B.E., M.SC., F.I.C.

(Department of Coal Gas and Fuel Industries, The University, Leeds.)

The determination of the volatile matter is one of the most important tests applied to fuels both for commercial and scientific purposes. For commercial testing a high degree of precision in the determination is unnecessary, but owing to the empirical character of the tests a uniformity of method is desirable which will not be secured unless the apparatus is simple and inexpensive. The method originally proposed by the American Chemical Society in its modified form has been widely adopted as forming the nearest approach to this want. Unfortunately in this method the use of a crucible of platinum is specified. Now platinum has obvious advantages, but as its cost is practically prohibitive, there is no hope that it will come into general use for the commercial testing of coal. Materials such as porcelain and silica differ so much in properties from platinum as to make their substitution in the American test impossible. A satisfactory substitute should be metallic, as otherwise the temperature necessary is unattainable in a crucible heated in the Bunsen flame.

After examining a number of metals and alloys we have found two materials, though, of course, there may be others untried by us, which proved reasonably satisfactory. They were Monel metal and mild steel treated with aluminium powder. For this purpose the crucible embedded in aluminium powder enclosed in an iron tube was heated in the muffle. Some such process is employed commercially under the name of "calorising."

The crucibles (turned out of the solid) were similar in dimensions to the ordinary platinum crucible—height 1⅜ in., diameter of top 1¼ in., diameter at base 1 in., and thickness of wall $\frac{1}{32}$ in. The well-fitting lid was pierced with a hole $\frac{1}{16}$ in. in diameter. To test the constancy of weight the crucibles were heated for periods of 7 minutes in the flame of a Méker burner to a temperature of 950° C. The gain in weight indicated that the effect of oxidation of the crucible in a determination of volatile matter on 1 gram of fuel would be to lower the result by 0·5% or less as compared with determinations in platinum.

	Treated steel crucible		Monel metal crucible	
	g.	Gain.	g.	Gain.
Original weight of crucible ..	47·2728	—	52·7800	—
Weight after 1st 7 mins. heating	47·2798	0·0070	52·7840	0·0040
,, ,, 2nd ,, ,,	47·2850	0·0052	52·7848	0·0008
,, ,, 3rd ,, ,,	47·2900	0·0050	52·7820	—0·0028
,, ,, 4th ,, ,,	47·2950	0·0050	52·7836	0·0016
,, ,, 5th ,, ,,	47·2956	0·0006	52·7848	0·0012
,, ,, 6th ,, ,,	47·3005	0·0049		

In use the gain in weight should be still less owing to the reducing atmosphere inside the crucible. The crucibles also seemed to develop in use a protective film of oxide.

A large number of coals have been tested, and some of the figures obtained for the volatile matter content using these two base metal crucibles are set out in a table, together with the results obtained when using a platinum crucible.

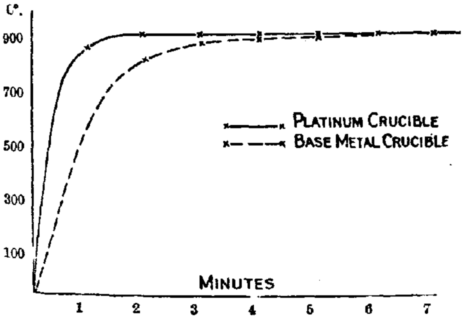
The method used was substantially the same as that specified by the United States Bureau of Mines. A large Méker burner was used surrounded by a sheet iron chimney lined with asbestos. The crucible was supported so that the bottom was 2½ cm. above the burner. The gas was adjusted to a predetermined pressure indicated by a simple water gauge so that the maximum temperature attained in the crucible was 930° C. The temperature was checked from time to time by means of a platinum/platinum-rhodium thermocouple. The crucible containing 1 g. of coal ground to pass a 60-mesh sieve (I.M.M.) was heated for exactly 7 minutes. It was then removed and placed on a clean steel block until cool enough to transfer to the desiccator. When quite cool it was reweighed.

The temperatures in the crucibles at the end of each minute during a period of 7 minutes' heating under the conditions of a test were measured. The temperature inside the platinum crucible rose rapidly to the maximum in 2 minutes, but in the base metal crucibles only after 4 minutes. Thus the charge was at 930° C. in the platinum crucible for 5 minutes and for 3 minutes only in the others (see fig.).

Percentage of volatile matter.

Sample.	Platinum crucible.	Steel treated with aluminuim.	Monel metal.
Coke	12·56	—	12·15
Dutch anthracite	10·17	—	10·12
Wyndham steam coal	18·60	—	17·81
Various Cumberland coals	27·10	27·65	26·34
	31·44	30·60	31·02
	33·90	33·56	33·62
	35·36	35·00	35·10
	36·86	36·17	36·02
Lignite	59·40 (54·55)	—	57·07 (53·80)

The loss of carbon particles in the stream of volatile matter was very noticeable in the last sample. When the crucible and its contents were subjected to a preliminary gentle heating for two minutes before heating for 7 minutes at the full temperature, the results (in brackets) in each case were lower and more concordant.



The results obtained in the base-metal crucibles are generally about 0·5% low when compared with those determined in platinum. This difference may be ascribed to various causes, of which the most obvious are:—(1) The increase in weight of the crucible depressing the apparent loss of volatile matter. (2) The greater loss by entrainment of carbon particles in the stream of volatile matter, due to the more rapid rise in temperature in the platinum crucible. (3) The fact that whereas the platinum crucible is at a temperature above 900° C. for about 6 minutes of the 7 minutes period, the base-metal crucibles are only maintained above this temperature for about 4 minutes.

But whatever crucible is used for volatile matter determinations, in order to obtain concordant results a specified procedure must be strictly adhered to. In commercial work extreme precision is unnecessary, and a knowledge of the volatile matter to the nearest 0·5% in most cases is sufficient.

In view of this and the fact that consistently good results can be obtained with suitable base-metal crucibles, the use of platinum does not seem essential.

Of the two materials tried Monel metal seems to behave the better. The crucibles can be turned in the lathe to a standard size and thickness. The finished crucible has, and maintains in use, its smooth surface and original shape. In this respect it is superior to platinum, which is soft and easily deformed. Above all, the metal withstands the continued action of heat exceedingly well. To test this the crucibles were put into regular use in the laboratory of the St. Helen's Coke Ovens, Cumberland. The original crucible after at least 50 determinations of volatile matter seemed quite unimpaired. Heating for 1 hour in the muffle furnace at nearly 1000° C. had little visible effect on it. It developed a thin oxidation film, tough and adherent. The increase in weight, however, exceeded the limit of permissible error in a determination of volatile matter. Under this harsh treatment it behaved better than the treated steel crucible which showed signs of disintegration, but it had also been previously used without much deterioration in more than 50 determinations. These experiments showed that the crucibles may not be used for determinations of volatile matter made in the muffle, the protective atmosphere of the flame being essential.

DISCUSSION.

Professor Cobb said that the determination of volatile matter in coal by the crucible method was always rather comparative than absolute and that agreement between observers was only to be attained by defining carefully the conditions of operation. Platinum was a reasonably satisfactory material for the crucible but very expensive. About two years ago at Leeds they had experimented with porcelain and silica but with limited success. Mr. Hodsman and Mr. Wedgwood continuing the work with metallic crucibles had, however, found Monel metal (and to a less extent "calorised" iron) much more promising. Of course, other alloys might be as good, or better, but they had given results which indicated definitely that a metallic substitute for platinum in this estimation could be found and probably had already been found in Monel metal.

Dr. Forster suggested that nichrome might be suitable, as it formed a thin layer of oxide on its surface which acted as a protection against further oxidation.

Mr. W. McD. Mackey said that with lignites it was better to dry the sample first, since the water vapour was liable to carry out small pieces. The old method of determining the volatile matter in coal was 3½ minutes on a Bunsen flame and 3½ minutes with a strong blowpipe; the results were much the same as those got now. using the adjusted Bunsen flame, 7 minutes. The essential thing seemed to be to get the temperature up as quickly as possible. It would be a good thing if the crucible could first be heated to the desired temperature and the coal dropped in. He thought a temperature above 750° C. could be got with silica if sufficient time were given.

Mr. Hodsman said that if a silica crucible were used in place of platinum, other conditions being as specified, the temperature within the crucible as measured by means of a thermocouple was about 750°. It would, of course, be possible to attain a higher temperature by suitably modifying the heating arrangements. That would, however, involve a departure from the conditions of the test. The coke with 12·5% of volatile matter had been carbonised at a low temperature.

Mr. Burrell asked if the roughness on the steel crucible could be removed by rubbing with sand. He noted that the bottom of the Monel metal crucible was rather thick.

Mr. Hodsman replied that the crucibles of treated steel had a roughened surface, even when new. They were thicker at the bottom than platinum and therefore attained the maximum temperature more slowly. He added that duplicate determinations might vary by 0·3%, but two observers might differ by 1% or more in their results, showing the need for uniformity of procedure. There were several pieces of apparatus for effecting the laboratory distillation of coal, among which was one described by Bone. Such methods had their uses but did not meet the need for a simple procedure suited to the summary analysis of fuels as daily practised by very large numbers of chemists in all kinds of laboratories.

Communication.

THE ACCELERATION OF VULCANISATION BY CINCHONA ALKALOIDS.

BY B. J. EATON, O.B.E., F.I.C., AND R. O. BISHOP, M.B.E., A.I.C.

In the course of an investigation on a residue obtained from cinchona bark, comparative experiments have been carried out on pure rubber-sulphur and rubber-sulphur-zinc oxide mixes, with the object of determining the accelerating effect of quinine, cinchonine, cinchonidine, and a mixture of the uncrystallisable alkaloids of cinchona bark known pharmaceutically as quinoidine.

The particular residue under investigation (referred to subsequently as Accelerator X) was obtained by one of us (B.J.E.) while on leave in England in 1921. It is stated to contain the amorphous alkaloids remaining after the separation of quinine and other crystalline alkaloids from the extract of the total alkaloids in cinchona bark. It is understood that the material is being used in certain rubber manufactories in England, and it appears from information since received that American rubber manufacturers have been acquainted with its use for some years.

Accelerator X is a brown, somewhat deliquescent substance which is very sticky under the moist, hot atmospheric conditions in Malaya. The solubility in water is slight, but in alcohol (95% by volume) complete solution can be effected. It is basic (soluble in acids and reprecipitated by alkalis), and has a distinct odour of quinoline and benzaldehyde. The nitrogen content, as determined by Kjeldahl's method, is 2·52%.

In the investigations described in this paper the accelerator was dissolved in 95% alcohol to produce a 20% solution. Different volumes of this solution were allowed to drip on to the raw rubber (in the form of crêpe) from a pipette. The samples of rubber thus treated were left exposed on glass plates until the alcohol had completely evaporated. A test was made on rubber treated with alcohol alone, which was found to vulcanise at the same rate as a control sample.

The subsequent addition of sulphur or sulphur and zinc oxide and the milling and calendering of the mix were carried out according to the standard practice adopted in this laboratory (Bull. 27, Dept. Agric. F.M.S., 1918). Vulcanisation was carried out in moulds in a steam autoclave at 140° C. The vulcanised samples were cut in the form of rings and these were tested on a Schopper testing machine in the usual manner, 24 hours after vulcanisation.

The results of the cures are judged by comparing the stress-strain curves with the "standard" curve (Bull. 27) and by a comparison of the stress-strain figures at break. The figures recorded are those giving the maximum product as a result of testing two rings, the curves of which have been shown previously to be sufficient for a comparison of rates of vulcanisation.

In order to compare the effect of Accelerator X with that of the crystalline alkaloids quinine,

cinchonine, and cinchonidine and with the product known as quinoidine a further series of vulcanisations were carried out with two types of mixings as below:—

Mix. A.	
Rubber	90
Sulphur	10
Alkaloid	1

Mix. B.	
Rubber	90
Sulphur	10
Zinc oxide	4
Alkaloid	1

In both series the pure alkaloid was added in the form of the solid crystals to the rubber during the mixing process. The quinine used for samples 163 Es and 163 Ec was a sample of Howard's quinine, while that used for samples 163 Jc, Fs, and Fc was a sample of Java quinine. Since the tensile curves for samples 163 Ec and 163 Jc coincide, it may be concluded that both samples of quinine are identical in their effect on vulcanisation.

(3) Quinoidine and Accelerator X are not as powerful as quinine, cinchonine, and cinchonidine, but they are possibly not pure amorphous alkaloidal bases, and probably contain a certain quantity of inert constituents which have no accelerating effect on vulcanisation.

(4) As one of us has shown previously, although the addition of organic and inorganic accelerators accelerated the vulcanisation of a slow-curing rubber (crêpe) relatively to a much greater extent than that of a naturally rapid-curing rubber (slab), the differences between a naturally rapid- and slow-curing rubber still exist after the addition of the artificial accelerator, *i.e.*, the slab or fast-curing samples still cure rather more rapidly than the crêpe or slow-curing rubber, both when (*a*) accelerator alone is added, and (*b*) accelerator plus zinc oxide is added.

Additional comparative vulcanisations carried out on crêpe and slab rubber, using smaller proportions of quinoidine and Accelerator X, gave the results shown in Table 5.

The relationships between the various samples, especially in respect of rates of vulcanisation, are shown very clearly in the tensile curves, which are not reproduced here. The following points are, however, of interest:

(1) All the cinchona alkaloidal bases used, viz., quinine, cinchonine, cinchonidine, quinoidine, and Accelerator X, are fairly powerful accelerators.

(2) Quinine, cinchonine, and cinchonidine appear to be practically identical in their accelerating effect.

(5) Generally, the superiority of the slab rubber samples containing the added accelerator compared with the crêpe samples is maintained, but is not so marked except in the case of the samples to which zinc oxide has been added.

(6) The addition of zinc oxide accelerates the rate of vulcanisation of all the samples. It is not possible, however, to judge the samples containing zinc oxide by the same tensile curve used for the pure rubber-sulphur mixings, since the curve is different in type, and the highest tensile figures for the samples containing zinc oxide are obtained in the case of a curve indicating an "over-cured" rubber, as judged by the standard curve employed in comparing tests on pure rubber-sulphur mixings.

(7) The results show that Accelerator X is probably a very useful organic accelerator, and also indicate that it probably consists of the amorphous alkaloids of cinchona bark known technically as quinoidine. Since this product is otherwise a waste product, it should be comparatively inexpensive compared with many artificial organic vulcanisation accelerators on the market.

Note.—No attempt has been made to isolate a more active accelerator from the crude product (Accelerator X) nor from quinoidine, neither have we determined whether all or any of the accelerator in these products is volatile in steam. It is proposed to continue the investigation on these points.
